Hundreds of different viruses infect humans and other animals. Most viruses cannot survive very long outside a living host cell, so their survival depends on their being transmitted from animal to animal. The type of attachment proteins on the surface of a virus determines what type of cell it can infect. Some viruses, such as the adenoviruses, have fibers that project from the capsid and may help the virus adhere to complementary receptor sites on the host cell. Other viruses, such as those that cause herpes, influenza, and rabies, are surrounded by a lipoprotein envelope with projecting glycoprotein spikes that aid in attachment to a host cell.

Receptor sites typically vary with each species and sometimes with each type of tissue. Thus many human viruses can infect only humans because their attachment proteins combine only with receptor sites found on human cell surfaces. The measles virus and the pox viruses infect many types of human tissue because their attachment proteins combine with receptor sites on a variety of cells. In contrast, polioviruses attach to specific types of cells, such as those that line the digestive tract and motor neurons of the brain and spinal cord.

Viruses have several ways to penetrate animal cells (Fig. 23-4). After attachment to a host-cell receptor, some enveloped viruses fuse with the animal cell's plasma membrane. The viral capsid and nucleic acid are both released into the animal cell. Other viruses enter the host cell by *endocytosis.* In this process, the plasma membrane of the animal cell invaginates to form a membrane-bounded vesicle that contains the virus.

In DNA animal viruses, the synthesis of viral DNA and protein is similar to the processes by which the host cell would normally carry out its own DNA and protein synthesis. In most RNA viruses, RNA replication and transcription take place with the help of an RNA-dependent RNA polymerase. However, **retroviruses** are RNA viruses that have a DNA polymerase called **reverse transcriptase** used to transcribe the RNA genome into a DNA intermediate (Fig. 23-5 on page 441). This DNA becomes integrated into the host DNA by an enzyme also carried by the virus. Copies of the viral RNA are synthesized as the incorporated DNA is transcribed by host RNA polymerases. The human immunodeficiency virus (HIV) that causes acquired immunodeficiency syndrome (AIDS) is a retrovirus. Certain cancer-causing viruses are also retroviruses.

After the viral genes are transcribed, the viral structural proteins are synthesized. The capsid is produced, and new virus particles are assembled. Viruses that do not have an outer envelope exit by cell lysis. The plasma membrane ruptures, releasing many new viral particles. Enveloped viruses obtain their lipoprotein envelopes by picking up a fragment of the host plasma membrane as they leave the infected cell (see Fig. 23-4b and Fig. 23-5).

Viral proteins damage the host cell in a variety of ways. These proteins may alter the permeability of the plasma membrane or may inhibit synthesis of host nucleic acids or proteins. Viruses sometimes damage or kill their host cells by their sheer numbers. A poliovirus can produce 100,000 new viruses within a single host cell!

Animal viruses cause hog cholera, foot-and-mouth disease, canine distemper, swine influenza, and certain types of cancer (such as feline leukemia). Most humans suffer from two to six viral infections each year, including common colds. Viruses cause chickenpox, herpes simplex (one type causes genital herpes), mumps, rubella (german measles), rubeola (measles), rabies, warts, infectious mononucleosis, influenza, viral hepatitis, and AIDS (Table 23-1 on page 442 and *On the Cutting Edge: Emerging and Re-emerging Diseases* on page 443).

Some viruses infect plant cells

Viral diseases are spread among plants by insects such as aphids and leafhoppers as they feed on plant tissues. Because of the thick cell wall, viruses cannot penetrate plant cells unless the cells are damaged. Plant viruses are inherited by way of infected seeds or by asexual propagation. Once a plant is infected, the virus spreads through the plant body by passing through plasmodesmata (cytoplasmic connections) that penetrate the walls between adjacent cells (see Fig. 5-25). The genome of most plant viruses consists of RNA.

Symptoms of viral infection include reduced plant size, and spots, streaks, or mottled patterns on leaves, flowers, or fruits (Fig. 23-6 on page 442). Infected crops almost always produce lower yields. Cures are not known for most viral diseases of plants, so it is common to burn plants that have been infected. Some agricultural scientists are focusing their efforts on pre-

TABLE 23-1 Animal Viruses

Group	Diseases Caused	Characteristics
DNA Viruses		
Poxviruses	Smallpox, cowpox, monkeypox, and economically important diseases of domestic fowl	dsDNA; large, complex viruses; replicates in the cytoplasm of the host cell*
Herpesviruses	Cold sores (herpes simplex virus type 1); genital herpes, a sexually transmitted disease (herpes simplex virus type 2); chickenpox and shingles (herpes varicella-zoster virus); infectious mononucleosis and Burkitt's lymphoma (Epstein-Barr virus)	dsDNA; medium to large, enveloped viruses; replicates in the the host nucleus†
Adenoviruses	Respiratory tract disorders (e.g., sore throat, tonsillitis), conjunctivitis, and gastrointestinal disorders are caused by more than 40 types of adenoviruses in humans; other varieties infect other animals	dsDNA; replicates in the host nucleus
Papovaviruses	Human warts and some degenerative brain diseases; some cancers	dsDNA‡
Parvoviruses	Infections in dogs, swine, arthropods, rodents; gastroenteritis in humans (transmitted by consumption of infected shellfish)	ssDNA; some require a helper virus in order to multiply
RNA Viruses		
Picornaviruses	Polio (poliovirus); hepatitis A (hepatitis A virus); intestinal disorders (enteroviruses); common cold (rhinoviruses); aseptic meningitis (coxsackievirus, echovirus)	ssRNA that can serve as mRNA; diverse group of small viruses
Togaviruses	Rubella (german measles)	ssRNA that can serve as mRNA; large diverse group of medium-sized, enveloped viruses; many transmitted by arthropods
Orthomyxoviruses	Influenza (flu) in humans and other animals	ssRNA that serves as template for mRNA synthesis; medium-sized viruses that often exhibit projecting spikes
Paramyxoviruses	Rubeola (measles) and mumps in humans; distemper in dogs	ssRNA; resemble orthomyxoviruses but somewhat larger
Rhabdoviruses	Rabies	ssRNA
Coronaviruses	Upper respiratory infections, SARS	ssRNA; envelope
Flaviviruses	Yellow fever; West Nile virus; hepatitis C (the most common reason for liver transplants in the United States)	ssRNA
Filoviruses	Hemorrhagic fever, including that caused by the Ebola virus	ssRNA
Bunyaviruses	St Louis encephalitis; hantavirus pulmonary syndrome (caused by Sin Nombre Virus, a hantavirus)	ssRNA; envelope
Reoviruses	Vomiting and diarrhea; encephalitis	dsRNA; no envelope
Retroviruses	AIDS; some types of cancer	RNA viruses that contain reverse transcriptase for transcribing the RNA genome into DNA; two identical molecules of ssRNA

*The vaccinia (cowpox) virus is used to produce genetically engineered vaccines.
†These viruses frequently cause latent infections; some cause tumors.
‡The virus SV40 has been used as a vector to transport genes into cells.

Hypothesis: Outbreaks of emerging or re-emerging diseases can be quickly contained to minimize loss of life and to prevent widespread epidemics.

Method: A combination of new technology, increased awareness, and greater cooperation among public health agencies, health care providers, and the media.

Results: Responses to recent outbreaks of SARS have been encouraging.

Conclusion: Not yet known

The development of antibiotics, vaccines, and improved healthcare have made it possible for public health officials to effectively control some diseases. However, many familiar diseases, for example, malaria, tuberculosis, bacterial pneumonias, and smallpox, continue to infect large numbers of people, and sometimes reappear in forms that are resistant to drug treatments. Re-emerging diseases are those that have been almost eradicated, and then strike unpredictably, causing an epidemic, sometimes in a new geographic area. Emerging diseases, those new to the human population—such as AIDS, SARS, ebola, eastern equine encephalitis, and West Nile virus—often appear suddenly. The outbreak of severe acute respiratory syndrome (SARS) in 2003 is a grim reminder that pathogens can strike quickly and spread rapidly.

According to the U.S. Centers for Disease Control and Prevention, more than 200 new, continual, or re-emerging pathogens have the potential to strike globally. Historically, new viral strains have claimed many human lives. For example, in 1918 an influenza epidemic killed more 20 million people throughout the world. Some epidemiologists warn that an influenza epidemic today could kill huge numbers of people, perhaps as many as one third of the human population.

As new technology is developed, researchers are able to more quickly characterize emerging disease organisms and explore treatments and vaccines. For example, hepatitis E, a viral disease that may be re-emerging, was documented as an epidemic in India in 1955, but was not isolated as a separate virus until the development of modern immunologic research tools in the early 1980s. In contrast, severe acute respiratory syndrome (SARS), first recognized as a global threat in mid-March 2003, was successfully contained in less than four months. The SARS virus was isolated and identified as a coronavirus in a matter of a few weeks. This information coupled with public health response helped speed efforts to diagnose and treat the disease, and to reduce transmission, thus preventing a global epidemic of this deadly disease. Still, the World Health Organization cautions that the SARS virus could hide in some animal or environmental reservoir, and resurface when conditions again become favorable for spread to its new human host. Epidemiologists are modeling the SARS epidemic in an effort to answer basic questions such as whether we can move from control of local outbreaks to global eradication of this disease.*

Even at the level of our current knowledge about viruses and epidemiology, just how prepared are we to contain a particularly virulent virus? How well are we containing HIV (the virus that causes AIDS), which continues to claim more than 3 million lives worldwide each year? Since the September 11, 2001 terrorist attacks in the United States, bioterrorism has become a critical concern worldwide. Bioterrorism is the intentional use of microorganisms or toxins derived from living organisms to cause death or disease in humans, animals, or plants on which humans depend. For example, in 2001 *Bacillus anthracis,* the causative agent of anthrax, was intentionally released and disseminated through the U.S. postal system. Terrorists could conceivably initiate epidemics of anthrax, smallpox, plague, and other potentially fatal diseases. The quest for effective treatments and vaccines for these diseases has taken on new urgency.

Whether disease outbreaks occur naturally or intentionally, countries must be prepared to protect their citizens. Are public health agencies prepared to quickly detect and investigate new outbreaks? Are they prepared to help the health care community contain the spread of disease? Are we training physicians, nurses, and other health care providers to recognize, report, and treat infectious diseases? Do we have sufficient supplies of medications and vaccines that would be necessary to contain an epidemic? Are systems of communication effective in reporting and sharing information among health care agencies, providers, and the public?

Human activity, including social factors such as urbanization, global travel, and war, contributes to epidemics of infectious disease. For example, as human populations concentrate in cities, large numbers of people come into close contact, permitting the rapid spread of viruses. Living conditions, including sanitation, nutrition, physical stress, level of health care, and sexual practices, are important factors in the spread of disease. In the United States and other highly developed countries, infectious disease accounts for about 4% to 8% of deaths compared with death rates of 30% to 50% in developing regions.

Changing natural habitats can create the conditions necessary for new pathogens to emerge. For example, cutting down forests can bring disease-carrying insects into contact with humans. Sometimes, even naturally occurring ecological changes can spawn outbreaks of disease. The 1993 outbreak of hantavirus in the Southwestern United States killed more than 50 people. A mild winter coupled with heavy rainfall resulted in a large crop of seeds, which supported a population explosion of field mice. The mice carry the virus. Lessons learned from dealing with emerging viruses and the resurgence of old ones will help us contain future epidemics, but much more research is needed.

VIROIDS AND PRIONS

Learning Objective

6 Compare and contrast viroids and prions.

In 1961, an infective agent in potatoes was discovered that had a short RNA strand but no protein coat. The agent, named a **viroid,** is much smaller than a virus and has no protective protein coat and no associated proteins to assist in duplication. Each viroid consists of a very short strand of naked RNA (only 250–400 nucleotides) that serves as a template copied by host RNA polymerases. Viroids cause a variety of plant diseases. These infective agents are generally found within the host cell nucleus and may interfere with gene regulation. Viroids are extremely hardy and

resist heat and ultraviolet radiation because of the condensed folding of their RNA.

PROCESS OF SCIENCE

Stanley Prusiner, professor of neurology and biochemistry at the University of California School of Medicine, San Francisco, began his studies of prions in the early 1970s, motivated by the death of a patient from Creutzfeldt-Jakob disease (CJD, a degenerative brain disease). Prusiner discovered that the infective agent was not affected by radiation (which typically mutates nucleic acids), and he could not find DNA or RNA in the particles. In 1982 he named the infective agent **prion** for "proteinaceous infectious particle." Prusiner's hypothesis that a pathogen could exist and transfer information without nucleic acids went against all accepted biological dogma. However, Prusiner and other researchers continued to study prions, and their findings continued to support Prusiner's hypothesis. In 1997 Prusiner was awarded the Nobel Prize in physiology or medicine for his discovery of prions—a new biological principle of infection.

Prusiner and others have shown that animals have a gene that encodes the prion, a protein consisting of 208 amino acids. This protein is normally harmless and may help process copper. However, it sometimes converts to a different shape, an insoluble variant that accumulates in the brains of patients with **transmissible spongiform encephalopathies (TSEs).** This group of fatal degenerative brain diseases, which have been identified in birds and mammals, are called TSEs because when infected, the brain appears to develop holes, becoming somewhat spongelike. Genetically engineered mice that lack the prion protein gene are immune to TSE infection. According to Prusiner, mutations in the prion protein gene increase the risk that the protein will change shape.

One of the most studied prion diseases is *scrapie* in sheep and goats. When infected, animals lose coordination, become irritable, and itch so severely that they scrape off their wool or hair. Bovine spongiform encephalopathy (BSE), a related prion disease popularly referred to as "mad cow disease," became epidemic in cattle in the United Kingdom in the 1990s. Scientists hypothesized that cattle became infected when they ate feed that had been mixed with sheep offal—brains and other organs—containing prions. After sheep offal was banned as feed, the epidemic was slowly brought under control. This disease led to widespread bans on the export and consumption of British cattle.

More than 120 people in Europe have died from a human variety of BSE, providing evidence that the disease is transmissible from cow to human. The human disease is called vCJD because it is a variant of CJD. The infectious agent has been recovered from infected human neural tissue and appears similar to the prion that causes scrapie in sheep. Human-to-human transmission has been associated with tissue and organ transplants and transfusion with contaminated blood. Recently, *chronic wasting disease,* a disease related to mad cow disease, has spread among deer and elk populations in the United States. Studies are under way to determine whether this disease can infect livestock and humans. Efforts to develop treatments for prion diseases have not yet been successful.

PROKARYOTES

Learning Objectives

7 Describe the structure and common shapes of prokaryotic cells.

8 Describe asexual reproduction in prokaryotes, and summarize three mechanisms (transformation, conjugation, and transduction) that may lead to genetic recombination.

9 Characterize the metabolic diversity of autotrophic and heterotrophic prokaryotes, including aerobes, facultative anaerobes, and obligate anaerobes.

In contrast to viruses, viroids, and prions, which consist only of nucleic acid and/or protein, **prokaryotes** are cellular organisms. Recall from Chapters 4 and 22 that the cell structure of prokaryotes is fundamentally different from the cells of other living organisms. Microbiologists assign prokaryotes to two domains: **Archaea** and **Eubacteria.**

Most prokaryotic cells are very small. Typically, their diameter ranges from 0.5 to 1.0 μm. Their cell volume is only about one thousandth that of small eukaryotic cells, and their length is only about one tenth. Most prokaryotes are unicellular, but some form colonies or filaments containing specialized cells.

Prokaryotes have several common shapes

Prokaryotes have two basic shapes: spherical and rods. Spherical prokaryotes, known as **cocci** (sing., *coccus*), occur singly in some species and in groups of independent cells in others (Fig. 23-7a). Cells may be grouped in twos *(diplococci),* in long chains *(streptococci),* or in irregular clumps that look like bunches of grapes *(staphylococci).* Rod-shaped prokaryotes, called **bacilli** (sing., *bacillus*), may occur as single rods or as long chains of rods (Fig. 23-7b). Some prokaryotes form spirals. If the spiral-shaped cell is flexible, it is a **spirochete;** if rigid, if it is a **spirillum** (pl., *spirilla*) (Fig. 23-7c). A spirillum shaped like a comma is called a **vibrio.**

Prokaryotic cells lack membrane-enclosed organelles

Prokaryotic cells do not have membrane-enclosed organelles typical of eukaryotic cells. Thus these cells do not have nuclei, mitochondria, chloroplasts, endoplasmic reticula, Golgi complexes, or lysosomes (Fig. 23-8). The dense cytoplasm of the prokaryotic cell contains ribosomes (smaller than those found in eukaryotic cells) and storage granules that hold glycogen,

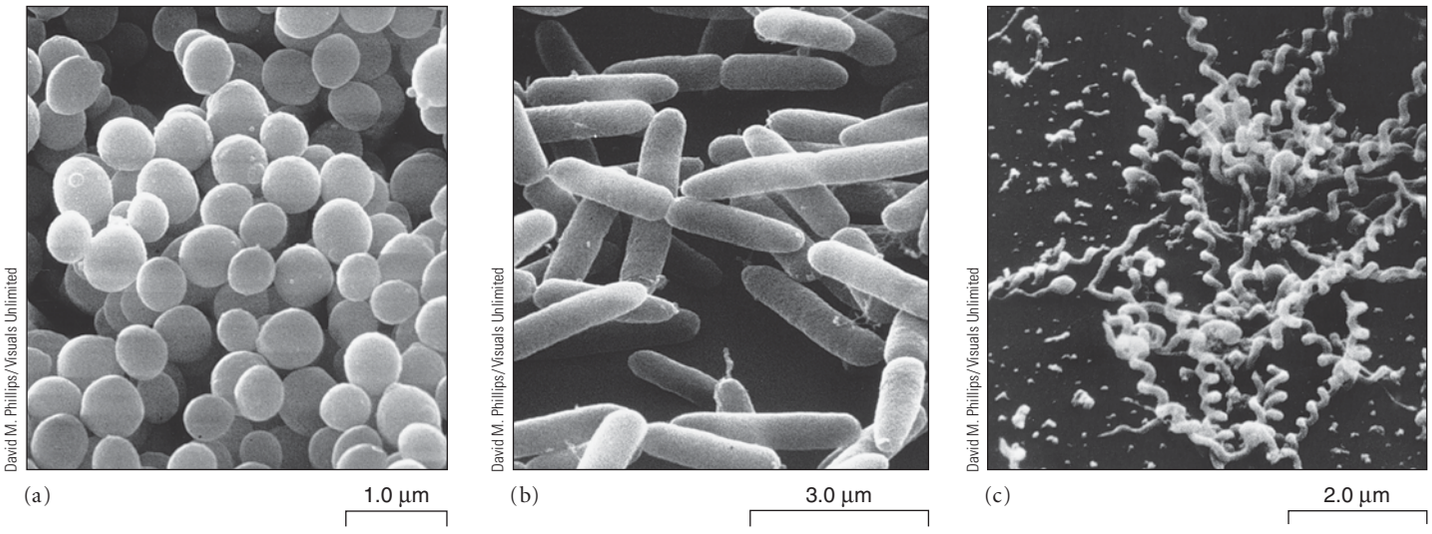

FIGURE **23-7** **Common shapes of prokaryotes.**

lipid, or phosphate compounds. Enzymes needed for metabolic activities may be located in the cytoplasm. Although the membranous organelles of eukaryotic cells are absent, in some prokaryotic cells the plasma membrane is extensively folded inward. Enzymes needed for cellular respiration and photosynthesis may be associated with the plasma membrane or its folds.

A cell wall typically covers the cell surface

Most prokaryotic cells have a cell wall surrounding the plasma membrane. The cell wall provides a rigid framework that supports the cell, maintains its shape, and keeps it from bursting under hypotonic conditions (see Chapter 5). Most bacteria are adapted to hypotonic surroundings. When wall-less forms of bacteria are produced experimentally, they must be maintained in isotonic solutions to keep them from bursting. However, cell walls are of little help when a bacterium is in a hypertonic environment, as in food preserved by a high sugar or salt content. That is why most bacteria grow poorly in jellies, jams, salted fish, and other foods preserved in these ways.

The eubacterial cell wall includes **peptidoglycan,** a complex polymer that consists of two unusual types of sugars (amino sugars) linked with short polypeptides. The sugars and polypeptides are linked to form a single macromolecule that surrounds the entire plasma membrane.

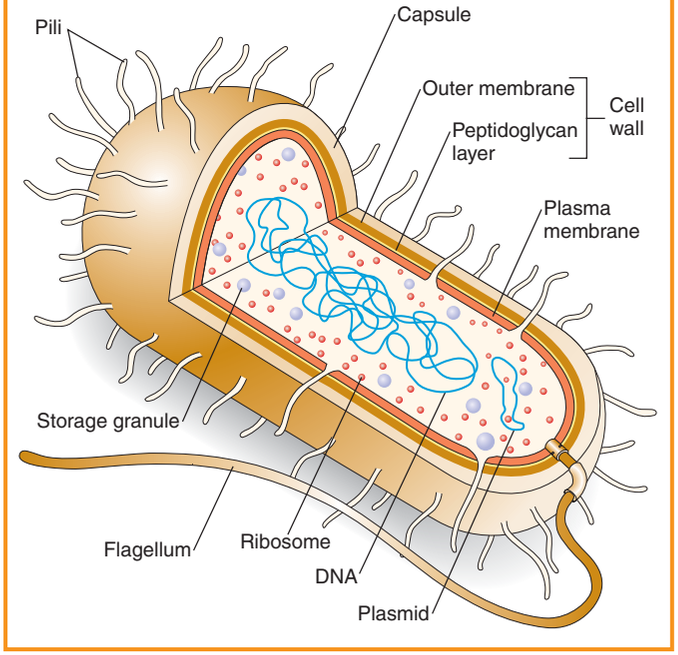
Differences in bacterial cell wall composition are of great interest to microbiologists and are important clinically. In 1888 the Danish physician Christian Gram developed the Gram staining procedure. Bacteria that absorb and retain crystal violet stain in the laboratory are referred to as **Gram-positive,** whereas those that do not retain the stain when rinsed with alcohol are **Gram-negative.** The cell walls of Gram-positive bacteria are very thick and consist primarily of peptidoglycan. The cell walls of Gram-negative bacteria have two layers: a thin peptidoglycan layer and a thick outer membrane. The outer membrane resembles the plasma membrane but contains polysaccharides bonded to lipids (Fig. 23-9).

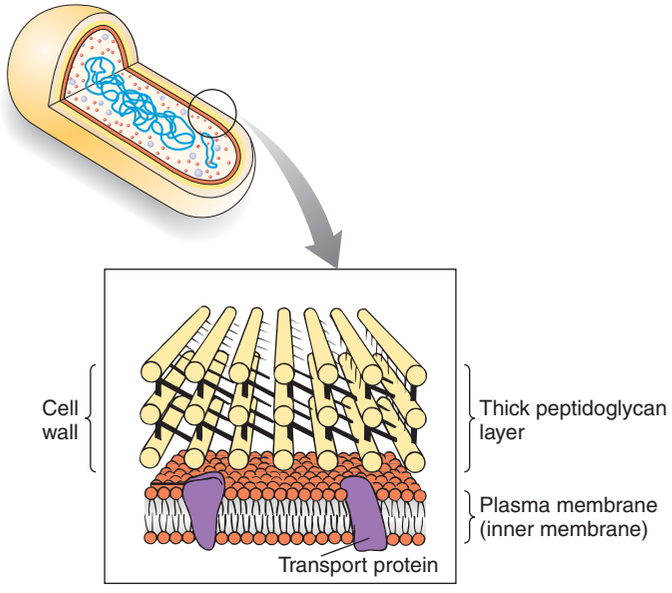
Distinguishing between Gram-positive and Gram-negative bacteria is important in treating certain diseases. For example,

FIGURE **23-8** **Structure of a prokaryotic cell.**

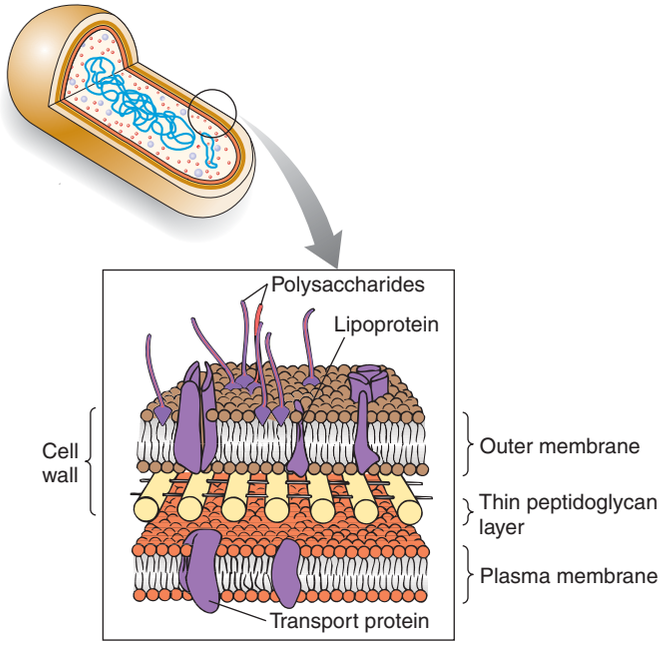
This bacillus is a gram-negative bacterium (discussed in text). Note the absence of a nuclear envelope surrounding the bacterial DNA.

KEY CONCEPT: Prokaryotic cells are fundamentally different from eukaryotic cells. The organelles of prokaryotic cells are not enclosed by membranes.





(a) Gram-positive cell wall



(b) Gram-negative cell wall

FIGURE **23-9** **Bacterial cell walls.**

(a) In the Gram-positive cell wall, a thick layer of peptidoglycan molecules is held together by amino acids. **(b)** In the Gram-negative cell wall, a thin peptidoglycan layer is covered by an outer membrane.

the antibiotic penicillin interferes with peptidoglycan synthesis, ultimately resulting in a fragile cell wall that cannot protect the cell (see Chapter 6, section on drugs that are enzyme inhibitors). Predictably, penicillin works most effectively against Gram-positive bacteria.

Some species of bacteria produce a **capsule** or slime layer that surrounds the cell wall. In free-living species, the capsule may provide the cell with added protection against phagocytosis (engulfment; see Chapter 5) by other microorganisms. In disease-causing bacteria, the capsule may protect against phagocytosis by the host's white blood cells. For example, the ability of *Streptococcus pneumoniae* to cause bacterial pneumonia depends on its capsule. A strain of *S. pneumoniae* that lacks a capsule does not cause the disease. Bacteria also use their capsules to attach to surfaces such as rocks, plant roots, or human teeth (where they cause dental plaque).

Some bacteria have hundreds of hairlike appendages known as **pili** (sing., *pilus*). These protein structures help bacteria adhere to one another or to certain surfaces, such as the cells they infect. Some elongated pili, called *sex pili,* are involved in transmitting DNA between bacteria.

Many types of prokaryotes are motile

Can you imagine trying to swim through molasses? Water has the same relative viscosity to prokaryotes that molasses has to humans. Most motile prokaryotes move by means of rotating **flagella.** The number and location of flagella are important in classifying some bacterial species.

Unlike eukaryotic flagella, prokaryotic flagella do not consist of microtubules (see Chapter 4). A bacterial flagellum consists of three parts: a basal body, a hook, and a single filament (Fig. 23-10). The basal body is a complex structure that anchors the flagellum into the cell wall by disc-shaped plates. The curved hook connects the basal body to the long, hollow filament that extends into the outside environment. The basal body is a motor. The bacterium uses energy from ATP to pump protons out of the cell. Diffusion of these protons back into the cell powers the motor that spins the flagellum, producing a rotary motion that pushes the cell much like a propeller pushes a ship through the water.

Prokaryotes have a circular DNA molecule

The genetic material of a prokaryote lies in the cytoplasm and is not surrounded by a nuclear envelope. In most species, it is contained in a single, circular DNA molecule. If stretched out to its full length, this molecule would be about 1000 times longer than the cell itself. Unlike eukaryotic chromosomes, prokaryote DNA has little protein associated with it.

In addition to the genomic DNA, most bacteria have a small amount of genetic information present as one or more **plasmids,** smaller circular fragments of DNA. Plasmids replicate independently of the genomic DNA (see Chapter 14) or become integrated into it. Bacterial plasmids often have genes that code for catabolic enzymes, for genetic exchange, or for resistance to antibiotics.

Most prokaryotes reproduce by binary fission

Prokaryotes reproduce asexually, generally by **binary fission,** a process in which one cell divides into two similar cells as in the chapter introduction photograph. First the circular DNA repli-

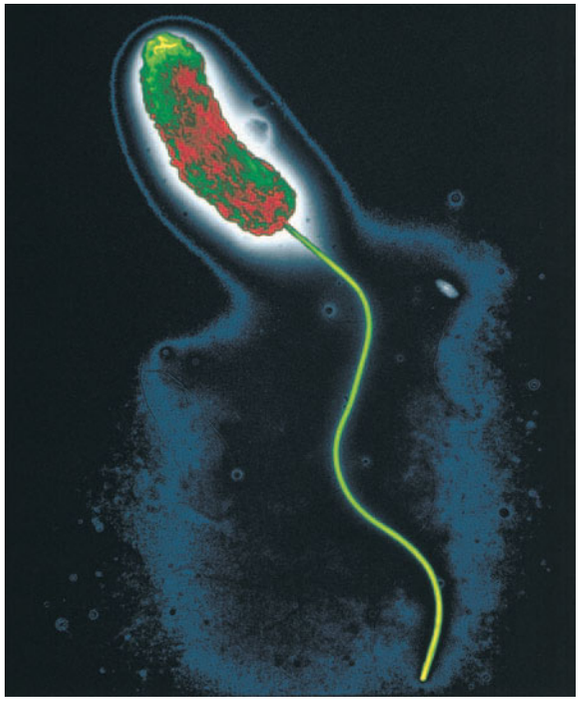


FIGURE **23-10** **Bacterial flagella.**

(a) Color-enhanced TEM of *Vibrio cholerae,* the flagellated bacterium that causes cholera. **(b)** Structure of a bacterial flagellum. The motor is the basal body, which consists of a series of disc-shaped plates that anchor the flagellum to the cell wall and plasma membrane and spin the hook and filament of the flagellum.

cates, and then a transverse wall is formed by an ingrowth of both the plasma membrane and the cell wall.

Binary fission occurs with remarkable speed. Under ideal conditions, some bacterial species divide in less than 20 minutes. At this rate, if nothing interfered, one bacterium could give rise to more than 1 billion bacteria within 10 hours! However, bacteria cannot reproduce at this rate for very long before lack of food or the accumulation of waste products affects their population expansion.

A less common form of asexual reproduction among bacteria is **budding.** In budding a cell develops a bulge, or bud, that enlarges, matures, and eventually separates from the mother cell. A few species of bacteria (actinomycetes) divide by **fragmentation.** Walls develop within the cell, which then separates into several new cells.

Although sexual reproduction involving the fusion of gametes does not occur in prokaryotes, genetic material is sometimes exchanged between individual bacteria. This exchange takes place by three different mechanisms: transformation, transduction, and conjugation.

1. In **transformation,** fragments of DNA released by a cell are taken in by another bacterial cell. Recall that this mechanism was used experimentally to demonstrate that genes are transferred from one bacterium to another and that DNA is the chemical basis of heredity (see Figure 11-1).
2. In a different process of gene transfer, **transduction,** a phage carries bacterial genes from one bacterial cell into another (Fig. 23-11 on the next page).
3. In **conjugation,** two cells of different mating types come together, and genetic material is transferred from one to the other (Fig. 23-12 on the next page). In contrast with transformation and transduction, conjugation involves contact between two cells.

Conjugation has been most extensively studied in the bacterium *Escherichia coli.* In the *E. coli* population there are donor cells (sometimes referred to as male cells) that have plasmids that can be transmitted to recipient (female) cells. A pilus on the donor cell recognizes the recipient cell and makes the first contact. A cytoplasmic bridge forms between the two cells, and DNA is transferred from donor to recipient cell.

Archaea reproduce by binary and multiple fission, budding, and fragmentation. Transduction, transformation, or conjugation has not been observed to date.

Some bacteria form endospores

When the environment becomes unfavorable, for example, when it gets very dry, the cells of some bacteria become dormant.

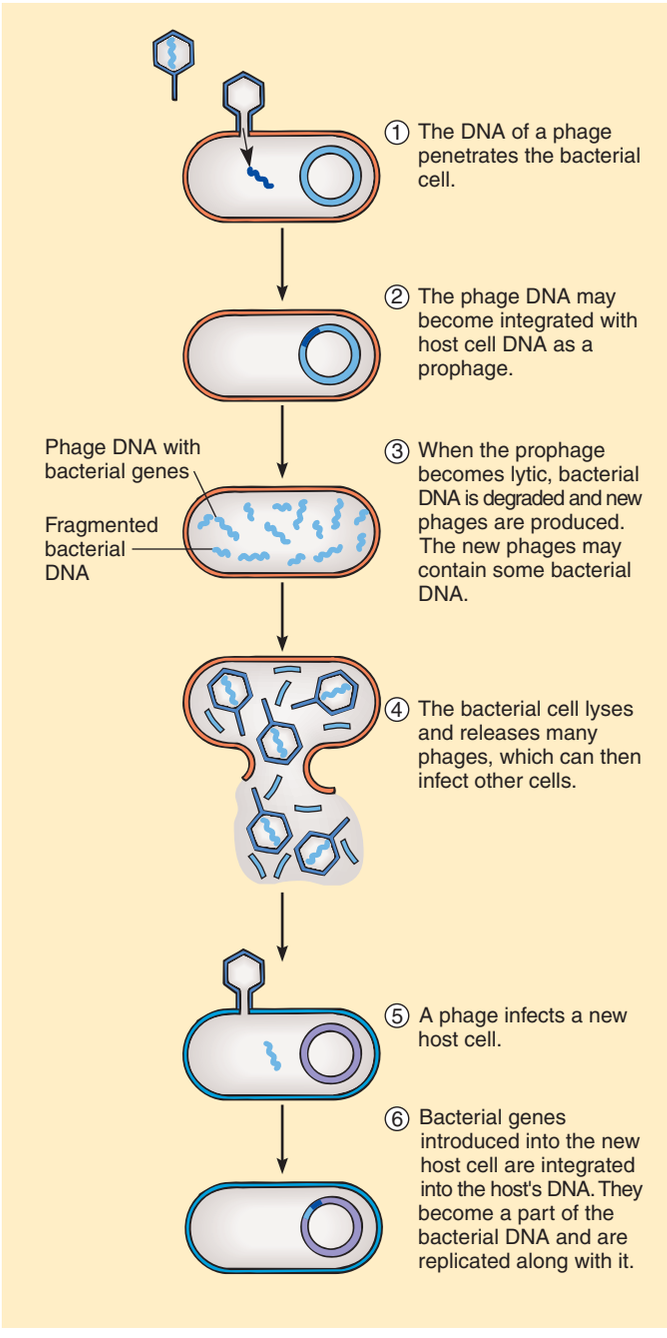

FIGURE **23-11** **Transduction.**

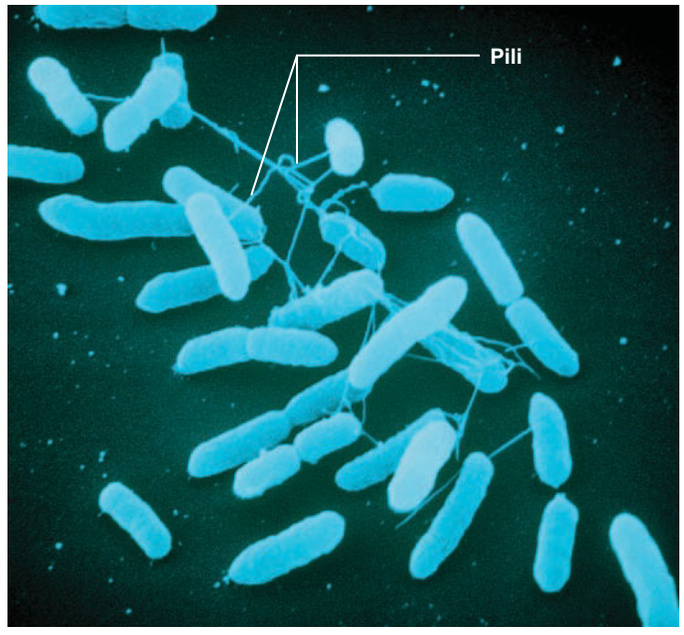
In this process, a phage transfers bacterial DNA from one bacterium to another.



Manfred Kage/Peter Arnold, Inc.

FIGURE **23-12** **Conjugation.**

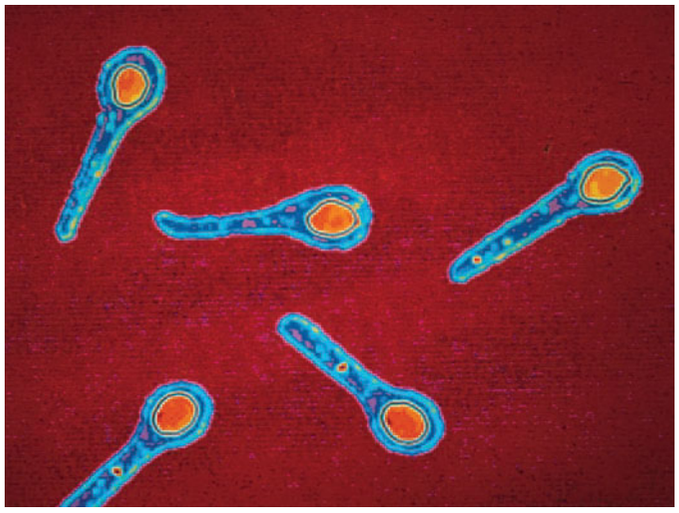
Color-enhanced SEM of *Serratia marcescens* bacteria, which are connected by pili. Stimulated by the contact, the cells pull close together and form cytoplasmic bridges between donor and recipient cells *(not shown)*.

Cells lose water, shrink slightly, and remain inactive until water is again available. Certain other bacteria form dormant, extremely durable cells called **endospores.** After the endospore forms, the cell wall of the original cell lyses, releasing the endospore. Formation of endospores is not a type of reproduction in bacteria; endospores are not comparable to the reproductive spores of fungi and plants. Only one endospore is formed per original cell, so the total number of individuals does not increase. Endospores have not been found in association with archaea; these prokaryotes produce unique enzymes on the cell surface that protect them from cold, heat, and dessication.

Endospores survive in very dry, hot, or frozen environments, or when food is scarce (Fig. 23-13). Some endospores are so resistant that they can survive an hour or more of boiling or centuries of freezing. When environmental conditions are again suitable for growth, the endospore germinates, forming an active, growing bacterial cell. Several types of bacteria that form endospores are medically important. For example, when surgical instruments are not effectively sterilized, endospores of pathogenic bacteria may survive. Patients may then be exposed to serious diseases such as tetanus (caused by *Clostridium tetani*) and gas gangrene (caused by several other species of *Clostridium*). The endospore of *Bacillus anthracis,* the bacterium that causes anthrax, is so hardy that this pathogen has become a concern as an agent of biological warfare.

Metabolic diversity is evident among prokaryotes

Several methods of obtaining energy and carbon have evolved among the prokaryotes. Most prokaryotes are **heterotrophs** that obtain energy and carbon atoms from the organic compounds of other organisms. The majority are **chemoheterotrophs,** which include free-living decomposers (sometimes called *saprotrophs*) that get their carbon and energy from dead organic



Alfred Pasieka/Peter Arnold, Inc.

2 µm

FIGURE **23-13** **Endospores.**

Color-enhanced TEM of *Clostridium tetani,* the bacterium that causes tetanus. Each bacterial cell *(blue)* contains one endospore *(orange),* a resistant, dehydrated cell that develops within the original cell.

matter. Some chemoheterotrophs are pathogens, which obtain their nourishment from living organisms and harm their hosts by causing diseases. Other heterotrophic bacteria benefit their hosts, for example by producing needed vitamins. The purple nonsulfur bacteria are **photoheterotrophs** that get their carbon from other organisms but use chlorophyll and other photosynthetic pigments to trap energy from sunlight.

Some bacteria are **autotrophs** that manufacture their own organic molecules from simple raw materials. **Photoautotrophs** use the energy from sunlight to synthesize organic compounds from carbon dioxide and other inorganic compounds. **Chemoautotrophs** also use carbon dioxide as a carbon source, but they do not use sunlight as their energy source. Instead, they obtain energy by oxidizing inorganic chemical substances such as ammonia (NH_3) and hydrogen sulfide (H_2S).

Whether they are heterotrophs or autotrophs, most bacterial cells are **aerobic** (like animal and plant cells), requiring atmospheric oxygen for cellular respiration. Many are **facultative anaerobes** that use oxygen for cellular respiration if it is available but can also carry on metabolism anaerobically when necessary. Other bacteria are **obligate anaerobes** that carry out energy-yielding metabolism only anaerobically. Certain obligate anaerobes are actually killed by even low concentrations of oxygen. Some bacteria respire with terminal electron acceptors other than oxygen, for example, sulfate (SO_4^{2-}), nitrate (NO_3^-), or iron (Fe^{2+}).

Review

- In what ways do prokaryotic cells differ from eukaryotic cells?
- How do prokaryotes reproduce? What mechanisms result in genetic recombination?
- How do facultative anaerobes differ from obligate anaerobes? How do they differ from aerobes?

THE TWO PROKARYOTE DOMAINS

Learning Objectives

10 Compare the three domains: Eubacteria, Archaea, and Eukarya.

11 Distinguish among the three main groups of the Archaea and among several groups of the Eubacteria as described in Table 23-3. Give examples of each group.

Under a microscope, most prokaryotes appear similar in size and form. However, using sequence analysis of small subunit 16S ribosomal RNA (SSU rRNA), Carl Woese and his coworkers demonstrated that there are two fundamentally different groups of prokaryotes (see Chapter 22). Each group has **signature sequences,** regions of SSU rRNA that have unique nucleotide sequences. This is because after they diverged, prokaryote populations diversified and mutations occurred that affect RNA sequences. Based on such analyses, Woese hypothesized that ancient prokaryotes split into two lineages early in the history of life.

Based on Woese's work, microbiologists now classify the modern descendants of these two ancient lines in two domains: the **Archaea** and the **Eubacteria,** also called **Bacteria** (Fig. 23-14). Domain Archaea, which corresponds to kingdom Archaebacteria, includes a group of prokaryotes that produce methane gas from simple carbon sources and two groups that live in extreme environments. Domain Eubacteria, which corresponds to kingdom Eubacteria, includes all other prokaryotes. In this system, all eukaryotes are classified in domain **Eukarya.**

Key characteristics that distinguish the Archaea from Eubacteria are the absence of peptidoglycan in their cell walls and the unique structure of their cell membranes (Table 23-2). Recall

TABLE **23-2** **Comparison of the Three Domains**

Characteristic	Eubacteria	Archaea	Eukarya
Peptidoglycan in cell wall	Present	Absent	Absent
Isoprene units and ether linkages in cell membranes	Absent	Present	Absent
Nuclear envelope	Absent	Absent	Present
Membrane-bounded organelles	Absent	Absent	Present
Simple RNA polymerase	Present	Absent	Absent
70S ribosomes*	Present	Present	Absent
Flagellum (if present) has single filament	Yes	Yes	No
Transcription is sensitive to the antibiotic rifamycin	Yes	No	No

*The number 70S refers to the sedimentation coefficient (a measure of relative size) when centrifuged.

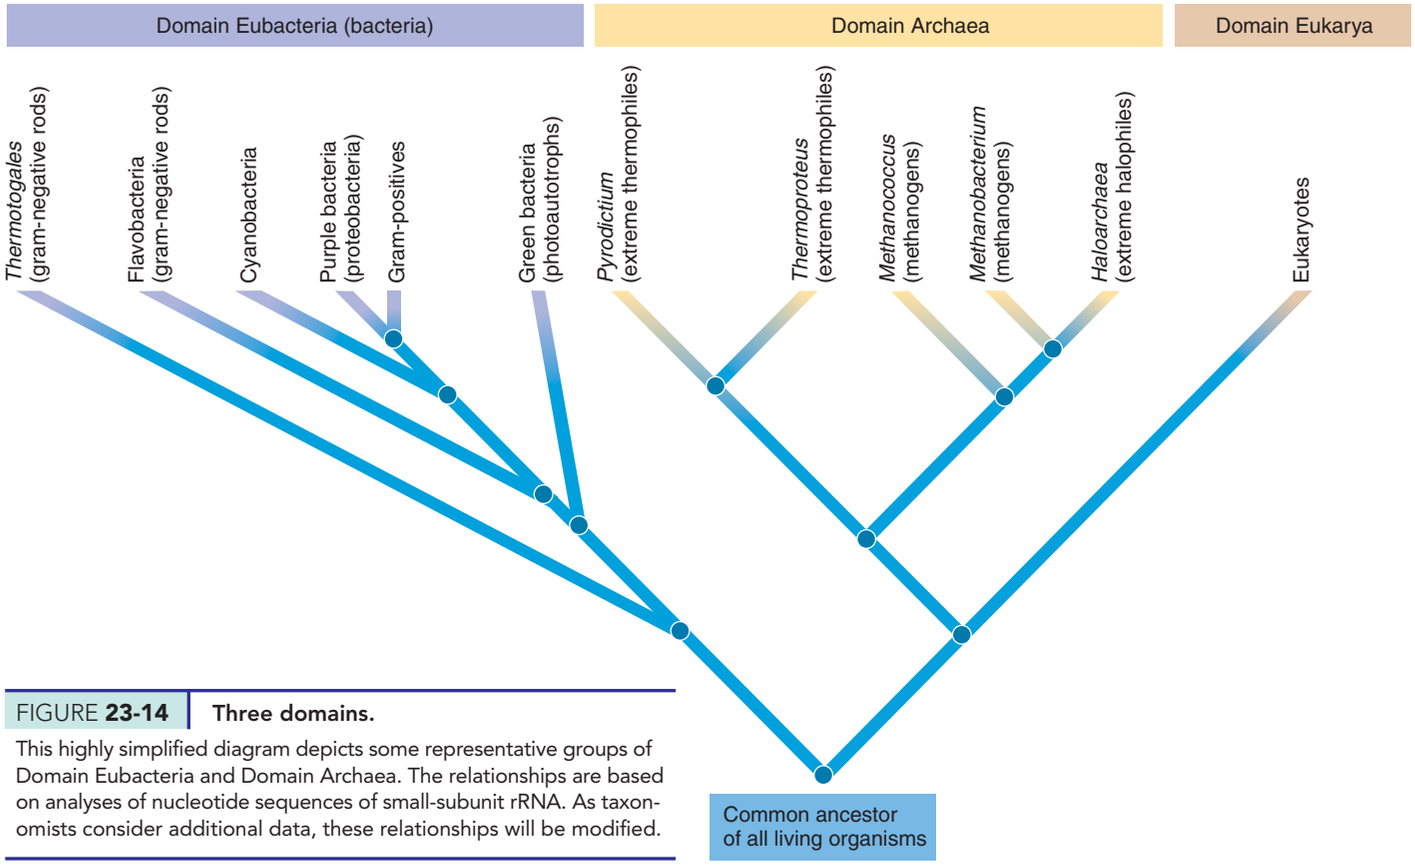

FIGURE **23-14** **Three domains.**

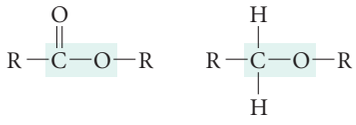
This highly simplified diagram depicts some representative groups of Domain Eubacteria and Domain Archaea. The relationships are based on analyses of nucleotide sequences of small-subunit rRNA. As taxonomists consider additional data, these relationships will be modified.

that the side chains in the phospholipids of the cell membranes of bacteria and eukaryotes are fatty acids. In contrast, the side chains in the cell membranes of archaea are isoprene units with unique side branches off the main chain. Eubacterial and eukaryotic phospholipids have their fatty acids attached to the glycerol by ester linkages. By contrast, archaeal side chains are bound by ether linkages.



Ester linkage **Ether linkage**

The absence of a second electronegative oxygen atom makes ether linkages stronger than ester linkages. This unique membrane structure may contribute to the ability of the Archaea to survive and thrive in harsh environments.

In some ways, the Archaea are more like the eukaryotes than like the Eubacteria. For example, they do not have the simple RNA polymerase found in eubacteria. Like eukaryotes, their transcription process is not sensitive to the antibiotic rifamycin. This antibiotic specifically inhibits the type of RNA polymerase found in Eubacteria. The translational mechanisms of archaebacteria are also more like those of eukaryotes.

Prokaryote taxonomy is increasingly based on RNA sequencing. Groups that branched off earlier had more time to accumulate mutations in their SSU rRNA. Their nucleotide sequences are less similar than those of groups that diverged more recently. However, some microbiologists are developing phylogenetic trees based on entire genomes. They argue that there may be 1000 genes that code proteins for every one gene that codes an rRNA. These researchers prefer to consider the proportions of genes (or proteins) that genomes of various groups have in common.

Although prokaryotic taxonomy is controversial and continuously changing, more than 1220 genera and 4000 species of prokaryotes have been classified. The editors of *Bergey's Manual of Systematic Bacteriology,*[1] considered the definitive reference text by microbiologists, have divided prokaryotes into several groups. Several representative groups of prokaryotes are described in Table 23-3 on pages 452–453.

Members of the Archaea survive in harsh environments

Many extant members of the Archaea inhabit environments thought to be similar to conditions on early Earth. *Bergey's Manual* divides the Archaea into two phyla: the Crenarchaeota, which is a small, diverse group that are extremely thermophilic (heat loving), and the Euryarchaeota. A third group, Kararchaeota,

[1] *Bergey's Manual of Systematic Bacteriology,* 2nd ed., Springer, New York, 2001 is the first of five volumes of the second edition.

has been recently named to include uncultured archaea with similar 16S rRNA sequences that inhabit terrestrial hot springs.

Based on their metabolism and ecology, we can identify three main types of archaea: methanogens, extreme halophiles, and extreme thermophiles. The **methanogens** (methane producers) are a large, diverse group that inhabit oxygen-free environments in sewage and swamps and are common in the digestive tracts of humans and other animals. They are strict anaerobes that produce methane gas from simple carbon compounds. The methanogens are important in recycling components of organic products of organisms that inhabit swamps. These archaea produce most of the methane in Earth's atmosphere.

Extreme halophiles are heterotrophs that live in saturated brine solutions such as salt ponds, the Dead Sea, and Great Salt Lake (Fig. 23-15). The extreme halophiles use aerobic respiration to make ATP. However, they also carry out a form of photosynthesis in which they capture the energy of sunlight using a purple pigment (bacteriorhodopsin). (This pigment is very similar to the pigment rhodopsin involved in animal vision.)

Extreme thermophiles normally grow in hot (45° to 110°C), sometimes acidic, environments. One species is found in the hot sulfur springs of Yellowstone Park at temperatures near 60°C and pH values of 1 to 2 (the pH of concentrated sulfuric acid). Others inhabit volcanic areas under the sea. One species, found in hot deep-sea vents on the sea floor, lives at temperatures from 80° to 110°C.

Members of the Archaea also inhabit less extreme conditions. For example, they are abundant in the soil and in the cold ocean surface waters near Antarctica. Microbiologists have suggested that the Archaea may be important in biogeochemical cycles and in marine food chains. The three main metabolic groups of the Archaea are summarized in Table 23-3.

FIGURE **23-15** **Sea water evaporating ponds.**

These salt ponds near San Francisco Bay are colored pink, orange, and yellow from the large number of extreme halophiles that inhabit them. The colors are a result of pigments (carotenoids) in the cell wall. These bacteria are harmless, and the ponds are used to produce salt commercially.

Helen E. Carr, Biological Photo Service

Eubacteria are the most familiar prokaryotes

The Eubacteria are widely distributed in the environment and are better known to microbiologists than are the Archaea. *Bergey's Manual* divides the Eubacteria into 21 phyla. Several groups of eubacteria are described in Table 23-3.

Review

- What are three main types of archaea based on ecology?
- How do these Eubacteria differ? (a) enterobacteria, (b) cyanobacteria, (c) mycoplasmas.

BiologyNow™ Assess your understanding of **the two prokaryote domains** by taking the pretest on your BiologyNow CD-ROM.

EFFECTS OF PROKARYOTES ON THE ENVIRONMENT

Learning Objective

12 Discuss the ecological roles of prokaryotes, their importance as pathogens, and their commercial importance.

Prokaryotes are of great ecological importance

The metabolically diverse prokaryotes are vital members of the biosphere. Bacteria, especially actinomycetes and myxobacteria, are the most numerous inhabitants of soil. As described in the chapter introduction, prokaryotes are essential **decomposers** (saprotrophs) that break down dead organic matter and wastes. They use the products of decomposition as an energy source. When prokaryotes break down organic compounds, chemical components are recycled. Many nutrients, including nitrogen, oxygen, carbon, phosphorus, sulfur, and certain trace elements, are recycled in this way. (The roles of bacteria in biogeochemical cycles, particularly the nitrogen cycle, are discussed in Chapter 53.)

Nitrogen is constantly removed from the soil by plants and other natural processes, as well as by human activities, such as agriculture. Plant growth depends on the availability of usable nitrogen, so it must be continually added to the soil. Several

TABLE 23-3 Some Major Groups of Prokaryotes

Eubacteria with Gram-Negative Cell Walls

Proteobacteria **A large, very diverse group; not monophyletic and so not included as a clade in Figure 23-14.**

SEM of *Escherichia coli* colony. *(David Scharf/Peter Arnold, Inc.)*

Image not available due to copyright restrictions

Purple bacteria are photoautotrophs that do not produce oxygen.

Enterbacteria include decomposers that live on decaying plant matter, pathogens, and a variety of bacteria that inhabit humans. Although *Escherichia coli* is a normal inhabitant of the animal intestinal tract, certain strains can cause moderate to severe diarrhea. One species of *Salmonella* infects food and produces a toxin that causes a form of food poisoning; another species causes typhoid fever.

Vibrios are mainly marine; some are bioluminescent. *Vibrio cholerae* causes cholera.

Rhizobium species live symbiotically in root nodules of leguminous plants and convert atmospheric nitrogen to a form usable by plants (nitrogen fixation).

Pseudomonads are heterotrophs that produce nonphotosynthetic pigments. They cause disease in plants and animals, including humans.

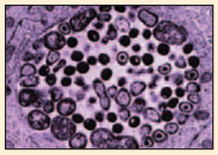
Azotobacteria inhabit the soil and fix nitrogen under aerobic conditions. They form a resting cell termed a cyst that is resistant to drying.

Rickettsias are very small, rod-shaped bacteria. A few species are pathogenic to humans and other animals and are transmitted by arthropods through bites or contact with their excretions. Among these are typhus (transmitted by fleas and lice) and Rocky Mountain spotted fever (transmitted by ticks).

Myxobacteria (slime bacteria) secrete slime and glide or creep along. When nutrients are exhausted, these bacteria form masses that develop into stalked, multicellular reproductive structures called *fruiting bodies.* During this process, bacterial cells within the fruiting body enter a resting stage. When conditions are favorable, the resting cells become active.

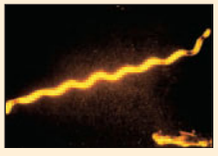
Other medically important Proteobacteria include *Neisseria gonorrhoeae,* which causes gonorrhea, and *Legionella pneumophila,* which causes Legionnaires' disease.

Other Gram-Negative Eubacterial Groups



TEM of *Chlamydia trachomatis* in human oviduct cell. *(David M. Phillips/Visuals Unlimited)*

Chlamydias lack peptidoglycan in their cell walls and do not depend on arthropod vectors for transmission. Chlamydias are energy parasites, that is, completely dependent on their host for ATP. Chlamydias infect almost every species of bird and mammal. Trachoma, the leading cause of blindness in the world, is caused by a strain of *Chlamydia;* sexually transmitted chlamydias are the major cause of pelvic inflammatory disease in women.



LM of *Treponema pallidum,* the spirochete that causes syphilis. *(Charles W. Stratton/ Visuals Unlimited/Science VU)*

Spirochetes are spiral-shaped bacteria with flexible cell walls. They move by means of unique internal flagella called *axial filaments.* Some species are free-living, whereas others form symbiotic associations; a few are parasitic. The spirochete of greatest medical importance is *Treponema pallidum,* which causes syphilis. Lyme disease, a tick-borne disease of humans and some other animals, is caused by a spirochete belonging to the genus *Borrelia.*

Cyanobacteria are gram-negative, photosynthetic bacteria that inhabit ponds, lakes, swimming pools, moist soil, dead logs, and the bark of trees. They contain chlorophyll *a* and use a photosynthetic process similar to that of plants and algae. Many species also fix nitrogen.

types of bacteria transform atmospheric nitrogen to forms that can be used by plants (Fig. 23-16 on page 454). Rhizobial bacteria, a type of motile bacteria that inhabit the soil, form mutualistic (mutually beneficial) relationships with the roots of legumes, a large family of plants that include important crops such as beans, peas, and peanuts. The bacteria fix nitrogen for the plant, and the plant provides the bacteria with organic compounds.

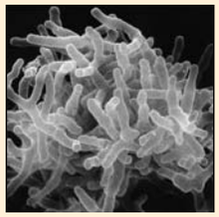
Many prokaryotes, such as the cyanobacteria, carry out photosynthesis using water as the electron source and generating oxygen. During this process, they fix huge amounts of carbon dioxide into organic molecules.

Microbiologists are only beginning to unravel the mysteries of prokaryote ecology. For example, the SAR11 clade of proteobacteria are among the most successful organisms on Earth. Although they are one of the most abundant organisms in the Atlantic Ocean, they were not successfully cultured until 2002 and very little is known about their ecological role.

Some types of bacteria may influence the course of evolution of other species. The proteobacteria *Wolbachia* infect many invertebrates, including insects, spiders, crustaceans, and nematodes (roundworms). These bacteria inhabit the cells of their host's reproductive system and have evolved remarkable mech-

TABLE **23-3** Continued

Eubacteria with Gram-Positive Cell Walls



SEM of *Actinomycetes naeslundi*, a soil-dwelling bacterium that forms filamentous colonies. *(David M. Phillips/Visuals Unlimited)*

Actinomycetes superficially resemble fungi. However, they have peptidoglycan in their cell walls, lack nuclear envelopes, and have other prokaryotic characteristics. Actinomycetes decompose organic materials in soil. Most are saprotrophs, and some are anaerobic. Several species of the genus *Streptomyces* produce antibiotics such as streptomycin, erythromycin, chloramphenicol, and the tetracyclines. Some actinomycetes cause serious lung disease or generalized infections in humans and other animals.

Lactic acid bacteria ferment sugar, producing lactic acid as the main end-product. They inhabit decomposing plant material, milk, and other dairy products. The characteristic taste of yogurt, pickles, sauerkraut, and green olives is caused by the action of lactic acid bacteria. These bacteria are also among the normal inhabitants of the human mouth and vagina.

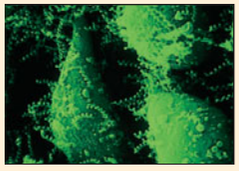
Mycobacteria are slender, irregular rods. They contain a waxy substance in their cell walls. One species causes tuberculosis; another causes leprosy.

Streptococci inhabit the mouth and digestive tract of humans and some other animals. Among the harmful species are those that cause "strep throat," dental caries, a form of pneumonia, scarlet fever, and rheumatic fever.

Staphylococci normally live in the nose and on the skin. They are opportunistic pathogens that cause disease when the immunity of the host is lowered. *Staphylococcus aureus* causes boils and skin infections (some extremely serious) and may infect wounds. Certain strains of *S. aureus* cause a form of food poisoning, and other strains cause toxic shock syndrome.

Clostridia are anaerobic. One species causes tetanus, another causes gas gangrene. *Clostridium botulinum* can cause botulism, an often fatal type of food poisoning.

Eubacteria That Lack Cell Walls



SEM of *Mycoplasma* on fibroblast cells. *(David M. Phillips/Visuals Unlimited)*

Mycoplasmas lack cell walls. These bacteria inhabit soil and sewage; some are parasitic on plants or animals. Some inhabit human mucous membranes but do not generally cause disease; one species causes a mild type of bacterial pneumonia in humans.

Archaea: Prokaryotes with Cell Walls That Have No Peptidoglycan

TEM of a methanogen *(Methanospirillum hungatii)* undergoing cell division. Two other archaea are visible in cross-section. When not dividing, these archaea are spiral shaped. *(Dr. Kari Lounatmaa/Science Photo Library/Photo Researchers, Inc.)*

Methanogens are anaerobes that produce methane gas from simple carbon compounds.

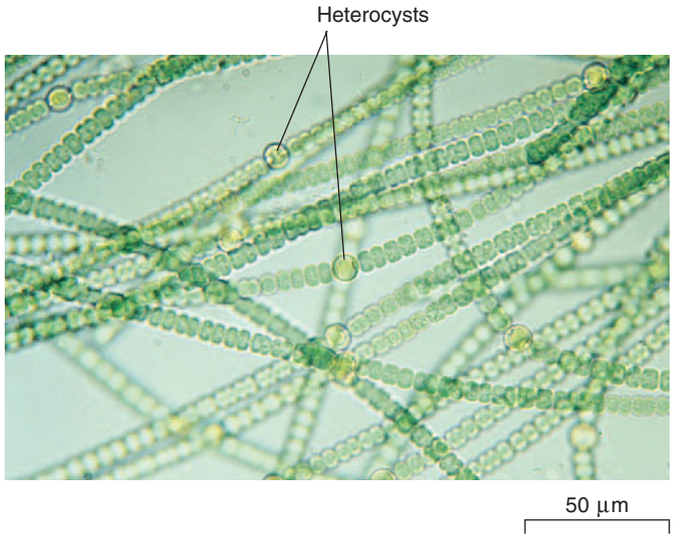
Extreme halophiles inhabit saturated salt solutions.

Extreme thermophiles grow at 70°C or higher; some thrive at temperatures greater than 100°C.

anisms that increase the probability of their transmission to new generations of hosts. *Wolbachia* are transmitted from generation to generation in the eggs of their hosts, so male hosts are not useful to them. Consequently, these parasites limit or eradicate males from the population. In some insect species, infected males can reproduce only when they mate with infected females carrying the same *Wolbachia* strain. In other species, these parasites convert male insects into females. Some infected females reproduce parthenogenetically (that is, their eggs develop without fertilization). Because they affect reproduction in their hosts, *Wolbachia* and other reproductive parasites may influence evolutionary divergence and even extinction in some species.

Some prokaryotes cause disease

Some prokaryote species have coevolved with eukaryotes and are interdependent with them. All plants and animals harbor a population of microorganisms that are considered normal microbiota (or microflora)—harmless symbiotic prokaryotes. In fact, the number of bacteria that normally inhabit the human body (approximately 700 trillion cells) exceeds the number of



Dennis Drenner

FIGURE **23-16** **LM of *Anabaena*, a filamentous cyanobacterium that fixes nitrogen.**

Nitrogen fixation takes place in the rounded cells, called *heterocysts*.

its own human cells (about 70 trillion cells). Some of these bacteria provide a beneficial service for their host. For example, the presence of certain bacterial populations prevents harmful microorganisms (including other bacteria) from flourishing. Some bacteria that inhabit the human intestine produce vitamin K and some of the B vitamins, which are then absorbed and used.

A small percentage of bacterial species are important pathogens of plants and animals. Some of the normal bacterial (and viral) inhabitants are opportunistic pathogens that cause disease only under certain conditions. For example, when the immune system is compromised, opportunistic bacteria may increase in number and cause disease.

PROCESS OF SCIENCE

The idea that some unknown agent causes disease was debated long before Leeuwenhoek discovered microorganisms with his microscope in the late 1600s. However, not until much later did scientists develop the tools or the methods needed to accurately understand the relationships between bacteria and disease. During the late 19th century several physicians, microbiologists, and chemists working independently laid the foundations for the science of microbiology. French chemist Louis Pasteur disproved the prevailing views of spontaneous generation by demonstrating that sterilization of a sugar and protein culture prevented bacterial growth. Pasteur also developed a rabies vaccine, showing that people can be stimulated to develop immunity to disease.

The German physician Robert Koch was the first to clearly demonstrate that bacteria cause infectious disease. In 1876 he showed that *Bacillus anthracis* causes anthrax. Using a microscope, Koch observed the bacteria in the blood and spleens of dead sheep. When he inoculated mice with the infected sheep blood, he was able to identify *B. anthracis* in the blood of the mice. He also cultured *B. anthracis* and showed that when he injected the bacteria into healthy mice, they developed anthrax.

Koch proposed a set of guidelines, now known as **Koch's postulates,** that are still used to demonstrate that a specific pathogen causes specific disease symptoms: (1) the pathogen must be present in every individual with the disease; (2) a sample of the microorganism taken from the diseased host can be grown in pure culture; (3) when a sample of the pure culture is injected into a healthy host, it causes the same disease; and (4) the microorganism can be recovered from the experimentally infected host.

Pathogenic microorganisms can enter the body in food, dust, droplets, or through wounds. Many diseases are transmitted by insect or animal bites. To cause disease, a pathogen must adhere to a specific cell type, multiply, and produce toxic substances. Adherence and multiplication occurs only when the pathogen competes successfully with the normal microbiota and counteracts the host's defenses against invasion.

Pathogens produce a variety of substances that increase their success. Some bacteria produce **exotoxins,** strong poisons that are either secreted from the cell or leak out when the bacterial cell is destroyed. The toxin, not the presence of the bacteria themselves, is responsible for the disease. As mentioned previously, diphtheria is caused by a Gram-positive bacillus *(Corynebacterium diphtheriae)* that is lysogenized by a phage. The diphtheria toxin kills cells and causes inflammation.

Botulism, a type of food poisoning that can lead to paralysis and sometimes death, results from eating improperly canned food. Botulism is caused by an exotoxin released by the Gram-positive, endospore-forming *Clostridium botulinum.* During the canning process, food must be heated sufficiently to kill any highly heat-resistant endospores that may be present. If not, the endospores can germinate. The resulting bacterial population grows and releases an exotoxin so powerful that 1 g could kill a million humans! Like many exotoxins, the one that causes botulism is inactivated by heating. (Food must be heated to 80°C for 10 minutes, or boiled for 3 to 4 minutes.) The botulism exotoxin, marketed under the trade name Botox, is used in extremely tiny amounts to treat several medical conditions involving spasms (involuntary muscle contractions). Because Botox is a neurotoxin that works by paralyzing muscles, it can also relax facial wrinkles caused by contraction of the underlying muscles. However, its effects last for only three to eight months.

Endotoxins are not secreted by pathogens but are components of the cell walls of most Gram-negative bacteria. These compounds affect the host only when they are released from dead bacteria. Endotoxins bind to the host's macrophages and stimulate them to release substances that cause fever and other symptoms of infection. Unlike exotoxins, which cause specific symptoms, endotoxins appear to affect the entire body. Endotoxins are not destroyed by heating.

Prokaryotes are used in many commercial processes

Many foods and beverages are produced with the help of microbial fermentation. Lactic acid bacteria are used in producing acidophilus milk, yogurt, pickles, olives, and sauerkraut (Fig. 23-17). Several types of bacteria are used to produce cheese. Bacteria

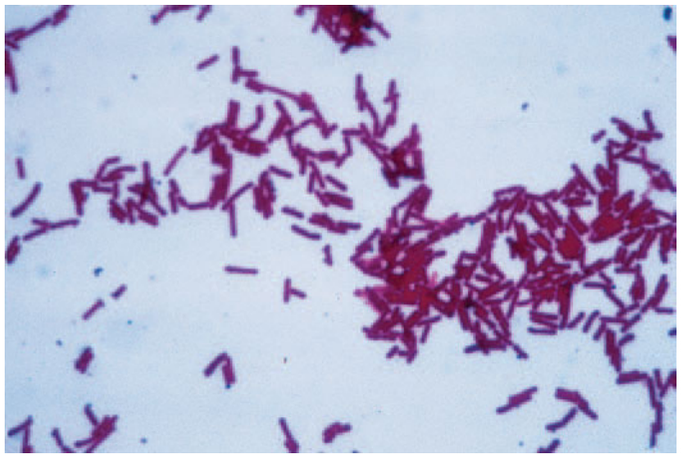


FIGURE **23-17** **LM of lactic acid bacteria *(Lactobacillus acidophilus).***

are involved in making fermented meats such as salami and in the production of vinegar, soy sauce, chocolate, and certain B vitamins (B_{12} and riboflavin). Bacteria are also used in producing citric acid, a compound added to candy and to most soft drinks.

Some microorganisms produce *antibiotics,* compounds that limit competition for nutrients by inhibiting or destroying other microorganisms. By the 1950s antibiotics had become important clinical tools that transformed the treatment of infectious disease. Today about 100 clinically useful antibiotics are available, and literally tons of antibiotics are produced annually. Pharmaceutical companies obtain most antibiotics from three groups of microorganisms: a large group of Gram-positive soil bacteria, the *actinomycetes,* Gram-positive bacteria of the genus *Bacillus,* and molds (eukaryotes belonging to kingdom Fungi).

Because of their prolific reproduction rates, bacteria are ideal "factories" for the production of biomolecules. They have been genetically engineered (see Chapter 14) to produce certain vaccines, human growth hormone, insulin, and many other clinically important compounds. Most of the insulin used to treat diabetics is now derived from genetically engineered bacteria. Researchers are developing genetically engineered bacteria for production of many other medically and agriculturally useful products.

Bacteria are used in sewage treatment and to break down solid wastes in landfills. They are also used in **bioremediation,** a process in which a contaminated site is exposed to microorganisms that break down the toxins, leaving behind harmless metabolic byproducts such as carbon dioxide and chlorides. More than 1000 different species of bacteria and fungi have been used to clean up various forms of pollution, and microbiologists are searching for others. In 2003, a team of German microbiologists reported that they had isolated a species of anaerobic bacteria that has the potential to bioremediate sites contaminated with dioxins, very toxic pollutants that persist in the environment.

Archaea also have achieved economic importance. For example, archaeal enzymes have been added to laundry and industrial detergents to increase their performance at higher temperatures and pH levels. Another enzyme has been useful in the food industry to convert corn starch to dextrins.

Review

- What important roles do prokaryotes play in ecosystems?
- Why is each of Koch's postulates essential?
- What is bioremediation?

BiologyNow™ Assess your understanding of **the effects of prokaryotes on the environment** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Describe the structure of a virus, and compare a virus with a free-living cell.

- A **virus,** or **virion,** is a tiny particle consisting of a DNA or RNA genome surrounded by a protein coat, called a **capsid.**
- Viruses are subcellular particles that cannot metabolize on their own. In the past, biologists considered them nonliving particles, but some now view them as life forms.

2 Trace the evolutionary origin of viruses according to current hypotheses.

- Viruses may be bits of nucleic acid that originally "escaped" from animal, plant, or bacterial cells.
- Some biologists hypothesize that viruses must have evolved before the three domains diverged; they think it unlikely that the similarities between viruses that infect the Archaea and those that infect the Eubacteria evolved twice.

3 Characterize bacteriophages, and contrast a lytic cycle with a lysogenic cycle.

- **Phages (bacteriophages)** are viruses that infect bacteria.
- A viral reproductive cycle can be lytic or lysogenic. In a **lytic cycle,** the virus destroys the host cell. The five steps in a lytic cycle are: **attachment** to the host cell; **penetration** of viral nucleic acid into the host cell; **replication** of the viral nucleic acid; **assembly** of newly synthesized components into new viruses; and **release** from the host cell.
- **Temperate** viruses do not always destroy their hosts. In a **lysogenic cycle** the viral genome is replicated along with the host DNA. The nucleic acid of some phages becomes integrated into the bacterial DNA, and is then called a **prophage.** Bacterial cells that carry prophages are **lysogenic** cells. In **lysogenic conversion,** bacterial cells containing certain temperate viruses exhibit new properties.

4 Explain how viruses infect animal and plant cells.

- Viruses enter animal cells by membrane fusion or by endocytosis. Viral nucleic acid is replicated within the host cell, proteins are synthesized, and new viruses are assembled and released from the cell.
- Plant viruses can be spread among plants by insect vectors. Viruses spread through the plant via plasmodesmata.

SUMMARY WITH KEY TERMS *(continued)*

5 Describe the reproductive cycle of a retrovirus such as human immunodeficiency virus (HIV).

- **Retroviruses,** such as HIV, use **reverse transcriptase** to transcribe their RNA genome into a DNA intermediate that becomes integrated into the host DNA. Copies of the viral RNA are then synthesized.

6 Compare and contrast viroids and prions.

- **Viroids** and **prions** are smaller than viruses. A viroid consists of a short strand of RNA with no protein coat.
- A prion consists only of protein. Prions cause **transmissible spongiform encephalopathies (TSEs).**

7 Describe the structure and common shapes of prokaryotic cells.

- Prokaryotic cells do not have membrane-enclosed organelles such as nuclei and mitochondria.
- Common shapes of bacterial cells include **coccus,** or spherical; **bacillus,** or rod-shaped; and spiral. Spiral bacteria include the **spirillum,** a rigid helix and **spirochete,** a flexible helix. **Vibrios** are comma shaped.
- Most eubacteria have cell walls composed of **peptidoglycan.** The walls of **Gram-positive** bacteria are very thick and consist mainly of peptidoglycan. The cell walls of **Gram-negative** bacteria consist of a thin peptidoglycan layer and an outer membrane resembling the plasma membrane. Some species of eubacteria produce a **capsule** that surrounds the cell wall.
- Some bacteria have **pili,** protein structures that extend from the cell and help bacteria adhere to one another or to certain other surfaces.
- Bacterial **flagella** are structurally different from eukaryotic flagella; each flagellum consists of a basal body, hook, and filament. They produce a rotary motion.

8 Describe asexual reproduction in prokaryotes, and summarize three mechanisms (transformation, conjugation, and transduction) that may lead to genetic recombination.

- The genetic material of a prokaryote typically consists of a circular DNA molecule and one or more **plasmids,** smaller circular fragments of DNA.
- Prokaryotes reproduce asexually by **binary fission** (the cell divides forming two cells), **budding** (a bud forms and separates from the mother cell) or **fragmentation** (walls form inside the cell and it separates into several cells.)
- In bacteria, genetic material may be exchanged by transformation, transduction, or conjugation. In **transformation,** a bacterial cell takes in DNA fragments released by another cell. In **transduction,** a phage carries bacterial DNA from one bacterial cell into another. In **conjugation,** two cells of two different mating types exchange genetic material.

9 Characterize the metabolic diversity of autotrophic and heterotrophic prokaryotes, including aerobes, facultative anaerobes, and obligate anaerobes.

- Most prokaryotes are **heterotrophs** that obtain energy and carbon from other organisms; some are **autotrophs** that make their own organic molecules from simple raw materials.
- The majority of heterotrophic bacteria are free-living **saprotrophs,** that obtain nourishment from dead organic matter.
- Autotrophs may be **photoautotrophs,** which obtain energy from light or **chemoautotrophs,** which obtain energy by oxidizing inorganic chemicals.
- Most bacteria are aerobic; some are **facultative anaerobes** which metabolize anaerobically when necessary; others are **obligate anaerobes,** which can carry on metabolism only anaerobically.

10 Compare the three domains: Eubacteria, Archaea, and Eukarya.

- Prokaryotes are assigned to domain **Eubacteria** and domain **Archaea.**
- Unlike those of the Eubacteria, the cell walls of the Archaea do not have peptidoglycan. The translational mechanisms of the Archaea more closely resemble eukaryotic mechanisms than those of other prokaryotes. Domain Eukarya includes the four kingdoms of eukaryotes.

11 Distinguish among three main groups of the Archaea based on their ecology, and among several groups of the Eubacteria as described in Table 23-3. Give examples of each group.

- Three main groups of the Archaea are methanogens, extreme halophiles, and extreme thermophiles. **Methanogens** produce methane gas from simple carbon compounds. They inhabit anaerobic environments such as marshes, marine sediments, and the digestive tracts of animals. **Extreme halophiles** inhabit saturated salt solutions. **Extreme thermophiles** can inhabit environments at temperatures higher than 100°C.
- See Table 23-3 to review some of the major groups of Eubacteria.

12 Discuss the ecological roles of prokaryotes, their importance as pathogens, and their commercial importance.

- Prokaryotes play essential ecological roles as **decomposers** and are important in recycling nutrients. Some prokaryotes carry out photosynthesis.
- Many bacteria are symbiotic with other organisms; some are important **pathogens** of plants and animals.
- Anton van Leeuwenhoek, Louis Pasteur, and Robert Koch were important pioneers in microbiology. **Koch's postulates** are a set of guidelines used to demonstrate that a specific pathogen causes specific disease symptoms.
- Some pathogenic bacteria produce strong poisons called **exotoxins;** others produce **endotoxins,** poisonous components of their cell walls. Endotoxins are released when bacteria die.

POST-TEST

1. Pathogens (a) are agents that cause disease (b) include most bacteria (c) include most myxobacteria (d) include many autotrophs (e) are cyanobacteria that cause disease

2. The genome of a virus consists of (a) DNA (b) RNA (c) prions (d) DNA and RNA (e) DNA or RNA

POST-TEST *(continued)*

3. The capsid of a virus consists of (a) protein (b) nucleic acid (c) helical proteins (d) a simple carbohydrate (e) RNA and lipid
4. Viruses that kill host cells are (a) lysogenic (b) lytic (c) viroids (d) prophages (e) temperate
5. The correct sequence in viral reproduction is (a) attachment, penetration, assembly, replication, release (b) penetration, absorption, assembly, replication, release (c) attachment, penetration, replication, assembly, release (d) release, assembly, penetration, replication, attachment (e) attachment, penetration, replication, release, assembly
6. In lysogenic conversion (a) bacterial cells may exhibit new properties (b) the host cell dies (c) prions sometimes convert to viroids (d) reverse transcriptase transcribes DNA into RNA (e) prion proteins convert to infective agents
7. Peptidoglycan is a chemical compound found in the cell walls of (a) most viroids (b) most Archaea (c) all prokaryotes (d) most Eubacteria (e) most Eukarya
8. Retroviruses (a) are DNA viruses (b) are RNA viruses (c) use reverse transcriptase to transcribe DNA into RNA (d) use prion protein to transcribe RNA (e) are DNA viruses that cause AIDS
9. Bacterial flagella (a) are homologous with eukaryotic flagella (b) exhibit a rotary motion (c) consist of a basal body and nine pairs of microtubules (d) are important in transduction (e) are characteristic of Gram-positive bacteria
10. In conjugation (a) two bacterial cells of different mating types come together, and genetic material is transferred from one to another (b) a bacterial cell develops a bulge that enlarges and eventually separates from the mother cell (c) fragments of DNA released by a broken cell are taken in by another bacterial cell (d) a phage carries bacterial genes from one bacterial cell into another (e) walls develop in the cell, which then divides into six new cells
11. Endospores (a) are formed by some viruses (b) are extremely durable cells (c) are comparable to the reproductive spores of fungi and plants (d) cause fever and other symptoms in the host (e) are extremely vulnerable to infection by phages
12. The majority of heterotrophic bacteria are (a) free-living saprotrophs (b) photoautotrophs (c) chemoautotrophs (d) facultative anaerobes (e) obligate anaerobes
13. Which of the following do *not* belong to domain Archaea? (a) bacteria that produce methane from carbon dioxide and hydrogen (b) thermophiles (c) halophiles (d) bacteriophages (e) prokaryotes with cell walls that lack peptidoglycan
14. Which of the following scientists proposed a set of guidelines to demonstrate that a specific pathogen causes specific disease symptoms? (a) Leeuwenhoek (b) Pasteur (c) Koch (d) Prusiner (e) Woese
15. Bacteria that thrive in puncture wounds are likely to be (a) saprotrophs (b) photoautotrophs (c) chemoautotrophs (d) endospores (e) obligate anaerobes
16. Prions (a) consist of a short strand of RNA with no protein coat (b) are deadly viruses that have caused several hundred deaths in Uganda and other parts of Africa (c) appear to consist only of protein; no nucleic acid component has been found (d) are responsible for causing hepatitis C (e) are not transmissible from human to human
17. Bacteria that are autotrophs (a) do not require atmospheric oxygen for cellular respiration (b) manufacture their own organic molecules from simple raw materials (c) must obtain organic compounds from other organisms (d) get their nourishment from dead organisms (e) produce endospores when oxygen levels are too low for active growth
18. Lactic acid bacteria (a) have Gram-negative cell walls (b) fix nitrogen under anaerobic conditions (c) were formerly known as blue-green algae (d) contribute to the unique taste of yogurt, pickles, and sauerkraut (e) secrete slime on which they glide
19. Which group of bacteria contains the Gram-positive, anaerobic bacterium that causes botulism? (a) clostridia (b) actinomycetes (c) enterobacteria (d) spirochetes (e) streptococci

CRITICAL THINKING

1. Historically, biologists thought that viruses, because of their simple structure, evolved before cellular organisms. Later, the hypothesis that viruses escaped from cells gained favor. Recently, microbiologists have again suggested that viruses evolved early in the history of life. Based on what you have learned about viruses, present an argument for one of these hypotheses.
2. Imagine that you discover a new microorganism. After careful study you determine that it should be classified in the domain Archaea. What characteristics might lead you to this classification?
3. How might life be different if all prokaryotes were killed?

Protists

Gopal Murti/Science Photo Library/Photo Researchers, Inc.

Human red blood cells filled with malarial parasites. As shown in this colorized TEM, the parasites multiply inside human red blood cells *(red),* safe from the body's immune system. Malaria is a tropical disease caused by the protist *Plasmodium* and transmitted to humans by the mosquito *Anopheles gambiae* as it feeds on human blood.

CHAPTER OUTLINE

- **Introduction to the Protists**
- **Evolution of the Eukaryotes**
- **Representative Protists**

In Chapter 22 you learned that the kingdom Protista was first proposed in 1866, to include bacteria and other microorganisms that differ from plants and animals. When Robert Whittaker recommended the five-kingdom system of classification in 1969, only unicellular eukaryotic organisms were placed in kingdom Protista. Since then the boundaries of this kingdom have expanded to include any eukaryote that isn't a fungus, animal, or land plant. More recently, some biologists have proposed eliminating the kingdom Protista by splitting it into several kingdoms based largely on molecular data that have clarified certain evolutionary relationships. Many relationships among protists remain uncertain, however.

Kingdom Protista currently consists of a vast assortment of primarily aquatic eukaryotic organisms whose diverse body forms, types of reproduction, modes of nutrition, and lifestyles make them difficult to characterize. **Protists** are unicellular, colonial, or simple multicellular organisms that have a eukaryotic cell organization. The word *protist,* from the Greek for "the very first," reflects the idea that protists were the first eukaryotes to evolve.

Protists are members of Eukarya, the third domain on the tree of life. Eukaryotic cells are characteristic of protists as well as of complex multicellular organisms belonging to the kingdoms Fungi, Animalia, and Plantae. However, having a eukaryotic cell structure clearly differentiates protists from members of the prokaryotic domains Eubacteria and Archaea. Recall from Chapter 4 that, unlike prokaryotic cells, eukaryotic cells have nuclei and other membrane-enclosed organelles such as mitochondria and plastids, 9 + 2 flagella, and multiple chromosomes in which DNA and proteins form a complex called *chromatin.* Sexual reproduction, meiosis, and mitosis are also characteristic of eukaryotes.

Size varies considerably within the protist kingdom, from microscopic protists to giant kelps, which are brown algae that reach 75 m (about 250 ft) in length. Although most protists are unicellular, some form **colonies,** loosely connected groups of cells; some are **coenocytic,** consisting of a multinucleate mass

of cytoplasm; and some are **multicellular,** composed of many cells. Unlike animals, plants, and many fungi, most multicellular protists have relatively simple body forms without specialized tissues.

Because of their huge numbers, members of kingdom Protista are crucial to the natural balance of the living world. Protists are an important source of food for other organisms, and photosynthetic protists supply oxygen to aquatic and terrestrial ecosystems. Certain protists are economically important, and others cause devastating diseases (see photograph).

Biologists currently recognize as many as 60 major groups of protists. Consideration of all protist groups is beyond the scope of this text, but we discuss a number of representative taxa. ■

INTRODUCTION TO THE PROTISTS

Learning Objectives

1 Characterize the features common to the members of kingdom Protista.

2 Discuss in general terms the diversity inherent in the protist kingdom, including means of locomotion, modes of nutrition, interactions with other organisms, habitats, and modes of reproduction.

Size and structural complexity are not the only variable features of protists. During the course of evolutionary history, organisms in kingdom Protista have evolved diversity in their (1) means of locomotion, (2) ways of obtaining nutrients, (3) interactions with other organisms, (4) habitats, and (5) modes of reproduction.

Protists, most of which are motile at some point in their life cycle, have various means of locomotion. They may move by pushing out cytoplasmic extensions (*pseudopodia*) as an amoeba does; by flexing individual cells; by gliding over surfaces; by waving *cilia,* short, hairlike organelles; or by lashing *flagella,* long, whiplike organelles (Fig. 24-1). Some protists have two or more means of locomotion—for example, both flagella and pseudopodia.

Methods of obtaining nutrients differ widely in kingdom Protista. Most algae are autotrophic and photosynthesize as plants do. Some heterotrophic protists obtain their nutrients by absorption, as fungi do, whereas others resemble animals in that they ingest food. Some protists switch their modes of nutrition and are autotrophic at certain times and heterotrophic at others.

Although many protists are free-living, others form stable symbiotic associations with unrelated organisms. These intimate associations range from **mutualism,** a more or less equal partnership where both partners benefit, to **commensalism,** where one partner benefits and the other is unaffected, to **parasitism,** where one partner (the parasite) lives on or in another (the host) and metabolically depends on it (see Chapter 52). Some parasitic protists are important pathogens (disease-causing agents) of plants or animals. Throughout this chapter, we describe specific examples of symbiotic associations involving protists.

Most protists are aquatic and live in the ocean or in freshwater ponds, lakes, and streams. They make up most of the **plankton,** the floating, often microscopic organisms that inhabit surface waters and are the base of the food web in aquatic ecosystems. Other aquatic protists attach to rocks or other surfaces in the water. Even parasitic protists are aquatic, because they live in the watery environments of other organisms' body fluids. Terrestrial protists are restricted to damp places such as soil, cracks in bark, and leaf litter.

Reproduction is varied in kingdom Protista. Almost all protists reproduce asexually, and many also reproduce sexually, often by **syngamy,** the union of gametes. However, most protists do not develop multicellular reproductive organs, nor do they form embryos the way more complex organisms do.

Review

- What are the features of a "typical" protist?
- How do protists vary in their means of obtaining nutrients?
- What are some of the ways protists interact with other organisms?

EVOLUTION OF THE EUKARYOTES

Learning Objectives

3 Discuss the endosymbiont theory, and briefly explain some of the evidence that supports it.

4 Describe the kinds of data biologists use to classify eukaryotes.

Biologists hypothesize that protists were the first eukaryotic cells to evolve from ancestral prokaryotes. They may have appeared in the fossil record as early as 1.5 to 1.6 billion years ago. The first eukaryotes were probably *zooflagellates,* heterotrophic unicellular protists that have flagella. However, other than a few

protists with hard shells, such as diatoms and foraminiferans, most ancient protists did not leave many fossils, because their bodies were too soft to leave permanent traces. Evolutionary studies of protists focus primarily on molecular and structural comparisons of present-day organisms, which contain many clues about their evolutionary history.

Mitochondria and chloroplasts probably originated from endosymbionts

According to the **endosymbiont theory,** advanced since the 1960s by U.S. biologist Lynn Margulis, certain eukaryotic organelles (particularly mitochondria and chloroplasts) arose from symbiotic relationships between larger cells and smaller prokaryotes that were incorporated and lived within them (see Fig. 20-7). Cell biologists hypothesize mitochondria originated from aerobic eubacteria. Studies of mitochondrial DNA suggest it is a remnant from the mitochondrion's past, when it was an independent organism. Gene sequence data suggest that rickettsias—bacteria that are obligate parasites (see Chapter 23)—are the closest extant relatives of mitochondria.

Chloroplast evolution is more complex, as there were probably several endosymbiotic events. Molecular evidence supports the view that incorporation of an ancient cyanobacterium within a host cell, known as the *primary endosymbiosis,* resulted in the chloroplasts in today's red algae, green algae, and plants. Biologists hypothesize that these chloroplasts, which are enclosed by two external membranes, later provided other nonphotosynthetic eukaryotes with their chloroplasts during *secondary endosymbiosis* (Fig. 24-2).

Secondary endosymbiosis occurred frequently in eukaryote evolution, as evidenced by the presence of additional chloroplast membranes. For example, *three* membranes envelop the chloroplasts of euglenoids and dinoflagellates, and *four* membranes surround the chloroplasts of diatoms, golden algae, and brown algae. Understanding how these membranes originated is an essential aspect of the endosymbiont theory, and many researchers are studying the origin of chloroplasts in different organisms.

Even nonphotosynthetic protists may contain chloroplast relics from secondary endosymbiotic events. Apicomplexans, protists such as *Plasmodium,* which causes malaria, have a nonfunctional chloroplast surrounded by four membranes. This chloroplast, which is probably derived from either a red alga or a green alga, has great medical potential in treating malaria, because some researchers hypothesize that drugs that inhibit chloroplasts also may kill *Plasmodium.*

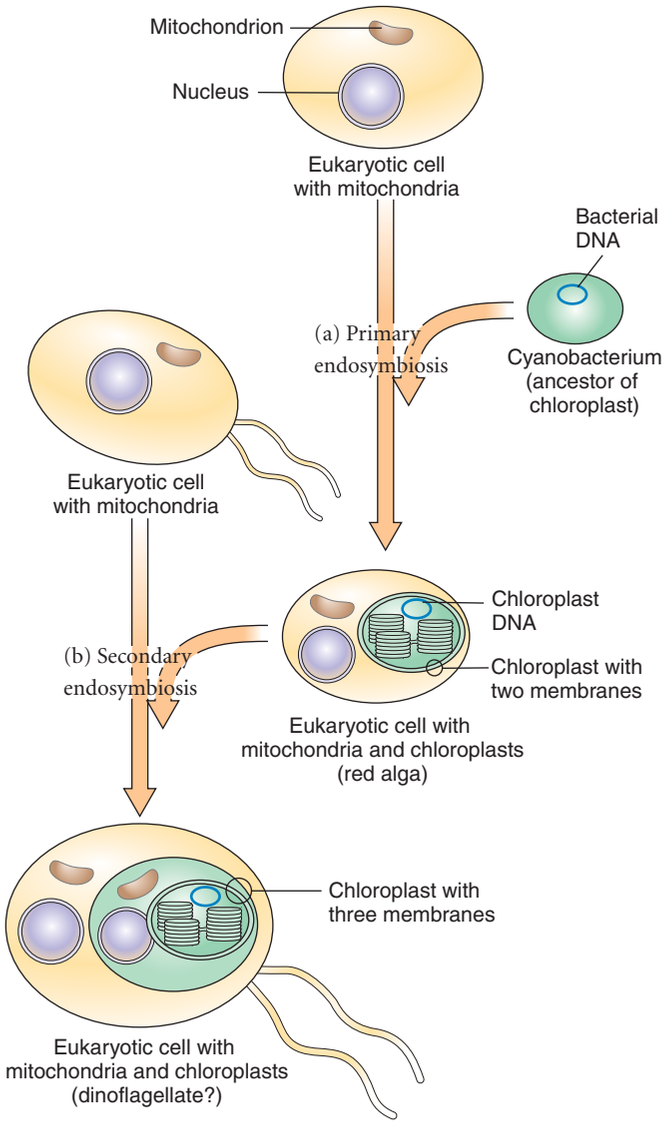

FIGURE **24-2** **Chloroplast evolution by primary and secondary endosymbiosis.**

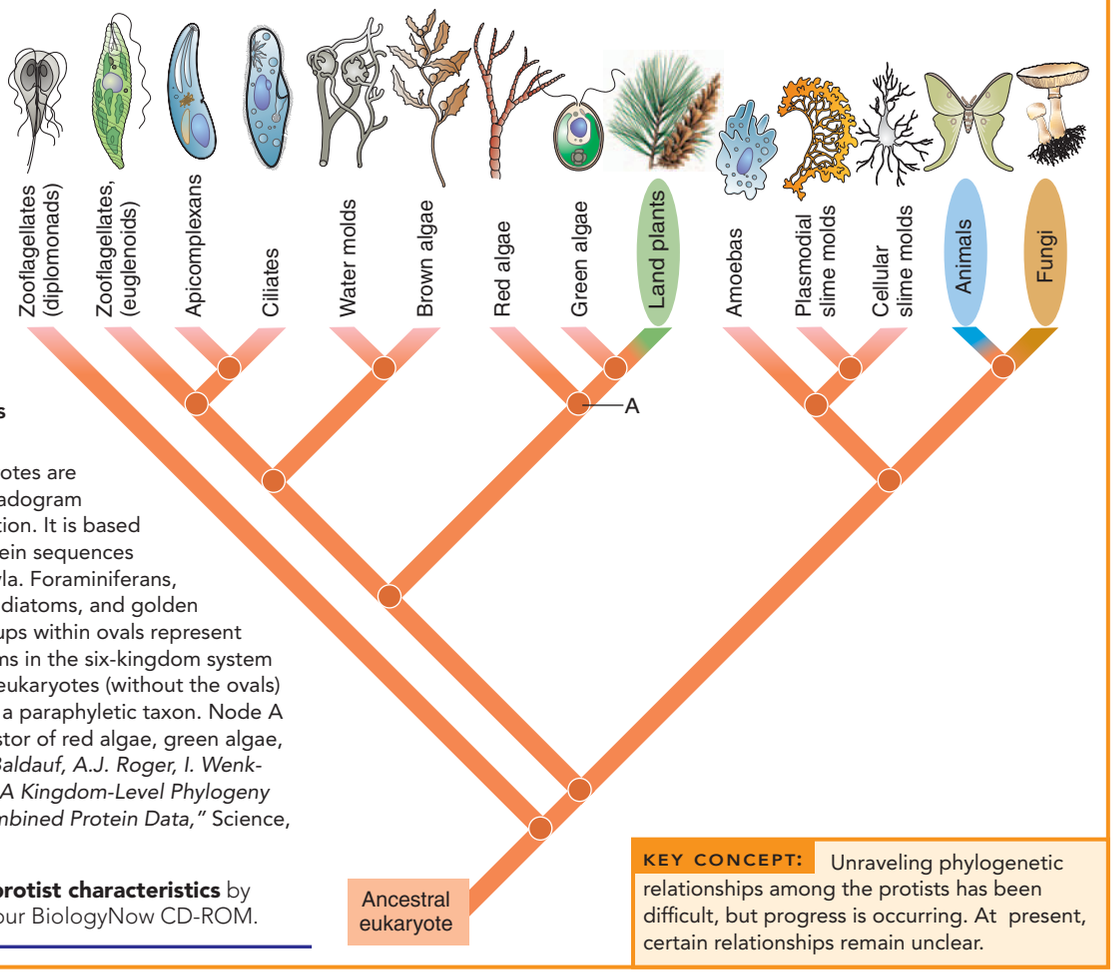
(a) In primary endosymbiosis, an ancient eukaryotic cell engulfed a cyanobacterium, which survived and evolved into a chloroplast. The ancient cell is depicted as a eukaryotic cell because mitochondria almost certainly evolved before chloroplasts. **(b)** In a secondary endosymbiotic event, a heterotrophic eukaryotic cell (with mitochondria) engulfed a eukaryotic cell with chloroplasts (a red alga is depicted). The red alga survived and evolved into a chloroplast surrounded by three membranes (a dinoflagellate chloroplast is depicted). Other secondary endosymbiotic events resulted in more complex chloroplast membrane structures.

A consensus is slowly emerging in eukaryote classification

PROCESS OF SCIENCE

Scientists re-evaluate evolutionary relationships among the eukaryotes as additional evidence becomes available. Two types of modern research, molecular and ultrastructure, have contributed substantially to scientific understanding of the phylogenetic relationships among protists. Molecular data were initially obtained for the gene that codes for small subunit ribosomal RNA in different eukaryotes (SSU rRNA; see Chapter 23). More recently, biologists compared other nuclear genes, many of which code for proteins, for different protist groups.

Ultrastructure is the fine details of cell structure revealed by electron microscopy. In many cases, ultrastructure data complement molecular data. Electron microscopy reveals similar structural patterns among those protist groups that comparative molecular evidence suggests are **monophyletic**—that is, evolved



ACTIVE FIGURE **24-3**

Evolutionary relationships among eukaryotes.

Relationships among eukaryotes are diverse and debated; this cladogram presents just one interpretation. It is based on comparisons of four protein sequences among many eukaryotic phyla. Foraminiferans, actinopods, dinoflagellates, diatoms, and golden algae are not included. Groups within ovals represent separate eukaryotic kingdoms in the six-kingdom system used in this book. All other eukaryotes (without the ovals) are in the kingdom Protista, a paraphyletic taxon. Node A indicates the common ancestor of red algae, green algae, and plants. *(Based on S.L. Baldauf, A.J. Roger, I. Wenk-Siefert, and W.F. Doolittle, "A Kingdom-Level Phylogeny of Eukaryotes Based on Combined Protein Data," Science, Vol. 290, 3 Nov. 2000)*

BiologyNow™ Explore **protist characteristics** by clicking on this figure on your BiologyNow CD-ROM.

KEY CONCEPT: Unraveling phylogenetic relationships among the protists has been difficult, but progress is occurring. At present, certain relationships remain unclear.

from a common ancestor (see Chapter 22). For example, molecular and ultrastructure data suggest that water molds, diatoms, golden algae, and brown algae—protist groups that at first glance seem to share few characteristics—are a monophyletic group.

Given the diversity in protist structures and molecules, most biologists regard the protist kingdom as a **paraphyletic group**—that is, the protist kingdom contains some, but not all, of the descendants of a common eukaryote ancestor. Molecular and ultrastructural analyses continue to help biologists clarify relationships among the various protist phyla and among protists and the other eukaryotic kingdoms (Fig. 24-3). Biologists also use these data to develop various proposals that split organisms in kingdom Protista into several kingdoms. One proposal, for example, removes red algae and green algae from the protists and classifies them within the plant kingdom. Figure 24-3 supports such a classification change, because it suggests they share a common ancestor (see node A).

Review

- How does the endosymbiont theory explain the origin of mitochondria and chloroplasts?
- What kinds of evidence support the hypothesis that the protist kingdom is a paraphyletic group?

BiologyNow™ Assess your understanding of **the evolution of the eukaryotes** by taking the pretest on your BiologyNow CD-ROM.

REPRESENTATIVE PROTISTS

Learning Objectives

5 Explain why zooflagellates are no longer classified in a single phylum, and distinguish among diplomonads, euglenoids, and choanoflagellates.

6 Briefly describe and compare the following alveolates: ciliates, dinoflagellates, and apicomplexans.

7 Briefly describe and compare the following heterokonts: water molds, diatoms, golden algae, and brown algae.

8 Describe the foraminiferans and actinopods, and explain why many biologists classify them in the monophyletic group cercozoa.

9 Support the hypothesis that red algae and green algae are a monophyletic group with land plants.

10 Briefly describe and compare the following amoebozoa: amoebas, plasmodial slime molds, and cellular slime molds.

The protists include those organisms traditionally known as protozoa, algae, and "lower fungi." Biologists continue to resolve evolutionary relationships among the protists and between the protists and other eukaryotes (plants, animals, and fungi). As a result of ongoing research, many biologists are developing different ways to classify eukaryotes, including new names for major groups. In the classification scheme we are currently

using in this book almost all known eukaryotes are assigned to one of eight major groups: excavates, discicristates, alveolates, heterokonts, cercozoa, plants, amoebozoa, and opisthokonts (Table 24-1). Figure 24-4, shows the groups superimposed over Fig. 24-3. As additional data accumulate, these groups may be elevated to the status of kingdoms, resulting in a 10-kingdom system that replaces the 6-kingdom system currently in use (see Chapter 22). However, it is also possible new data will prompt biologists to abandon or reorganize at least some of the eight groups.

Excavates are anaerobic zooflagellates

Zooflagellates are mostly heterotrophic, unicellular (a few are colonial) organisms with spherical or elongated bodies. They move rapidly by lashing one to many long, whiplike **flagella** which are usually located at the anterior (front) end. Some zooflagellates ingest food by means of a definite "mouth," or *oral groove.* Biologists traditionally classified zooflagellates in a single phylum. However, evidence indicates zooflagellates are polyphyletic, and most biologists have separated them into several groups, such as the excavates and discicristates, based on close evolutionary relationships.

Most **excavates** are endosymbionts and live in anoxic (without oxygen) environments. Unlike virtually all other protists, excavates lack mitochondria, or if they are present, the mitochondria are atypical. Excavates do not carry out aerobic respiration; they obtain energy by glycolysis. These protists are so named because most have a deep, or *excavated,* oral groove.

From an evolutionary perspective, one of the most interesting groups of modern-day excavates is the **diplomonads** (phylum Retortamonada), which retain some characteristics of ancient protists. Diplomonads have one or two nuclei, no mitochondria, no Golgi complex, and up to eight flagella.

Giardia is a parasitic diplomonad. Comparative ribosomal RNA sequencing suggests diplomonads such as *Giardia* may be more closely related to prokaryotes than are any other protists (Fig. 24-5a). Interestingly, *Giardia's* cell structure—it has two haploid nuclei— suggests a partial explanation of how diploid eukaryotes may have arisen from haploid prokaryotes. Some biologists hypothesize that the first eukaryotes had a single haploid nucleus. Most eukaryotes today have a single diploid nucleus formed at some stage in the life cycle when two haploid nuclei fuse. Perhaps the ancestors of *Giardia* represent an intermediate stage in eukaryotic evolution when cells each had two haploid nuclei but fusion had not yet occurred:

Haploid prokaryote ⟶ eukaryote with single haploid nucleus ⟶ eukaryote with two haploid nuclei ⟶ eukaryote with single diploid nucleus

Giardia also lacks mitochondria, which initially suggested the nucleus may have evolved earlier than other membrane-enclosed organelles such as mitochondria. Arguments based on some molecular data dispute this idea, however. *Giardia* contains certain genes that code for proteins associated with mitochondria in other organisms. This information suggests an early eukaryote ancestor of *Giardia* may have possessed mitochondria, which were somehow lost at a later time during its evolutionary history.

Giardia intestinalis causes backpackers' diarrhea, a common infection among campers and hikers, particularly in the mountains of the western United States. *Giardia* is eliminated as a resistant cyst in the feces of many vertebrate animals. These cysts

TABLE 24-1 Major Monophyletic Eukaryote Taxa

Monophyletic Group	Representative Members	Key Characteristics
Excavates	Diplomonads and other zooflagellates	Mitochondria absent or atypical; cells specialized for glycolysis instead of aerobic respiration
Discicristates	Euglenoids and other zooflagellates	Disc-shaped cristae in mitochondria
Alveolates	Ciliates Dinoflagellates Apicomplexans	Alveoli, flattened vesicles just inside the plasma membrane; tubular cristae in mitochondria
Heterokonts	Water molds Diatoms Golden algae Brown algae	No flagella or two flagella, one plain and one with hairs
Cercozoa	Foraminiferans Actinopods	Tests (hard shells) through which cytoplasmic projections extend
Plants	Red algae Green algae Land plants	Chloroplasts surrounded by two membranes (inner and outer membranes)
Amoebozoa	Amoebas Plasmodial slime molds Cellular slime molds	Naked amoebas (no tests) with pseudopods
Opisthokonts	Fungi Choanoflagellates Animals	No flagella or single posterior flagellum on motile cells; flattened cristae in mitochondria

Biophoto Associates/Photo Researchers, Inc.

are a common contaminant in mountain streams. Campers and hikers become infected when they drink or rinse dishes in the "clean" mountain water. In a heavy infection, much of the wall of the small intestine is coated with these zooflagellates, which interfere with the absorption of digested nutrients and cause weight loss, abdominal cramps, and diarrhea.

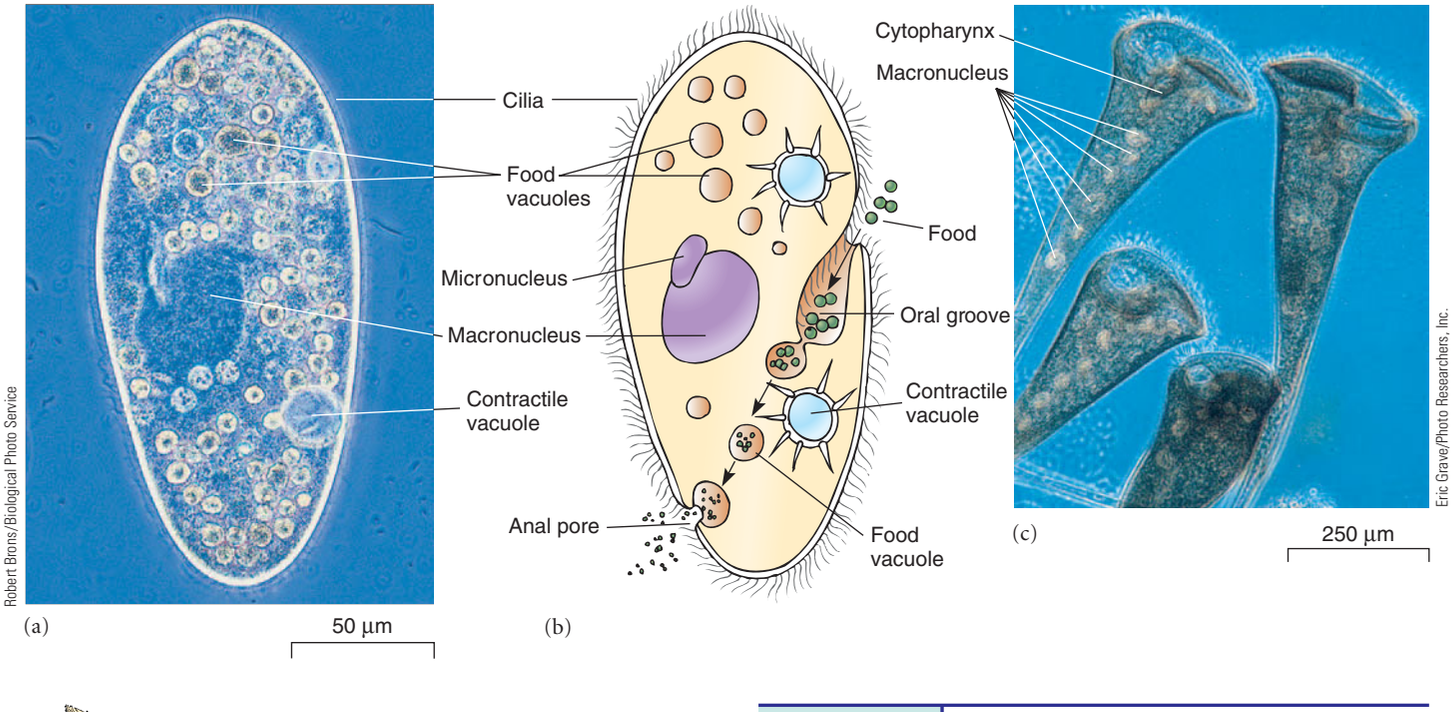
Trichonymphs (phylum Axostylata) are specialized excavates with hundreds of flagella, that live in the guts of termites and wood-eating cockroaches (Fig. 24-5b). These zooflagellates lack mitochondria but have Golgi complexes. Trichonymphs ingest wood chips and rely on endosymbiotic bacteria to digest cellulose in the wood that termites or roaches eat; the insects, trichonymphs, and bacteria obtain their nutrients from this source. This is an excellent example of mutualism.

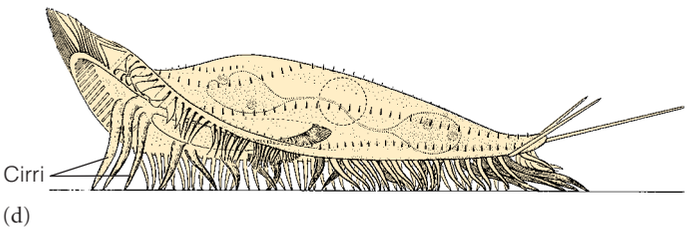
Discicristates include euglenoids and trypanosomes

Discicristates are zooflagellates named for their *disc*-shaped mitochondrial *cristae.* Discicristates include euglenoids, which are somewhat familiar to most students. Most **euglenoids** (phylum Euglenozoa) are unicellular flagellates, and about one third of them are photosynthetic (Fig. 24-6a,b). They generally have two flagella: one long and whiplike and one so short that it does not extend outside the cell. Some euglenoids, such as *Euglena,* change shape continually as they move through the water, because their **pellicle,** or outer covering, is flexible. Euglenoids reproduce asexually by mitosis; none has been observed to reproduce sexually.

At various times scientists classified euglenoids in the plant kingdom (with the algae) and in the animal kingdom (when protozoa were considered animals). Autotrophic euglenoids have chlorophylls *a* and *b* and yellow and orange **carotenoids,** the same photosynthetic pigments that green algae and plants have. Although the euglenoids have the same pigments as the green algae and plants, they are not closely related to either group, as shown in Fig. 24-3. They store energy reserves as *paramylon,* a polysaccharide. Some photosynthetic euglenoids lose their chlorophyll when grown in the dark, and they obtain their nutrients heterotrophically, by ingesting organic matter. Other species of euglenoids, such as *Peranema,* are always colorless and heterotrophic. Some heterotrophic species absorb organic compounds from the surrounding water, whereas others engulf bacteria and protists by **phagocytosis;** they digest the prey within food vacuoles.

Euglenoids inhabit freshwater ponds and puddles, particularly those with large concentrations of organic material. For that reason, researchers use them as indicator species of organic pollution. Some euglenoids also live in marine waters and mud flats.





(d)

FIGURE **24-7** **Ciliates.**

(a) Note the complex cell structure in this phase contrast LM of *Paramecium,* a freshwater ciliate. Like many ciliates, *Paramecium* has multiple nuclei: a macronucleus and one or more smaller micronuclei. **(b)** Food particles are swept into *Paramecium's* ciliated oral groove and incorporated into food vacuoles. Lysosomes fuse with the food vacuoles, and the food is digested and absorbed; undigested wastes are eliminated through the anal pore. **(c)** LM of *Stentor,* a sessile ciliate. Note the numerous cilia that direct food particles into its funnel-like cytopharynx ("throat"). The elongated macronucleus resembles a string of beads. **(d)** The hypotrich *Euplotes* has stiff ciliary tufts called cirri. *(Source for 24-7(d): By H. Machemer, in K. G. Grell,* Protozoology, *© 1973 Springer-Verlag.)*

Trypanosomes (also in phylum Euglenozoa) are colorless discicristates, many of which are parasitic and cause disease. In vertebrates, including humans, trypanosomes live in the blood. For example, *Trypanosoma brucei* is a human parasite that causes African sleeping sickness (Fig. 24-6c). It is transmitted by the bite of infected tsetse flies. Early symptoms include recurring attacks of fever. Later, when the trypanosomes have invaded the central nervous system, infected people are lethargic and have difficulty speaking or walking; if untreated, African sleeping sickness can cause death. Trypanosomes, like euglenoids, reproduce asexually by mitosis; none has been observed to reproduce sexually.

Alveolates have flattened vesicles under the plasma membrane

The unifying features of protists classified as **alveolates** are similar ribosomal DNA sequences and **alveoli** (sing., *alveolus*), flattened vesicles located just inside the plasma membrane. In some alveolates, the vesicles contain plates of cellulose. Alveolates include the ciliates, dinoflagellates, and apicomplexans.

Ciliates use cilia for locomotion

Ciliates (phylum Alveolata, subphylum Ciliophora) are among the most complex of eukaryotic cells. These unicellular organisms have a flexible outer covering called a *pellicle* that gives them a definite but changeable shape. In *Paramecium,* the surface of the cell is covered with several thousand fine, short, hairlike **cilia** that extend through pores in the pellicle to facilitate movement (Fig. 24-7a,b; also see Fig. 1-1a). The cilia beat with such precise coordination that the organism can back up and turn around as well as move forward. Just under the pellicle, many ciliates have numerous small **trichocysts,** organelles that discharge filaments that may aid in trapping prey.

Not all ciliates are motile. Some sessile forms have stalks, and others, although capable of some swimming, are more likely to remain attached to a rock or other surface at one spot (Fig. 24-7c). Their cilia set up water currents that draw food toward them.

One group of ciliates, the **hypotrichs,** have greatly modified cilia and exhibit an unusual creeping-darting locomotion. Hypotrichs lack cilia over much of the body except on the ventral (lowermost) surface, where they occur in stiff tufts called **cirri** (sing., *cirrus,* from the Latin for "a curl of hair") (Fig. 24-7d). Hypotrichs crawl about by means of these cirri, which beat in a coordinated manner.

Ciliates have a wide range of feeding habits and diets; most ingest bacteria or other tiny protists. Their cilia draw the food into a simple opening in some species and into a funnel-like oral groove in others. A vacuole forms around the food at the end of the opening, and the food is digested. Special organelles called **contractile vacuoles** control water regulation in freshwater ciliates. Being hypertonic to their environment, freshwater ciliates continually take in water by osmosis; the contractile vacuole continually expels excess water.

Ciliates differ from other protists in having two kinds of nuclei: one or more small, diploid **micronuclei** that function in reproduction, and a larger, polyploid **macronucleus** that controls cell metabolism and growth. Most ciliates are capable of a sexual process called **conjugation,** in which two individuals come together and exchange genetic material. Biologists divide each ciliate species into several different mating types. Individuals with different mating types are identical in appearance but genetically different in terms of sexual compatibility. Because there are no known physical differences between the mating types, it is not appropriate to refer to them as "male" and "female."

During conjugation in *Paramecium,* two individuals of compatible mating types press their oral surfaces together (Fig. 24-8). Within each individual the macronucleus disintegrates and the micronucleus undergoes meiosis, forming four haploid nuclei. Three of these degenerate, leaving one, which divides mitotically to form two identical haploid nuclei. One of these remains within the cell, and the other nucleus crosses through the oral region into the other individual. A type of syngamy occurs; that is, the migrant haploid micronucleus fuses with the stationary haploid nucleus in that cell, and the two ciliates separate. The new diploid micronucleus in each cell divides a varying number of times, with one micronucleus developing into a new macronucleus.

A single act of conjugation yields two cross-fertilizations as each cell fertilizes the other. Conjugation results in two "new" cells that are genetically identical to each other but different from what they were before conjugation. Mitosis and cell division need not follow immediately after conjugation. Ciliates usually divide perpendicular to their longitudinal axis.

Most dinoflagellates are a part of marine plankton

The group of **dinoflagellates** (phylum Alveolata, subphylum Dinoflagellata) are among the most unusual protists. Most dinoflagellates are unicellular, although a few are colonial. Their alveoli contain interlocking cellulose plates impregnated with silicates (Fig. 24-9a). The typical dinoflagellate has two flagella. One flagellum wraps around a transverse groove in the center of the cell like a belt, and the other lies in a longitudinal groove (perpendicular to the transverse groove), projecting behind the cell. The undulation of these flagella propels the dinoflagellate through the water like a spinning top. Indeed, the name is derived from the Greek *dinos,* meaning "whirling." Many marine dinoflagellates are bioluminescent.

Most dinoflagellates are photosynthetic and possess chlorophylls *a* and *c* and carotenoids, including **fucoxanthin,** a yellow-brown carotenoid (Fig. 24-9b). However, a number are colorless; some of these ingest other microorganisms for food. Dinoflagellates usually store energy reserves as oils or polysaccharides.

Many dinoflagellates are endosymbionts that live in the bodies of marine invertebrates such as mollusks, jellyfish, and corals (see Fig. 52-11). These symbiotic dinoflagellates, called **zooxanthellae,** lack cellulose plates and flagella. Zooxanthellae photosynthesize and provide carbohydrates for their invertebrate partners. Zooxanthellae contribute substantially to the productivity of coral reefs. Other dinoflagellates that are endosymbionts lack pigments and are parasites that live off their hosts.

Reproduction in the dinoflagellates is primarily asexual, by mitosis, although a few species reproduce sexually. The dinoflagellate nucleus is distinctive because the chromosomes are permanently condensed and always evident. Meiosis and mitosis are unusual because the nuclear envelope remains intact throughout cell division and the spindle lies *outside* the nucleus. The chromosomes attach to the nuclear envelope, and the spindle separates the new nuclei from each other.

Ecologically, dinoflagellates are important producers in marine ecosystems. A few dinoflagellates are known to have occa-

Image not available due to copyright restrictions

sional population explosions, or blooms. These blooms, which frequently color coastal waters orange, red, or brown, are known as **red tides.** The environmental conditions that initiate dinoflagellate blooms are not known, but many experts think human-produced coastal pollution triggers red tides. Some dinoflagellate species that form red tides produce a toxin that attacks the nervous systems of fishes, leading to fish kills. Birds sometimes die when exposed to the toxin by eating the dead fish. Research has also linked red tides to manatee deaths in Florida.

Since 1991, millions of fish with open, bleeding sores have died in estuaries and tributaries of North Carolina and Maryland waters, the result of a population explosion of toxic dinoflagellates that are relatively new to science. The species *Pfiesteria piscicida* was first scientifically named and identified in 1991. *Pfiesteria* and related dinoflagellates may have complex life cycles with about 24 stages, including dormant cysts, nontoxic amoeboid forms, and both nontoxic and toxic flagellate forms. The algal blooms are circumstantially linked to nitrogen and phosphorus pollution in shallow estuaries near hog and chicken operations and municipal sewage treatment plants.

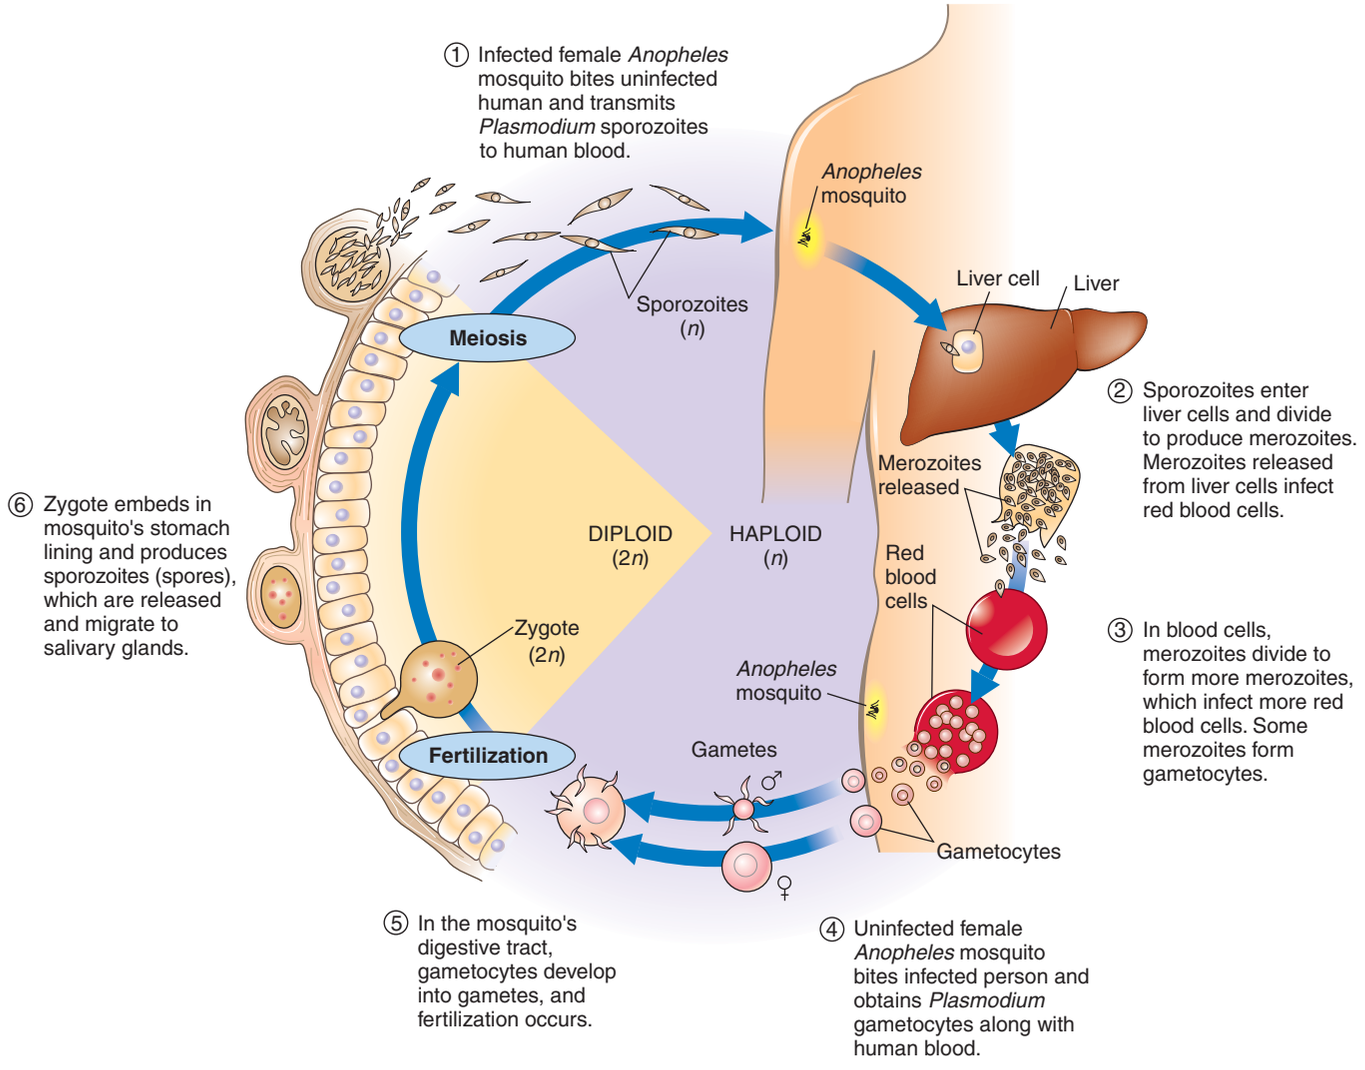
Humans sometimes get paralytic shellfish poisoning by eating filter-feeding mollusks, such as oysters, mussels, or clams, that have fed on certain dinoflagellates. The toxin may be produced by a bacterial endosymbiont living within the dinoflagellate. The poison is a neurotoxin that impairs breathing in humans who eat the contaminated shellfish; death from respiratory failure occasionally occurs. The dinoflagellates do not seem to harm the shellfish.

Apicomplexans are spore-forming parasites of animals

Apicomplexans (phylum Alveolata, subphylum Apicomplexa) are a large group of parasitic, spore-forming protists, some of which cause serious diseases such as malaria in humans. They contain a vestigial plastid and may have evolved from parasitic dinoflagellates living in the intestines of marine invertebrates. Apicomplexans lack specific structures for locomotion (cilia, flagella, or pseudopodia); instead, they move by flexing. Apicomplexans have an *apical complex* of microtubules that attaches the parasite to its host cell; the apical complex is only visible using electron microscopy. At some stage in their life cycle, apicomplexans produce **sporozoites,** small infective agents transmitted to the next host; for this reason, many biologists call these organisms **sporozoa.** Many apicomplexans spend part of their complex life cycle in one host species and part in a different host species.

Malaria is caused by an apicomplexan. According to the World Health Organization, approximately 500 million people currently have malaria, and more than 1 million people, mostly children in developing countries, die from the disease each year. Although for centuries Chinese, Greek, Arabic, and Roman writings described the disease, its causative agent and mode of transmission were not identified until the end of the 19th century. Ronald Ross, an Englishman, received the Nobel Prize in 1902 for his role in elucidating the life cycle. Four species of *Plasmodium* cause malaria in humans. *Plasmodium* sporozoites enter human blood through the bite of an infected female *Anopheles* mosquito (Fig. 24-10). *Plasmodium* first enters liver cells, where it multiplies, and then red blood cells, where it continues to proliferate. When each infected red blood cell bursts, many new parasites are released. The released parasites infect new red blood cells, and the process is repeated. The simultaneous bursting of millions of red cells causes the symptoms of malaria: a chill, followed by high fever caused by toxic substances that are released and affect other organs of the body.

Today malaria is recurring in many countries where it was under control for decades. Formerly effective control methods—antimalarial drugs and pesticides—have lost much of their effectiveness. Chloroquine and several other antimalarial drugs are taken prophylactically to prevent malaria, but *Plasmodium* has evolved resistance to several of these, necessitating



ACTIVE FIGURE **24-10**

The life cycle of *Plasmodium*, the causative agent of malaria.

BiologyNow™ Watch **the life-cycle of the malaria parasite** by clicking on this figure on your BiologyNow CD-ROM.

the use of a combination of drugs. Moreover, pesticides are used to control *Plasmodium's* vector (carrier), the mosquito, but mosquitoes have evolved resistance to many pesticides. New antimalarial drugs and several possible vaccines against malaria are currently being tested. In addition, the recent sequencing of the genomes of *Plasmodium falciparum* and the *Anopheles* mosquito has the potential to provide new diagnostics, drugs, and vaccines.

Motile cells of heterokonts are biflagellate

The **heterokonts** include water molds, diatoms, golden algae, and brown algae. At first glance, heterokonts appear too diverse to classify together. The name *heterokont,* derived from the Greek words for "different flagella," provides a clue. Heterokonts have motile cells with two flagella, one of which has tiny hairlike projections off the shaft.

Water molds produce flagellate reproductive cells

Water molds (phylum Oomycota) were once classified as fungi because of their superficial resemblance. Both water molds and fungi have a body, called a **mycelium,** that grows over organic material, digesting it and then absorbing the predigested nutrients. The threadlike **hyphae** that make up the mycelium in water molds are *coenocytic,* meaning that there are no cross walls, and the body consists of a single multinucleate cell. The cell walls of water molds are composed of cellulose (as in plants), chitin (as in fungi), or both.

When food is plentiful and environmental conditions are favorable, water molds reproduce asexually (Fig. 24-11). A hyphal tip swells and a cross wall is formed, separating the hyphal tip from the rest of the mycelium. Within this structure, called a **zoosporangium,** tiny biflagellate zoospores form, each of which develops into a new mycelium. When environmental conditions worsen, water molds initiate sexual reproduction. After fusion

(a) ① *Saprolegnia* reproduces sexually by antheridia and oogonia. ② Meiosis results in haploid sperm nuclei within the antheridia and in haploid oospheres (eggs) within the oogonia. ③ Following fertilization, oospores develop from zygotes. Each oospore has the potential to develop into a new mycelium. ④ *Saprolegnia* reproduces asexually by forming zoospores within a zoosporangium. **(b)** A mycelium of *Saprolegnia* radiates from this dead insect.

of male and female nuclei, thick-walled **oospores** develop from the oospheres. Water molds often spend the winter as oospores.

Some water molds have played infamous roles in human history. For example, the Irish potato famine of the 19th century was precipitated by the water mold *Phytophthora infestans,* which causes late blight of potatoes. (The genus *Phytophthora* is named from the Greek, meaning "plant destruction.") During several rainy, cool summers in Ireland in the 1840s, the water mold multiplied unchecked, causing potato tubers to rot in the fields. Because potatoes were the staple of the Irish peasants' diet, many people starved. Estimates of the number of deaths from the outbreak of the potato famine range from 250,000 to more than 1 million. The famine prompted a mass migration out of Ireland to such countries as the United States.

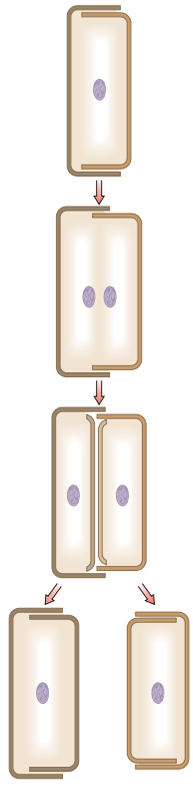
Late blight is still a problem today. New strains of *P. infestans* have appeared in the United States, Canada, northern Europe, Russia, South America, Japan, South Korea, the Middle East, and Africa. These strains resist the chemicals usually used to control the disease. Because today most people eat a varied diet, late blight does not cause famine, but it costs potato growers millions of dollars annually in lost crops.

A close relative of the late blight water mold, *Phytophthora ramorum,* causes sudden oak death, which is killing oak forests in California and Oregon. Plant pathologists are concerned the disease may spread to midwestern and eastern forests. This particular water mold also attacks redwoods, Douglas firs, bay trees, maples, and several other plant species, but most only have twig and leaf infections, not the rapid death observed in oaks.

Diatoms have shells composed of two parts

Most **diatoms** (phylum Bacillariophyta) are unicellular, although a few exist as colonies. The cell wall of each diatom consists of two shells that overlap where they fit together, much like

Image not available due to copyright restrictions



(b)

FIGURE **24-12** **Diatoms.**

(b) Asexual reproduction in diatoms. After cell division, each new cell retains half of the original shell. The newly synthesized half of the shell always fits *inside* the original half. As a result, one of the new cells is slightly smaller.

a petri dish. Silica is deposited in the shell, and this glasslike material is laid down in intricate patterns (Fig. 24-12a). There are two basic groups of diatoms: those with radial symmetry (wheel-shaped) and those with bilateral symmetry (boat-shaped or needle-shaped). Although some diatoms are part of the floating plankton, others live on rocks and sediments, where they move by gliding. This gliding movement is facilitated by the secretion of a slimy material from a small groove along the shell.

Diatoms contain the photosynthetic pigments chlorophylls *a* and *c* and carotenoids, including fucoxanthin; their pigment composition gives them a yellow or brown color. Energy reserves are stored as oils or the water-soluble carbohydrate *chrysolaminarin,* which is similar to the laminarin stored in brown algae.

Diatoms most often reproduce asexually by mitosis. When a diatom divides, the two halves of its shell separate, and each becomes the larger half of a new diatom shell (Fig. 24-12b). Because the glass shell cannot grow, some diatom cells get progressively smaller with each succeeding generation. When a diatom reaches a fraction of its original size, sexual reproduction occurs, with the production of shell-less gametes. Sexual reproduction restores the diatom to its original size because the resulting *zygote,* a $2n$ cell that results from the fusion of n gametes, grows substantially before producing a new shell.

Diatoms are common in fresh water, but they are especially abundant in relatively cool ocean water. They are major producers in aquatic ecosystems, because of their extremely large numbers. At least one species is toxic and linked to shellfish poisonings, marine mammal strandings, and the deaths of sea lions along the central California coast.

When diatoms die, their shells trickle to the ocean floor and accumulate in layers that eventually become sedimentary rock. After millions of years, geological upheaval exposed some of these deposits on land. Called *diatomaceous earth,* these deposits are mined and used as filtering, insulating, and soundproofing materials. As a filtering agent, diatomaceous earth is used to refine raw sugar and to process vegetable oils. Because of its abrasive properties, diatomaceous earth is a common ingredient in scouring powders and metal polishes; it is no longer added to most toothpastes because it is too abrasive for tooth enamel. The intricately detailed diatom shells are often used to test microscope resolution down to 1 μm.

Most golden algae are flagellate, unicellular organisms

Golden algae (phylum Chrysophyta) are found in both freshwater and marine environments. Most species are biflagellate, unicellular organisms, although some are colonial (Fig. 24-13a). A few lack flagella and are similar to amoebas in appearance except that they contain chloroplasts. Tiny scales of either silica or calcium carbonate may cover the cells. Reproduction in golden algae is primarily asexual and involves the production of flagellate, motile spores called **zoospores.**

Most golden algae are photosynthetic and produce the same pigments as diatoms: chlorophylls *a* and *c* and carotenoids, including fucoxanthin. The pigment composition of golden algae gives them a golden or golden brown color. As in diatoms, energy reserves are stored as oils or carbohydrates. A few species

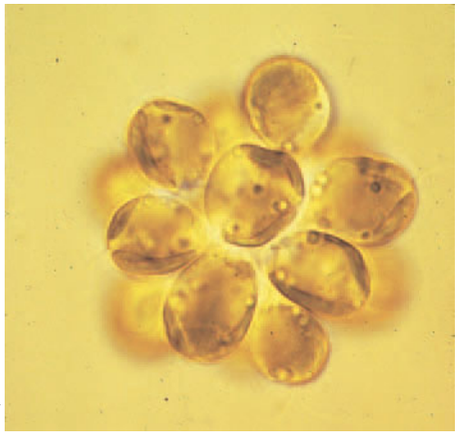


FIGURE **24-13** **Golden algae.**
(a) LM of a colonial golden alga (*Synura*) found in freshwater lakes and ponds.

Image not available due to copyright restrictions

ingest bacteria and other particles of food. Ecologically, golden algae are important producers in marine environments. They comprise a significant portion of the ocean's **nanoplankton,** extremely minute algae that are major producers because of their great abundance.

Classification of golden algae is controversial. Some biologists lump diatoms and golden algae in a single phylum, whereas others classify them as brown algae. At the other extreme, some biologists divide the golden algae into two phyla by placing many of the marine species, such as **coccolithophorids** (Fig. 24-13b), in a separate phylum.

Brown algae are multicellular seaweeds

Brown algae (phylum Phaeophyta) include the giants of the protist kingdom. They are the largest and most complex of all algae commonly called *seaweeds.* All brown algae are multicellular and range in size from a few centimeters (about an inch) to 75 m (about 250 ft). Their body forms are branched filaments, tufts, fleshy "ropes," or thick, flattened branches. The largest brown algae, called *kelps,* are tough and leathery in appearance. Many kelps have leaflike **blades** in which most photosynthesis occurs, stemlike **stipes,** and rootlike anchoring **holdfasts** (Fig. 24-14a). They often have gas-filled *bladders* that provide buoyancy. (The blades, stipes, and holdfasts of brown algae are not homologous to the leaves, stems, and roots of plants. Brown algae and plants arose from different unicellular ancestors, as shown in Fig. 24-3.)

Brown algae are photosynthetic and have chlorophylls *a* and *c* and carotenoids, including fucoxanthin, in their chloroplasts. The main energy storage reserve in brown algae is a carbohydrate called *laminarin.*

Reproduction is varied and complex in the brown algae. Their reproductive cells, both asexual zoospores and sexual gametes, are usually flagellate. Most have a life cycle that exhibits **alternation of generations,** in which they spend part of their life as haploid organisms and part as diploid organisms (see Fig. 9-16c).

Brown algae are commercially important for several reasons. Their cell walls contain a polysaccharide called *algin* that is harvested from kelps such as *Macrocystis* and used as a thickening and stabilizing agent in ice cream, toothpaste, shaving cream, hair spray, and hand lotion. Brown algae are an important human food, particularly in eastern Asia, and they are rich sources of certain vitamins and minerals such as iodine.

Brown algae are common in cooler marine waters, especially along rocky coastlines, where they live mainly in the intertidal zone or relatively shallow offshore waters. Kelps form extensive underwater "forests," or kelp beds (Fig. 24-14b). They are essential in that ecosystem for two reasons: as important food producers, and as habitat for many marine invertebrates, fish, and mammals. The diversity of life supported by kelp beds rivals that in coral reefs. There is also an extensive population of floating brown algae in a central area of the North Atlantic Ocean called the Sargasso Sea, named for the brown alga *Sargassum.* The Sargasso Sea is not greatly affected by the surface ocean currents rotating around the margins of the North Atlantic, so the floating *Sargassum* remains there.

Cercozoa are amoeboid cells enclosed in shells

The **cercozoa** are amoeboid cells that often have hard outer shells, called **tests,** through which cytoplasmic projections extend. The cytoplasmic projections suggest the name *cercozoa,* from the Greek *cerco,* meaning "rod." Foraminiferans and actinopods are cercozoa.

Foraminiferans extend cytoplasmic projections that form a threadlike interconnected net

Almost all **foraminiferans** (phylum Foraminifera) are marine organisms that produce elaborate tests (Fig. 24-15a). The ocean contains enormous numbers of foraminiferans, which secrete chalky, many-chambered tests with pores through which cytoplasmic projections are extended. The group gets its phylum name from this characteristic, as *foraminifera* is derived from the Latin for "bearing openings." The cytoplasmic projections form a sticky, interconnected net that entangles prey. Many foraminiferans contain unicellular algal endosymbionts (green algae, red algae, or diatoms) that provide food by photosynthe-

sis. Many foraminiferan species live on the ocean floor, but others are part of the plankton.

Dead foraminiferans settle on the bottom of the ocean, where their tests form a gray mud that is gradually transformed into chalk. With geological uplifting, these chalk formations become part of the land, like the White Cliffs of Dover in England (Fig. 24-15b). (The White Cliffs of Dover are the remains of a variety of carbonate organisms, not only foraminiferans.) Because foraminiferan tests often appear in rock layers covering oil deposits, geologists exploring for oil look for foraminiferan

tests in rock strata. Foraminiferans are well preserved in the fossil record, and biologists use some as **index fossils,** markers to help identify sedimentary rock layers (see Chapter 17).

Actinopods project slender axopods

Actinopods (phylum Actinopoda) are mostly marine plankton organisms with long, filamentous cytoplasmic projections called **axopods** that protrude through pores in their shells (Fig. 24-16). A cluster of microtubules strengthens each axopod. Unicellular algae and other prey become entangled in these axopods and are engulfed outside the main body of the actinopod; cytoplasmic streaming carries the prey inside the body. Many actinopods contain algal endosymbionts that provide them with the products of photosynthesis.

Some actinopods secrete elaborate and beautiful glassy shells made of silica. These **radiolarians,** are an important constituent of marine plankton. When radiolarians and other actinopods die, their shells settle and become an ooze (sediment) that can become several meters thick on the ocean floor.

Red algae, green algae, and land plants are collectively classified as plants

In the classification scheme adopted in this text, the monophyletic taxon of **plants** includes red algae and green algae, which are currently in the kingdom Protista, and land plants, which are in a separate kingdom (see Chapters 26 and 27). Biologists classify these together based on the presence of chloroplasts bounded by outer and inner membranes (see Fig. 8-4).

Red algae do not produce motile cells

The vast majority of **red algae** (phylum Rhodophyta) are multicellular organisms, although there are a few unicellular species. The multicellular body form of red algae commonly consists of complex, interwoven filaments that are delicate and feathery (Fig. 24-17a); a few red algae are flattened sheets of cells. Most multicellular red algae attach to rocks or other substrates by a basal holdfast. Reproduction in the red algae is remarkably complex, with an alternation of sexual and asexual stages. Although sexual reproduction is common, no flagellate cells develop during the life history of red algae.

The chloroplasts of red algae contain **phycoerythrin,** a red pigment, and **phycocyanin,** a blue pigment, in addition to chlorophylls *a* and *d* and carotenoids. The red algae store energy reserves as *floridean starch,* a polysaccharide similar to glycogen. They have the same pigment composition as the cyanobacteria, a group of photosynthetic eubacteria (see Chapter 23).

The cell walls of red algae often contain thick, sticky polysaccharides that have commercial value. For example, agar is a polysaccharide humans extract from certain red algae and use as a food thickener and culture medium, a substrate on which to grow microorganisms and propagate some plants, such as orchids. Another polysaccharide extracted from red algae, carrageenan, is a food additive used to stabilize chocolate milk and to provide a thick, creamy texture to ice cream and other soft processed foods. Carrageenan is also used to stabilize paints and cosmetics. Red algae are a source of vitamins (particularly

A and C) and minerals for humans, especially in Japan and other East Asian countries, where people eat red algae fresh, dried, or toasted in such traditional foods as sushi and nori.

Red algae primarily live in warm tropical ocean waters, although a few species occur in fresh water and in soil. Some red algae, known as *coralline algae,* incorporate calcium carbonate in their cell walls from the ocean waters (Fig. 24-17b). The hard calcium carbonate may protect coralline algae from the rigors of wave action. These coralline red algae are extremely important in building "coral" reefs—perhaps more crucial than coral animals in this process.

Green algae share many similarities with land plants

Green algae (phylum Chlorophyta) have pigments, energy reserve products, and cell walls that are chemically identical to those of land plants. Green algae are photosynthetic, with chlorophylls *a* and *b* and carotenoids present in chloroplasts of a wide variety of shapes. They store their main energy reserves as starch. Most green algae have cell walls with cellulose, although some lack walls. Because of these and other similarities, biologists generally accept that land plants arose from ancestral green algae (see Fig. 24-3). Using recent molecular and ultrastructure data, some biologists want to reclassify this extremely diverse group in the plant kingdom.

Green algae exhibit a variety of body types, from single cells to colonial forms, to coenocytic algae (multinucleate), to multicellular filaments and sheets (Fig. 24-18; also see Fig. 8-7a). The multicellular forms do not have cells differentiated into tissues, a characteristic that separates them from land plants. Most green algae have, or produce, flagellate cells during their life history, although a few are totally nonmotile.

Reproduction in the green algae is as varied as their body forms, with both sexual and asexual reproduction. Many green algae have life cycles with an alternation of generations. Asexual reproduction is by mitosis and cell division in single cells or by fragmentation in multicellular forms. Many green algae produce spores asexually by mitosis; if these spores have flagella and are motile, they are called *zoospores* (Fig. 24-19).

Sexual reproduction in the green algae involves gamete formation in unicellular **gametangia** (sing., *gametangium*), reproductive structures in which gametes are produced. Green algae have three types of sexual reproduction—isogamous, anisogamous, and oogamous. If the two flagellate gametes that fuse are identical in size and appearance, sexual reproduction is **isogamous** (see Fig. 24-19). **Anisogamous** sexual reproduction involves the fusion of two flagellate gametes of different sizes (Fig. 24-20). Some green algae are **oogamous** and produce a nonmotile egg and a flagellate male gamete. In addition to sexual reproduction by the fusion of gametes, some green algae exchange genetic information by a form of conjugation, in which the genetic material of one cell passes into a recipient cell (Fig. 24-21).

Green algae are found in both aquatic and terrestrial environments. Aquatic green algae primarily inhabit fresh water, although there are many marine species. Terrestrial green algae are restricted to damp soil, cracks in tree bark, and other moist places. Many green algae are symbionts with other organisms; some live as endosymbionts in body cells of invertebrates, and a few grow together with fungi as "dual organisms" called *lichens* (see Chapter 25). Regardless of where they live, green algae are ecologically important as producers.

FIGURE **24-19** **The life cycle of *Chlamydomonas*.**

Chlamydomonas, a haploid green alga with two mating types, (+) and (−), is an example of isogamous sexual reproduction. ① During sexual reproduction, a (+) gamete fuses with a (−) gamete, forming a diploid zygote ② Meiosis occurs, and ③ four haploid cells emerge, two (+) and two (−). ④ Both mating types reproduce asexually by mitosis; only the (−) strain is shown.

Amoebozoa have lobose pseudopodia

Most **amoebozoa** do not have tests and produce temporary cytoplasmic projections called **pseudopodia** (sing., *pseudopodium*, meaning "false foot") at some point in their life cycle. The pseudopodia of amoebozoa are *lobose*—that is, rounded and wide—as opposed to the slender cytoplasmic projections characteristic of the cercozoa. Biologists currently classify amoebas, plasmodial slime molds, and cellular slime molds as amoebozoa.

Amoebas move by forming pseudopodia

Amoebas (phylum Rhizopoda) are unicellular organisms found in soil, fresh water, the ocean, and other organisms (as parasites). Because of the extreme flexibility of their

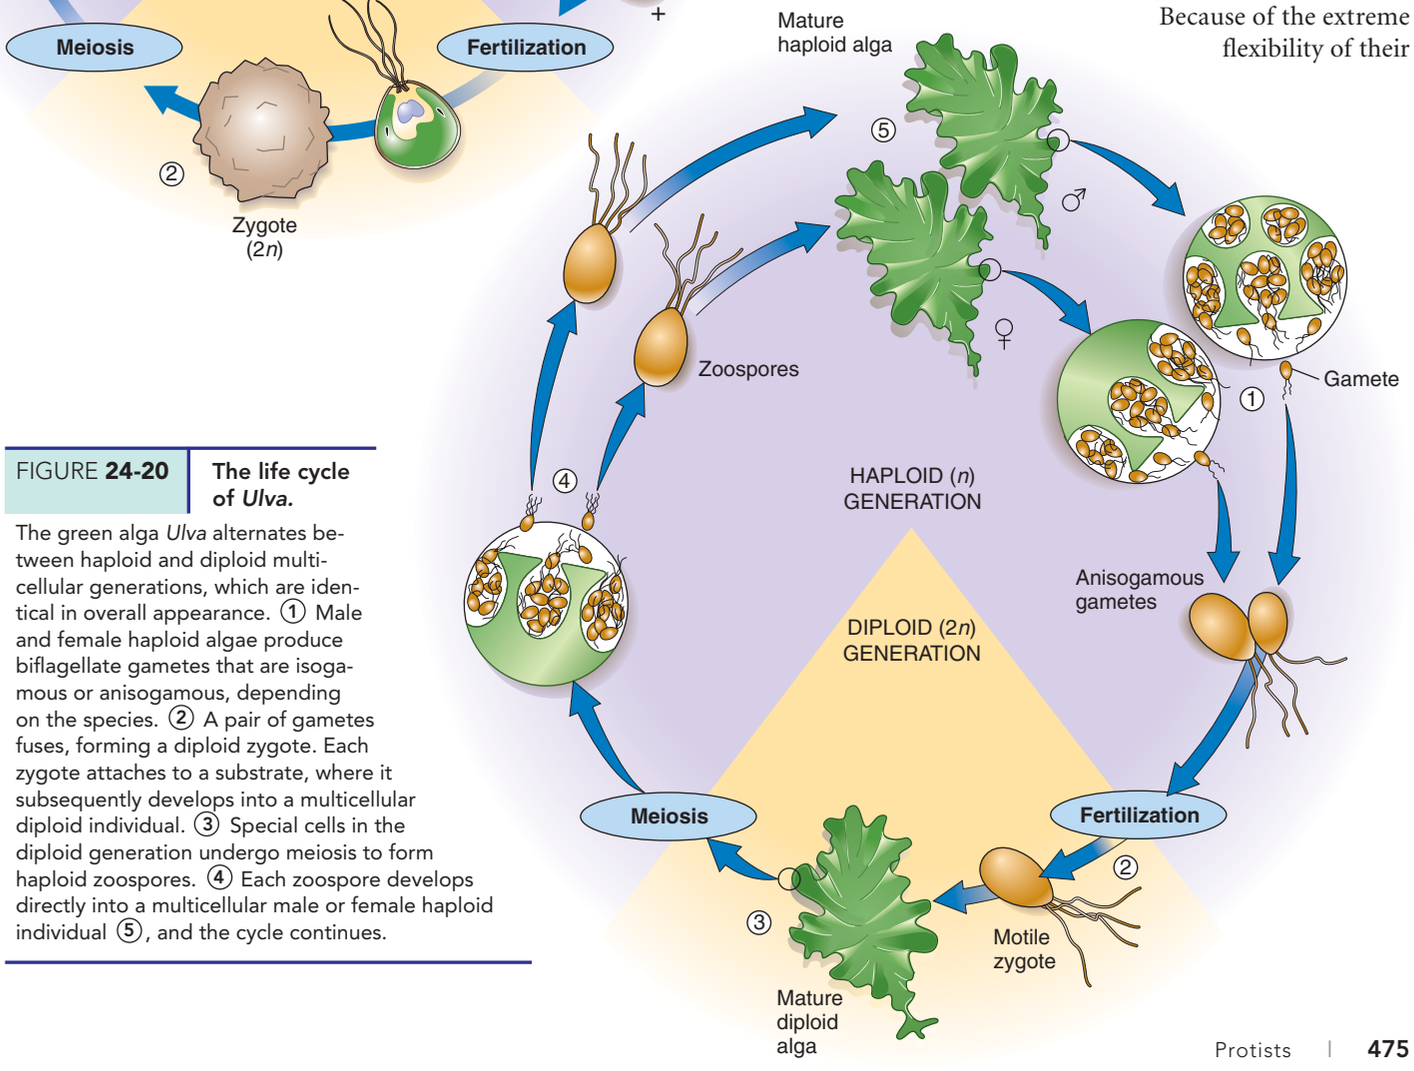

FIGURE **24-20** **The life cycle of *Ulva*.**

The green alga *Ulva* alternates between haploid and diploid multicellular generations, which are identical in overall appearance. ① Male and female haploid algae produce biflagellate gametes that are isogamous or anisogamous, depending on the species. ② A pair of gametes fuses, forming a diploid zygote. Each zygote attaches to a substrate, where it subsequently develops into a multicellular diploid individual. ③ Special cells in the diploid generation undergo meiosis to form haploid zoospores. ④ Each zoospore develops directly into a multicellular male or female haploid individual ⑤, and the cycle continues.

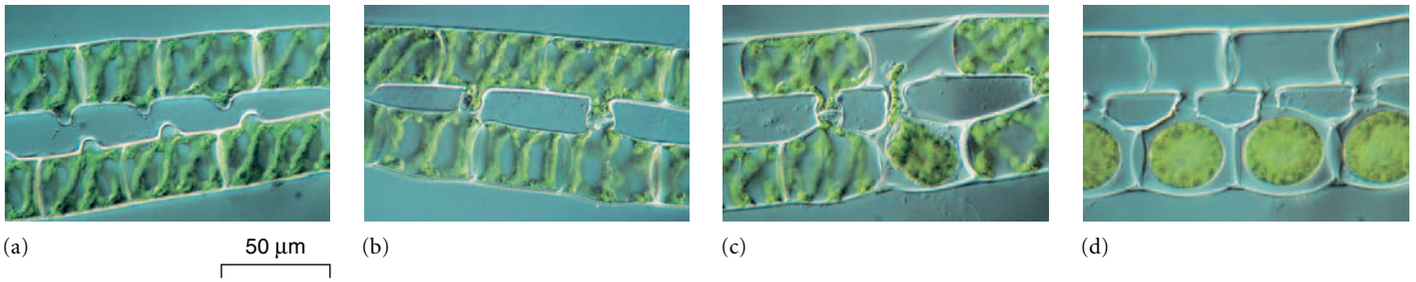

FIGURE **24-21** **Conjugation in *Spirogyra*.**

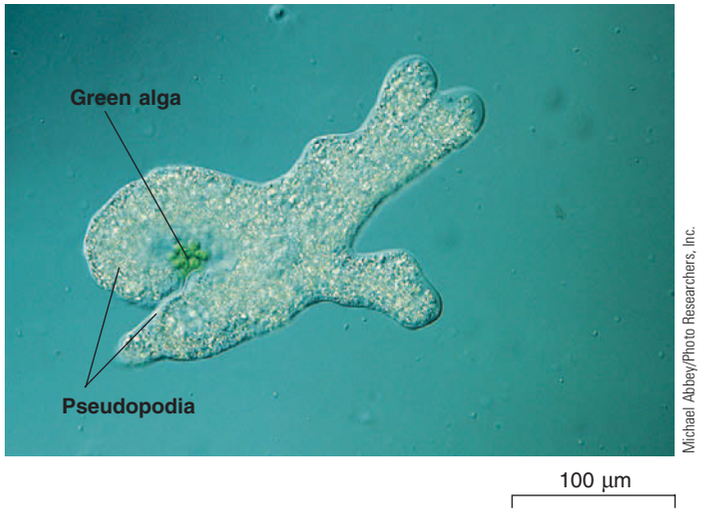
(a, b) Filaments of two different mating types of the green alga *Spirogyra* align, and conjugation tubes grow between cells of the two haploid filaments. **(c)** The contents of one cell passes into the other through the conjugation tube. **(d)** The two cells fuse, forming a diploid zygote. Following a period of dormancy, the rounded zygote undergoes meiosis, restoring the haploid condition.

outer plasma membrane, many members of this group have an asymmetrical body form and continually change shape as they move. (The word *amoeba* derives from a Greek word meaning "change.") An amoeba moves by pushing out lobose pseudopodia from the surface of the cell. More cytoplasm flows into the pseudopodia, enlarging them until all the cytoplasm has entered and the organism as a whole has moved. Pseudopodia also capture and engulf food by surrounding and forming a vacuole around it (Fig. 24-22). Food particles are digested when the food vacuole fuses with a lysosome containing digestive enzymes. Digested materials are absorbed from the food vacuole, which gradually shrinks as it empties. Amoebas reproduce asexually, splitting into two equal parts after mitotic division of the nucleus; sexual reproduction has not been observed.

Parasitic amoebas include *Entamoeba histolytica,* which causes *amoebic dysentery,* a serious human intestinal disease characterized by severe diarrhea, bloody stools, and ulcers in the intestinal wall. In especially severe cases, the organism spreads from the large intestine and causes abscesses in the liver, lungs, or brain. *Entamoeba histolytica* is transmitted as cysts in contaminated drinking water. A **cyst** is a thick-walled, resistant, resting stage in the life history of some protists. Other amoebas, like *Acanthamoeba,* are usually free-living but produce opportunistic infections such as eye infections in contact lens wearers.

FIGURE **24-22** **Amoeba.**

LM of a giant amoeba (*Chaos carolinense*). This unicellular protist, which moves and feeds by pseudopodia, is surrounding and ingesting a colonial green alga. *Chaos* amoebas are generally scavengers that feed on debris in freshwater habitats, but they ingest living organisms when the opportunity arises.



Plasmodial slime molds feed as multinucleate plasmodia

The feeding stage of a **plasmodial slime mold** (phylum Myxomycota) is a **plasmodium,** a multinucleate mass of cytoplasm that grows to 30 cm (1 ft) in diameter (Fig. 24-23a). The plasmodium, which is slimy in appearance, streams over damp, decaying logs and leaf litter, often forming a network of channels that covers a large surface area. As it creeps along, it ingests bacteria, yeasts, spores, and decaying organic matter.

When the food supply dwindles or there is insufficient moisture, the plasmodium crawls to an exposed surface and starts reproducing. Stalked structures of intricate complexity and beauty usually form from the drying plasmodium (Fig. 24-23b). Within these structures, called **sporangia,** meiosis produces haploid spores that are extremely resistant to adverse environmental conditions.

When conditions become favorable, the spores germinate, and a haploid reproductive cell emerges from each. This haploid cell is either a biflagellate *swarm cell* or an amoeboid *myxamoeba,* depending on available moisture; flagellate cells form in wet conditions. Swarm cells and myxamoebas act as gametes, which fuse to form a zygote with a diploid nucleus. The resultant diploid nucleus divides many times by mitosis, but the cytoplasm does not divide, so the result is a multinucleate plasmodium.

The plasmodial slime mold *Physarum polycephalum* is a model organism researchers have used to study many fundamental biological processes, such as growth and differentiation, cytoplasmic streaming, and the function of the cytoskeleton.

Images not available due to copyright restrictions

Cellular slime molds feed as individual amoeboid cells

The **cellular slime molds** (phylum Dictyostelida) have close affinities with amoebas and plasmodial slime molds. During its feeding stage, each cellular slime mold is an individual amoeboid cell that behaves as a separate, solitary organism. Each cell creeps over rotting logs and soil or swims in fresh water, ingesting bacteria and other particles of food as it goes. Each amoeboid cell has a haploid nucleus and reproduces by mitosis like a true amoeba.

When moisture or food becomes inadequate, certain cells send out a chemical signal, cyclic adenosine monophosphate (cAMP), that causes them to aggregate by the hundreds or thousands (Fig. 24-24a). During this stage the cells creep about for short distances as a single multicellular unit, called a **pseudoplasmodium,** or slug (Fig. 24-24b). Each cell of the slug retains its plasma membrane and individual identity. Eventually the slug settles and reorganizes, forming a stalked fruiting body containing spores (Fig. 24-24c). After being released, each spore opens and a single haploid amoeboid cell—the feeding stage—emerges. The spore-forming reproductive cycle is asexual, although sexual reproduction is observed occasionally. The life cycles of most cellular slime molds lack a flagellate stage.

The cellular slime mold *Dictyostelium discoideum* is a model organism for the study of cell differentiation, cell recognition, and cell motility and adhesion. Its biology has been studied intensively, particularly as it relates to **cell-signaling** molecules, such as cAMP, which are found in many organisms in addition to the cellular slime molds.

Opisthokonts include choanoflagellates, fungi, and animals

The **opisthokonts** are a monophyletic group that includes members of three kingdoms: choanoflagellates (kingdom Protista),

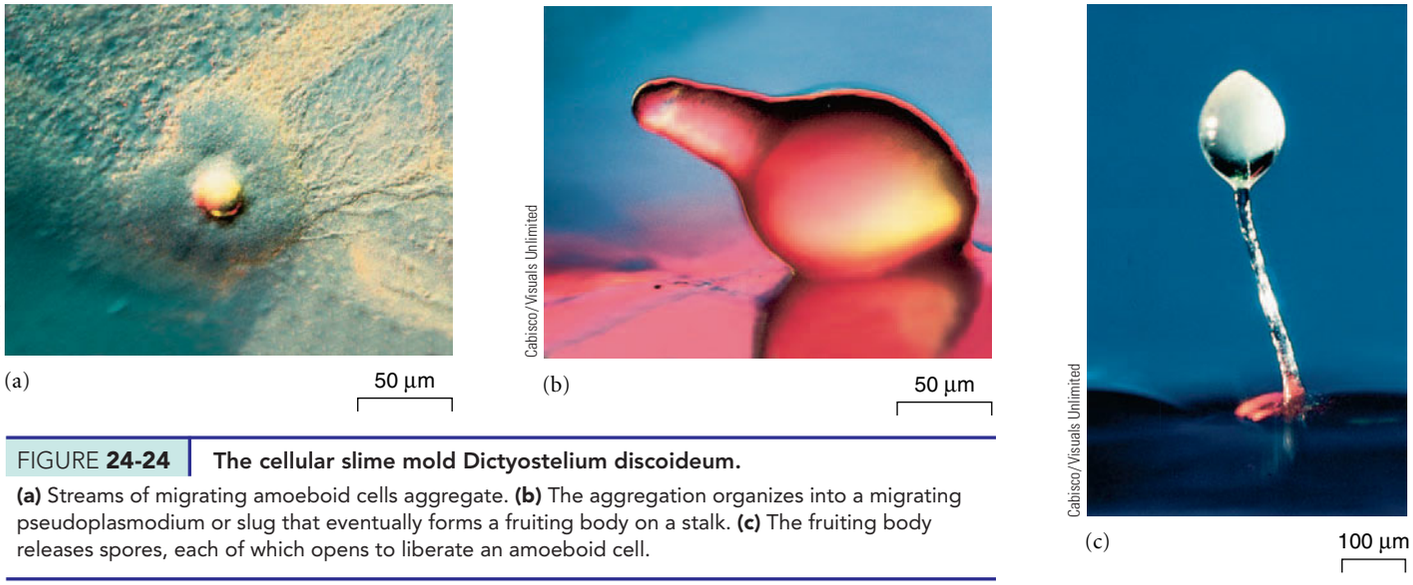


FIGURE **24-24** **The cellular slime mold Dictyostelium discoideum.**

(a) Streams of migrating amoeboid cells aggregate. **(b)** The aggregation organizes into a migrating pseudoplasmodium or slug that eventually forms a fruiting body on a stalk. **(c)** The fruiting body releases spores, each of which opens to liberate an amoeboid cell.

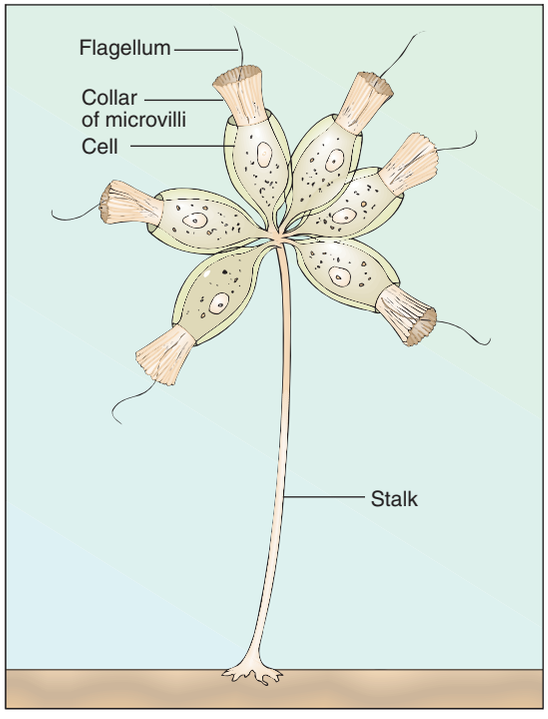

FIGURE **24-25** **Choanoflagellate.**
Choanoflagellates are free-living zooflagellates that obtain food by waving their flagella, causing water currents to carry bacteria and other small particles of food into the collar of microvilli. A colonial form is shown. Each cell is 5 to 10 µm long, not including the flagellum.

fungi (kingdom Fungi), and animals (kingdom Animalia). We consider fungi and animals in later chapters (see Chapters 25, 28, 29, and 30).

Choanoflagellates (phylum Choanoflagellata), are 600 species of collared zooflagellates. These small, inconspicuous marine and freshwater zooflagellates include both free-swimming and **sessile** species that are permanently attached by a thin stalk to bacteria-rich debris. Their single flagellum is surrounded at the base by a delicate collar of microvilli (Fig. 24-25). They are of special interest because of their striking resemblance to collar cells in sponges (see Fig. 28-6). Other animal phyla, such as flatworms and rotifers, also contain choanoflagellate-like cells. Given structural similarities and comparative ribosomal RNA and DNA sequence data, many biologists hypothesize that choanoflagellates are related to the ancestor of animals—that is, that living choanoflagellates and animals may share a common choanoflagellate-like ancestor.

Review

- What are some unique features of diplomonads?
- What characteristics do ciliates, dinoflagellates, and apicomplexans share?
- What are heterokonts?
- How do cercozoa and amoebozoa differ?
- Why do many biologists classify red algae and green algae with land plants?

Biology Now™ Assess your understanding of **representative protists** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Characterize the features common to the members of kingdom Protista.

- **Protists** are "simple" eukaryotic organisms, most of which are unicellular and live in aquatic environments.
- Protists range in size from microscopic unicellular organisms to **colonies** (loosely connected groups of cells) to **coenocytes** (multinucleate masses of cytoplasm) to **multicellular** organisms (composed of many cells).

2 Discuss in general terms the diversity inherent in the protist kingdom, including means of locomotion, modes of nutrition, interactions with other organisms, habitats, and modes of reproduction.

- Protists have various means of locomotion, including pseudopodia, flagella, and cilia. A few are nonmotile.
- Protists obtain their nutrients autotrophically or heterotrophically.
- Protists are free-living or symbiotic, with symbiotic relationships ranging from **mutualism** to **parasitism.**
- Most protists live in the ocean or in freshwater ponds, lakes, and streams. Parasitic protists live in the body fluids of their hosts.
- Many protists reproduce both sexually, often by **syngamy** (union of gametes), and asexually; others reproduce only asexually.

3 Discuss the endosymbiont theory, and briefly explain some of the evidence that supports it.

- According to the **endosymbiont theory,** mitochondria and chloroplasts arose from symbiotic relationships between larger cells and the smaller prokaryotes that were incorporated and lived within them.
- Mitochondria probably originated from aerobic eubacteria. Rickettsias are the closest living relatives of mitochondria.
- Chloroplasts of red algae, green algae, and plants probably arose in a single primary endosymbiotic event in which a cyanobacterium was incorporated into a cell. Multiple secondary endosymbioses led to chloroplasts in euglenoids, dinoflagellates, diatoms, golden algae, and brown algae, and to the nonfunctional chloroplasts in apicomplexans.

4 Describe the kinds of data biologists use to classify eukaryotes.

- Relationships among protists are determined largely by **ultrastructure,** which is the fine details of cell structure revealed by electron microscopy, and comparative molecular data. Most biologists consider the protist kingdom as a **paraphyletic group** that contains some, but not all, descendants of a common eukaryotic ancestor.

SUMMARY WITH KEY TERMS *(continued)*

5 Explain why zooflagellates are no longer classified in a single phylum, and distinguish among diplomonads, euglenoids, and choanoflagellates.

- **Zooflagellates** are mostly unicellular heterotrophs that move by means of whiplike **flagella.** Evidence indicates that zooflagellates are polyphyletic, and most biologists have separated them into several monophyletic groups.
- **Diplomonads** are **excavates** that have one or two nuclei, no mitochondria, no Golgi complex, and up to eight flagella.
- **Euglenoids** are **discicristates** that are unicellular and flagellate. Some euglenoids are photosynthetic. The discicristate *Trypanosoma* causes African sleeping sickness.
- **Choanoflagellates** are **opisthokonts** related to fungi and animals. A collar of microvilli surrounds their single flagellum at the base.

6 Briefly describe and compare the following alveolates: ciliates, dinoflagellates, and apicomplexans.

- **Ciliates** are **alveolates** that move by hairlike **cilia,** have **micronuclei** (for sexual reproduction) and **macronuclei** (for controlling cell metabolism and growth), and undergo a complex sexual reproduction called **conjugation.**
- **Dinoflagellates** are mostly unicellular, biflagellate, photosynthetic organisms of great ecological importance as major producers in marine ecosystems. Their **alveoli,** flattened vesicles under the plasma membrane, often contain cellulose plates impregnated with silicates. Some dinoflagellates produce toxic blooms known as **red tides.**
- **Apicomplexans** are parasites that produce **sporozoites** and are nonmotile. An apical complex of microtubules attaches the apicomplexan to its host cell. The apicomplexan *Plasmodium* causes malaria.

7 Briefly describe and compare the following heterokonts: water molds, diatoms, golden algae, and brown algae.

- **Water molds** are **heterokonts** that have a coenocytic **mycelium.** They reproduce asexually by forming biflagellate **zoospores** and sexually by forming **oospores.** The water mold *Phytophthora* causes serious plant diseases, such as late blight of potato and sudden oak death.
- **Diatoms,** which are major producers in aquatic ecosystems, are mostly unicellular, with shells containing silica. Some diatoms are part of floating **plankton,** and others live on rocks and sediments where they move by gliding.
- **Golden algae** are mostly unicellular, biflagellate freshwater and marine algae that are of ecological importance as a major component of the ocean's extremely minute **nanoplankton. Coccolithophorids** are golden algae covered by tiny, overlapping scales of calcium carbonate.
- **Brown algae** are multicellular seaweeds that are ecologically important in cooler ocean waters. The largest brown algae (kelps) possess leaflike **blades,** stemlike **stipes,** anchoring **holdfasts,** and gas-filled bladders for buoyancy.

8 Describe the foraminiferans and actinopods, and explain why many biologists classify them in the cercozoa.

- The **cercozoa** are amoeboid cells that often have hard outer shells, called **tests,** through which cytoplasmic projections extend.
- **Foraminiferans** secrete many-chambered tests with pores through which cytoplasmic projections extend to move and obtain food.
- **Actinopods** are mostly marine plankton that obtain food by means of **axopods,** slender cytoplasmic projections that extend through pores in their shells. **Radiolarians** are actinopods with glassy shells.

9 Support the hypothesis that red algae and green algae are a monophyletic group with land plants.

- Red algae, green algae, and land plants, collectively called **plants,** are monophyletic because all have chloroplasts bounded by outer and inner membranes.
- **Red algae,** which are mostly multicellular seaweeds, are ecologically important in warm tropical ocean waters. Red algae that incorporate calcium carbonate in their cell walls are important in reef building.
- **Green algae** exhibit a wide diversity in size, structural complexity, and reproduction. Botanists hypothesize ancestral green algae gave rise to land plants.

10 Briefly describe and compare the following Amoebozoa: amoebas, plasmodial slime molds, and cellular slime molds.

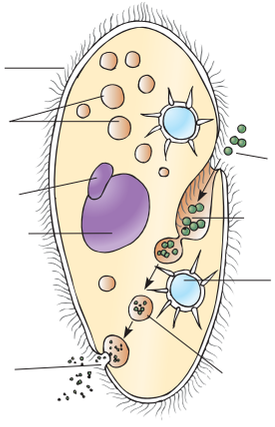
- **Amoebas** move and obtain food by **phagocytosis** using cytoplasmic extensions called **pseudopodia.** The parasitic amoeba *Entamoeba histolytica* causes amoebic dysentery.
- The feeding stage of **plasmodial slime molds** is a multinucleate **plasmodium.** Reproduction is by haploid spores produced within **sporangia.**
- **Cellular slime molds** feed as individual amoeboid cells. They reproduce by aggregating into a **pseudoplasmodium** (slug), then forming asexual spores.

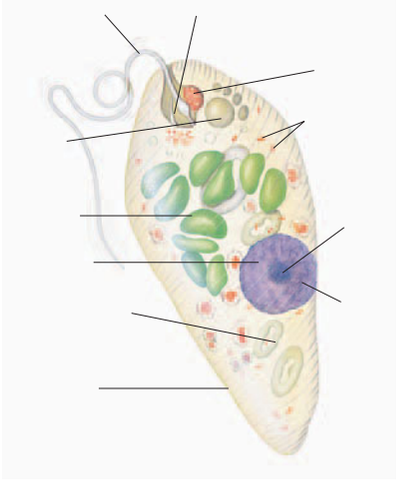
POST-TEST

1. Which of the following is *not* true of the protists? (a) they are unicellular, colonial, coenocytic, or simple multicellular organisms (b) their cilia and flagella have a 9 + 2 arrangement of microtubules (c) they are prokaryotic, like the eubacteria and archaebacteria (d) some are free-living, and some are endosymbionts (e) most are aquatic and live in the ocean or in freshwater ponds
2. Amoebas move and obtain food by means of (a) pseudopodia (b) flagella (c) cilia (d) gametangia (e) trichocysts
3. Foraminiferans (a) are endosymbionts in many marine invertebrates (b) were responsible for the Irish potato famine in the 19th century (c) secrete many-chambered tests with pores through which cytoplasmic extensions project (d) have numerous trichocysts that may aid in trapping and holding prey (e) contain phycocyanin and phycoerythrin, pigments found in no other protist group

POST-TEST *(continued)*

4. Unicellular protists that are free-living or parasitic, move by means of flagella, and do not photosynthesize are called (a) euglenoids (b) dinoflagellates (c) myxamoebas (d) zooflagellates (e) apicomplexans
5. *Paramecium* and other ciliates often display a sexual phenomenon called (a) oogamy (b) conjugation (c) anisogamy (d) red tide (e) alternation of generations
6. Parasitic alveolates that form spores at some stage in their life belong to which group? (a) actinopods (b) ciliates (c) coccolithophorids (d) apicomplexans (e) dinoflagellates
7. Malaria (a) is transmitted by the bite of a female tsetse fly (b) is caused by a parasitic zooflagellate, *Giardia intestinalis* (c) is a serious form of amoebic dysentery caused by *Entamoeba histolytica* (d) is caused by an apicomplexan that spends part of its life cycle in the *Anopheles* mosquito and part in humans (e) is transmitted when people drink water tainted by a red tide
8. Alveolates characterized by two flagella, one wrapped around the center of the cell like a belt and the other projecting behind the cell, are (a) actinopods (b) ciliates (c) coccolithophorids (d) apicomplexans (e) dinoflagellates
9. Photosynthetic protists with shells composed of two halves that fit together like a petri dish are (a) golden algae (b) diatoms (c) euglenoids (d) brown algae (e) foraminiferans
10. Chlorophyll *a,* chlorophyll *b,* and carotenoids are found in (a) green algae, red algae, and land plants (b) green algae, euglenoids, and land plants (c) brown algae, green algae, and golden algae (d) brown algae, diatoms, and golden algae (e) green algae, euglenoids, and diatoms
11. Which protists have photosynthetic pigments similar to those of the cyanobacteria? (a) golden algae (b) diatoms (c) euglenoids (d) brown algae (e) red algae
12. The multicellular bodies of _____ are differentiated into blades, stipes, holdfasts, and gas-filled floats. (a) golden algae (b) diatoms (c) euglenoids (d) kelps (e) green algae
13. The feeding stage of plasmodial slime molds is a multinucleate (a) plasmodium (b) pseudoplasmodium (c) pseudopodium (d) gametangium (e) mycelium
14. Cellular slime molds (a) include *Physarum* and *Phytophthora* (b) are more closely related to prokaryotes than are any other protists (c) are responsible for late blight of potatoes, which led to starvation in Ireland in the 1840s (d) have isogamous sexual reproduction (e) form a pseudoplasmodium when cells aggregate in response to cyclic AMP
15. Water molds reproduce asexually by forming _____, and sexually by forming _____. (a) oospores; holdfasts (b) zoospores; zooxanthellae (c) zoospores; oospores (d) holdfasts; isogametes (e) oospores; isogametes
16. Label the diagrams. Use Figures 24-7b and 24-6b to check your answers.





CRITICAL THINKING

1. Given what you have learned about dinoflagellates, where would you place them in the Figure 24-3 cladogram?
2. Where on Figure 24-3 would you place the common ancestor of brown algae and water molds? The common ancestor of animals and fungi? The common ancestor of animals?
3. In this chapter we discussed the hypothesis that choanoflagellates and animals share a common choanoflagellate-like ancestor. If this hypothesis is true, where would you place the choanoflagellate branch on Figure 24-3? Explain.

Kingdom Fungi

Jeff Lepore/Photo Researchers, Inc.

Fungal spores. The rounded earthstar (*Geastrum saccatum*) releases a puff of microscopic spores after the sac, which is about 1.3 cm (0.5 in) wide, is hit by a raindrop. This fungus is common in leaf litter under trees throughout North America.

CHAPTER OUTLINE

- **Characteristics of Fungi**
- **Fungal Diversity**
- **Lichens**
- **Ecological Importance of Fungi**
- **Economic and Medical Importance of Fungi**

Mushrooms, morels, and truffles, delights of the gourmet, have a lot in common with baker's yeast, the black mold that forms on stale bread, and the mildew that collects on damp shower curtains. These life forms belong to the kingdom Fungi, a diverse group of more than 81,000 known species, most of which are terrestrial. Although they vary strikingly in size and shape, all **fungi** (sing., *fungus*) are eukaryotes; their cells contain membrane-enclosed nuclei, mitochondria, and other membranous organelles.

Fungi are heterotrophs: They cannot produce their own organic materials from a simple carbon source (carbon dioxide) but instead obtain preformed carbon molecules produced by other organisms. Moreover, fungi do not ingest food as animals do. Instead, they secrete digestive enzymes onto the food source and then absorb the predigested food (as small organic molecules) through their cell walls and plasma membranes.

Most fungi are decomposers; they get their nutrients from dead organic matter. As decomposers, fungi, along with prokaryotes (see Chapter 23), play an important ecological role. Some fungi are parasites that cause disease in animals or plants.

Fungi grow best in moist habitats, but they are found universally wherever organic material is available. They require moisture to grow, and they obtain water from a humid atmosphere as well as from the medium on which they live. When the environment becomes dry, fungi survive by going into a resting stage or by producing spores (see photograph) that resist desiccation (drying out).

Although the optimum pH for most species is about 5.6, various fungi can tolerate and grow in environments where the pH ranges from 2 to 9. Many fungi are less sensitive to high osmotic pressures than are bacteria. As a result, they can grow in concentrated salt solutions, or in sugar solutions such as jelly, that discourage or prevent bacterial growth. Fungi also thrive over a wide temperature range. Even refrigerated food may be invaded by fungi.

Fungi were classified in the plant kingdom until biologists realized they differ greatly from plants. In fact, molecular studies suggest fungi are related more closely to animals than to plants (see Fig. 24-3). Because fungi are distinct from plants, animals, and protists in many ways, they are assigned to a separate kingdom. ■

CHARACTERISTICS OF FUNGI

Learning Objectives

1. Describe the distinguishing characteristics of Kingdom Fungi.
2. Describe the body plan of a fungus.
3. Trace the fate of a fungal spore that lands in a favorable location, such as an overripe peach, and describe conditions that permit fungal growth.

Like the cells of bacteria, certain protists, and plants, fungal cells are enclosed by cell walls during at least some stage in their life cycle. Fungal cell walls, however, have a different chemical composition from cell walls of other organisms. In most fungi, the cell wall consists of complex carbohydrates, including **chitin,** a polymer that consists of subunits of a nitrogen-containing sugar (see Fig. 3-11). Chitin—which is coincidentally a component of the external skeletons of insects and other arthropods—is resistant to breakdown by most microorganisms.

Most fungi have a filamentous body plan

Mycologists (biologists who study fungi) identify two main types of fungi, based on body plan: molds and yeasts. Most fungi are **molds.** The vegetative (nonreproductive) body plan of molds consists of long, branched, threadlike filaments called **hyphae** (sing., *hypha*) (Fig. 25-1a, b). As hyphae elongate, the fungus infiltrates food sources and absorbs nutrients through its very large surface area. Hyphae form a tangled mass or tissue-like aggregation known as a **mycelium** (pl., *mycelia*). The cobweb-like mold sometimes seen on bread is the mycelium of a fungus. What is not seen is the extensive mycelium that grows into the bread.

Some hyphae are **coenocytic;** that is, they are not divided into individual compartments or cells and are instead an elongated, multinucleated giant cell (Fig. 25-1c). Other hyphae are divided by cross walls called **septa** (sing., *septum*) into individual cells containing one or more nuclei (Fig. 25-1d,e). The septa of many septate fungi are perforated by a pore that may be large enough to permit organelles to flow from cell to cell.

Hundreds of fungal species are unicellular, with a round or oval shape. These fungi, called **yeasts,** are widely distributed; they are found in the soil, on leaves, fruits, cured meats, and on and in our bodies. Yeasts are essential in making bread and fermenting alcoholic beverages (discussed later in this chapter). The yeast *Saccharomyces cerevisiae* is an important model eukaryotic organism. Its genome has been sequenced, and scientists are in the process of determining the functions of the 6000 identified proteins encoded by its genes.

Fungi reproduce by spores

Most fungi reproduce by means of microscopic **spores,** which are nonmotile (or, less commonly, motile) reproductive cells dispersed by wind, water, or animals. Spores are usually produced on specialized aerial hyphae or in fruiting structures. This

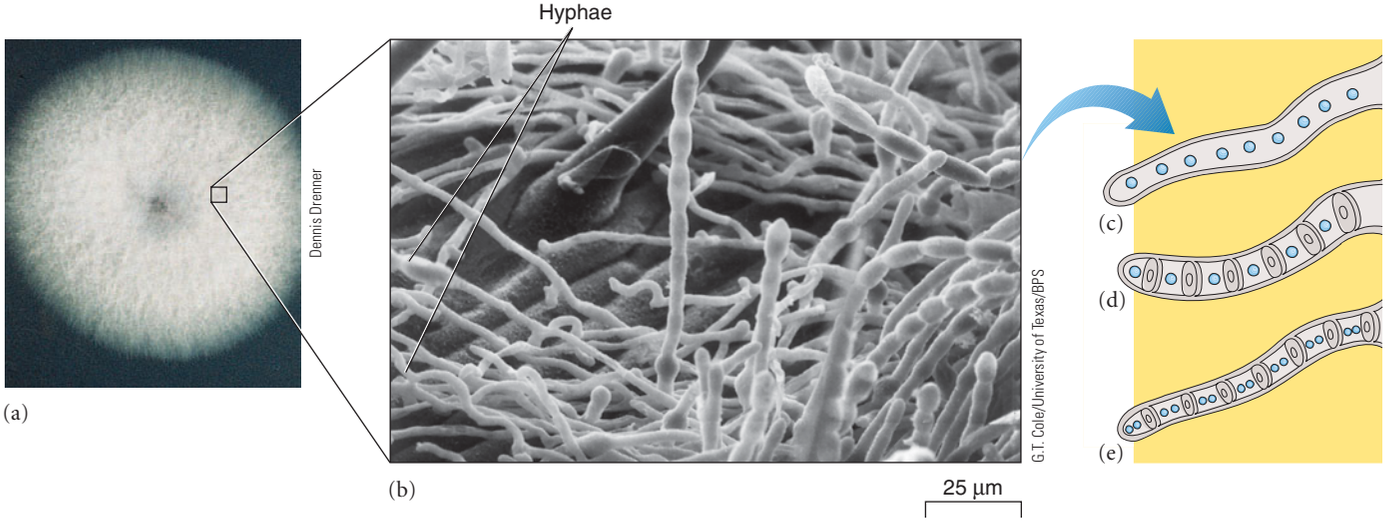

FIGURE **25-1** **Fungus body plan.**

(a) A fungal mycelium, a mass of threadlike hyphae (10 cm [4 in] wide), growing on agar in a culture dish. In nature, fungal mycelia are rarely so symmetric. **(b)** SEM of a mycelium of *Blumeria graminis,* growing on a leaf *(darker area underneath the mycelium).* **(c)** A coenocytic hypha. **(d)** A hypha divided into cells by septa; each cell is monokaryotic (has one nucleus). In some taxa the septa are perforated *(as shown),* permitting cytoplasm to stream from one cell to another. **(e)** A septate hypha in which each cell is dikaryotic (has two genetically distinct nuclei).

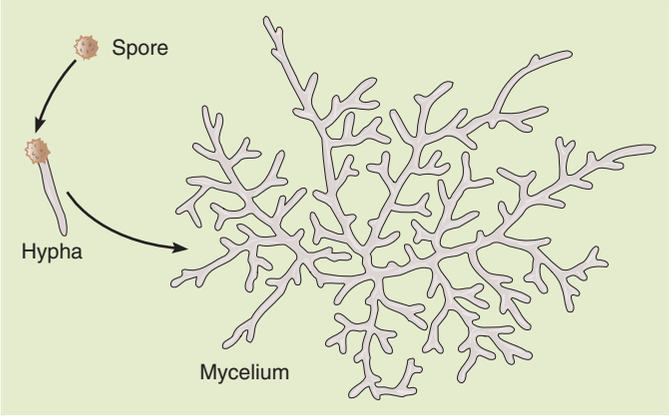

FIGURE **25-2** **Germination of a spore to form a mycelium.**
Because the filamentous mycelium spreads throughout its substrate (such as overripe fruit, wood, or soil), it is difficult to estimate the actual size of an individual fungus.

arrangement permits the spores to be more easily dispersed. The aerial hyphae of some fungi form large, complex reproductive structures, called **fruiting bodies,** in which spores are produced. The familiar part of a mushroom is a large fruiting body. We do not normally see the bulk of the fungus, a nearly invisible mycelium buried out of sight in the rotting material or soil on which it grows.

Fungi may produce spores either sexually or asexually. Unlike most animal and plant cells, most fungal cells contain haploid nuclei. In sexual reproduction, the hyphae of two genetically compatible mating types come together, and their cytoplasm and nuclei fuse, forming a diploid cell known as a **zygote.**[1] In some groups, the zygote is the only diploid nucleus. Three types of fungal reproductive structures are gametangia, sporangia, and conidiophores. **Gametangia** are structures in which gametes form. **Sporangia** (sing., *sporangium*) are structures in which spores are produced. **Conidiophores** (from the Greek, meaning "dust-bearers") are specialized hypha that produce asexual spores called **conidia** (sing., *conidium*). The arrangement of conidia on conidiophores varies from species to species.

In two fungal groups—the ascomycetes and basidiomycetes—the hyphae fuse, but the two different nuclei do not fuse immediately; rather, they remain separate within the fungal cytoplasm. Hyphae that contain two genetically distinct, sexually compatible nuclei within each cell are **dikaryotic.** This condition is described as $n + n$ rather than $2n$, because there are two separate haploid nuclei. Hyphae that contain only one nucleus per cell are said to be **monokaryotic.**

When a fungal spore comes into contact with an appropriate food source, perhaps an overripe peach that has fallen to the ground, it germinates and begins to grow (Fig. 25-2). A thread-like hypha emerges from the tiny spore and grows at its tip, branching frequently. Soon a mycelium infiltrates the peach, degrading its complex organic compounds to small organic molecules that the fungus can absorb. Fungi are very efficient at converting nutrients into new cell material. If excessive amounts of nutrients are available, fungi store them, usually as lipid droplets or glycogen, in the mycelium.

[1] In certain fungi (such as *Allomyces*), zygotes are typically formed by the union of two haploid gametes rather than the union of two haploid nuclei in compatible hyphae.

Review

- What characteristics distinguish fungi from other organisms?
- How does the body of a yeast differ from that of a mold?
- What is the function of fruiting bodies?

BiologyNow™ Assess your understanding of **the characteristics of fungi** by taking the pretest on your BiologyNow CD-ROM.

FUNGAL DIVERSITY

Learning Objectives

4 Give arguments to support the hypothesis that chytridiomycetes may have been the earliest fungal group to evolve from the common ancestor of fungi.

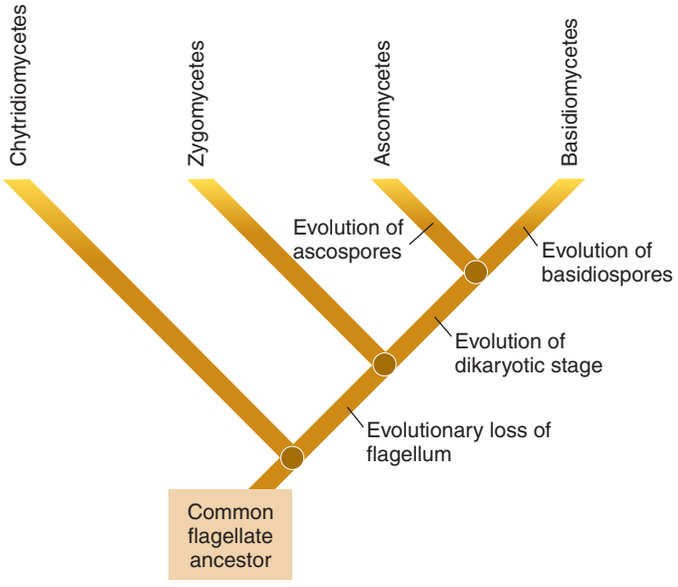
5 List distinguishing characteristics, describe a typical life cycle, and give examples of each of the following fungal groups: chytridiomycetes, zygomycetes, ascomycetes, basidiomycetes, and imperfect fungi.

There are few examples of fossilized fungi, and fossil evidence has not helped biologists unravel evolutionary relationships among different fungal groups. Historically, fungi have been classified mainly on the characteristics of their sexual spores and fruiting bodies. Recently, molecular data, such as comparative DNA and RNA sequences, have clarified relationships among fungi.

Biologists assign these diverse organisms to four main phyla: Chytridiomycota, Zygomycota, Ascomycota, and Basidiomycota. (Fig. 25-3 and Table 25-1). As discussed later in this chapter, fungi that do not fit into any of these groups are assigned to a polyphyletic group, Deuteromycota, also referred to as *imperfect fungi.* As biologists learn more about these fungi, they are reassigned. Slime molds and water molds were originally classified as fungi but are now generally considered protists (see Chapter 24).

Chytridiomycetes are the most primitive fungi

Until recently, many biologists considered the **chytridiomycetes,** also called *chytrids,* (phylum Chytridiomycota) to be fungus-like protists similar in many respects to the water molds. However, molecular comparisons, particularly of DNA and RNA sequences, have provided compelling evidence that the approximately 750 species of chytridiomycetes are fungi. The molecular evidence also indicates that chytridiomycetes, which are small, relatively simple aquatic fungi, are the most primitive group of fungi living today. *Primitive* in this context implies that chytridiomycetes were probably the earliest fungal group to evolve from the ancient flagellate protist hypothesized as the common an-



ACTIVE FIGURE **25-3** **Fungal evolution.**

This cladogram shows phylogenetic relationships among living fungi, based on comparisons of ribosomal and nuclear gene sequence data of many species. The chytridiomycetes were the lineage that branched off first during fungal evolution. The deuteromycetes are not shown, because the group is polyphyletic.

BiologyNow™ Learn about **the diversity of fungi** by clicking on this figure on your on your BiologyNow CD-ROM.

John Taylor, University of California at Berkeley

FIGURE **25-4** **Chytrid.**

Nomarski differential interference micrograph of a common chytrid (*Chytridium convervae*). Many chytrids have a microscopic body form consisting of a coenocytic globose (rounded) thallus and branched rhizoids that superficially resemble roots. The rhizoids may anchor the chytrid thallus and absorb predigested food.

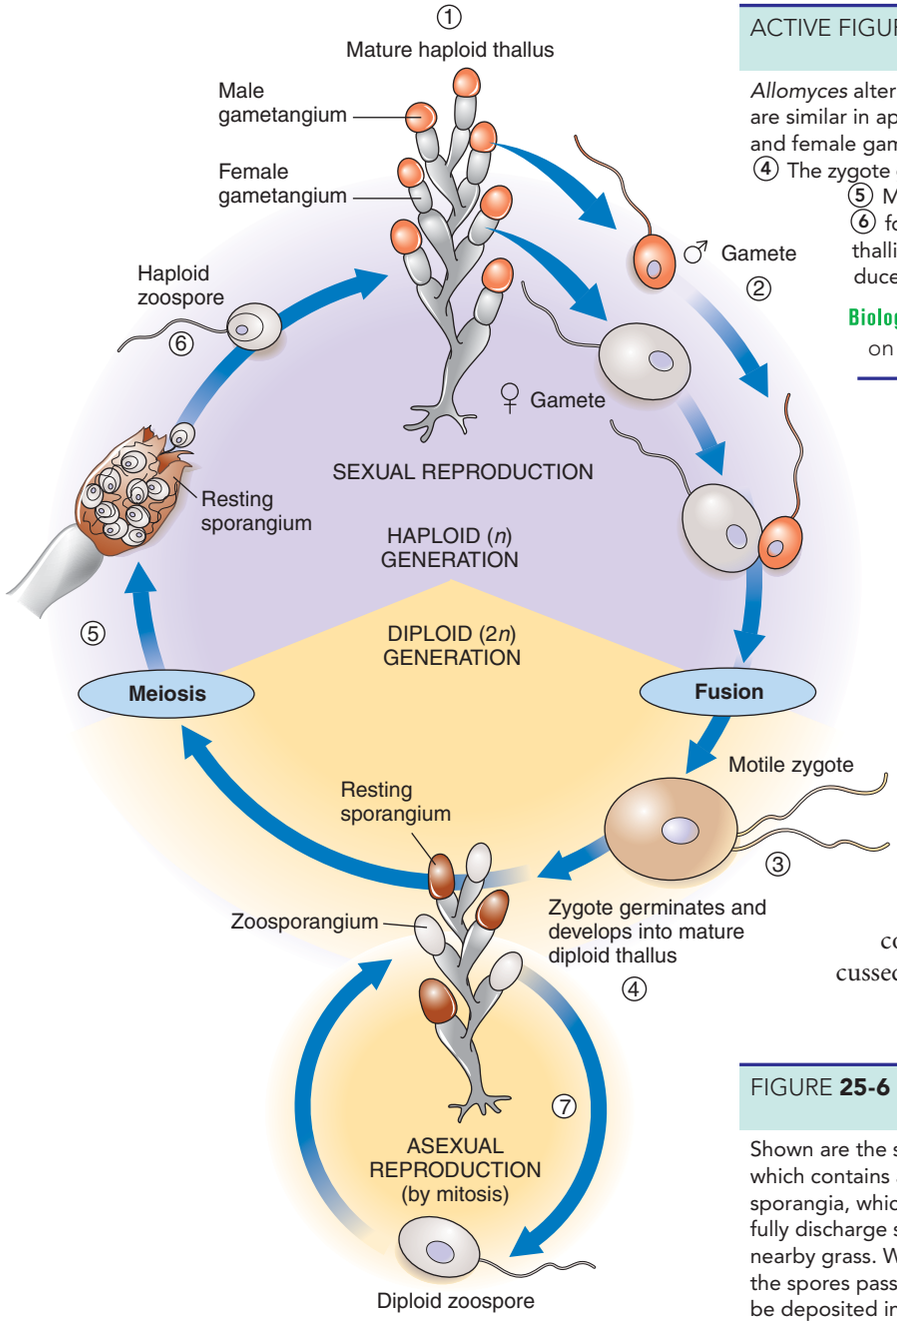
cestor of all fungi. Chytridiomycetes, which produce flagellate cells at some stage in their life history, have retained this feature of their protist ancestor. All other fungal phyla are nonflagellate; they apparently lost the ability to produce motile cells at some point in their evolutionary history, perhaps during the transition from aquatic to terrestrial habitats.

The motile cells of chytrids possess a single, posterior flagellum. They reproduce both sexually and asexually. Chytrids are parasites or decomposers found principally in fresh water (Fig. 25-4); however, a few species occur on land (in moist environments) and in marine water. Although the disease was not identified until 1998, a parasitic chytrid may be responsible for declining amphibian populations dating back to the 1970s. Infected frogs have been identified in many parts of the world. (see *Focus On: Declining Amphibian Populations,* in Chapter 55).

Allomyces, a common chytridiomycete, has an unusual life cycle compared to most fungi. It has an **alternation of generations** (common in plants, but rare in fungi), spending part of

TABLE **25-1** **Phyla of Kingdom Fungi**

Phylum	Common Types	Asexual Reproduction	Sexual Reproduction
Chytridiomycota (chytridiomycetes or chytrids)	*Allomyces*	Zoospores	Flagellate gametes in some chytrids
Zygomycota (zygomycetes)	Black bread mold	Nonmotile spores form in a sporangium	Zygospores
Ascomycota (ascomycetes or sac fungi)	Yeasts, powdery mildews, molds, morels, truffles	Conidia pinch off from conidiophores	Ascospores
Basidiomycota (basidiomycetes or club fungi)	Mushrooms, bracket fungi, puffballs, rusts, smuts	Conidia (uncommon)	Basidiospores
Deuteromycota (deuteromycetes or imperfect fungi)	Molds	Conidia	Sexual stage not observed



ACTIVE FIGURE **25-5** **Life cycle of *Allomyces arbuscula*, a chytridiomycete.**

Allomyces alternates between haploid and diploid stages, which are similar in appearance. The haploid thallus ① gives rise to male and female gametes ② that fuse, ③ forming a flagellate zygote. ④ The zygote germinates and develops into a diploid thallus. ⑤ Meiosis occurs in the diploid resting sporangia, ⑥ forming haploid zoospores that develop into haploid thalli, and the cycle continues. ⑦ *Allomyces* also reproduces asexually by forming diploid zoospores.

BiologyNow™ Explore **fungus life-cycles** by clicking on this figure on your BiologyNow CD-ROM.

Zygomycetes reproduce sexually by forming zygospores

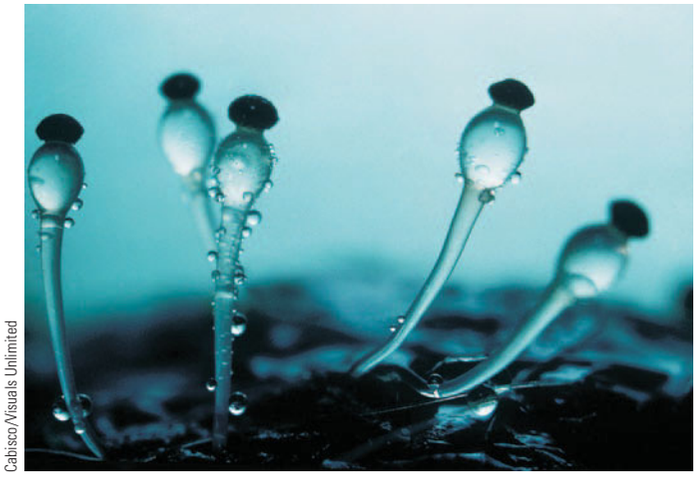
All the approximately 800 species of **zygomycetes** (phylum Zygomycota) produce sexual spores, called **zygospores.** Their hyphae are coenocytic; that is, they lack regularly spaced septa. Septa form, however, to separate the hyphae from reproductive structures. Most zygomycetes are decomposers that live in the soil on decaying plant or animal matter (Fig. 25-6). Some zygomycetes are parasites of plants and animals, and still others are mycorrhizal fungi associated with plant roots (discussed shortly).

FIGURE **25-6** ***Pilobolus*, a zygomycete that grows in animal dung.**

Shown are the stalked sporangia protruding from a pile of dung, which contains an extensive mycelium of the fungus. The stalked sporangia, which are 5 to 10 mm tall, act like shotguns and forcefully discharge sporangia (the black tips) away from the dung, onto nearby grass. When animals such as cattle or horses eat the grass, the spores pass unharmed through the animal's digestive tract to be deposited in a fresh pile of dung.

its life as a haploid *(n)* **thallus** and part as a diploid (2*n*) thallus (Fig. 25-5). The term *thallus* is used to describe the simple body plan of certain algae, fungi, or plants. The haploid and diploid thalli are similar in appearance and consist of a stout trunklike part with slender branches. At the tips of its branches, the haploid thallus bears male and female gametangia, structures in which gametes form by mitosis. When a flagellate male gamete fuses with a slightly larger, flagellate female gamete, the resulting zygote develops into a diploid thallus.

The diploid thallus bears two kinds of spore cases, zoosporangia and resting sporangia. Zoosporangia produce flagellate diploid **zoospores** that may settle down and develop into new diploid thalli. Meiosis occurs within resting sporangia to form haploid zoospores, each of which has the potential to settle down and develop into a haploid thallus.



Cabisco/Visuals Unlimited

KEY CONCEPT: Many fungi produce both asexual and sexual spores.

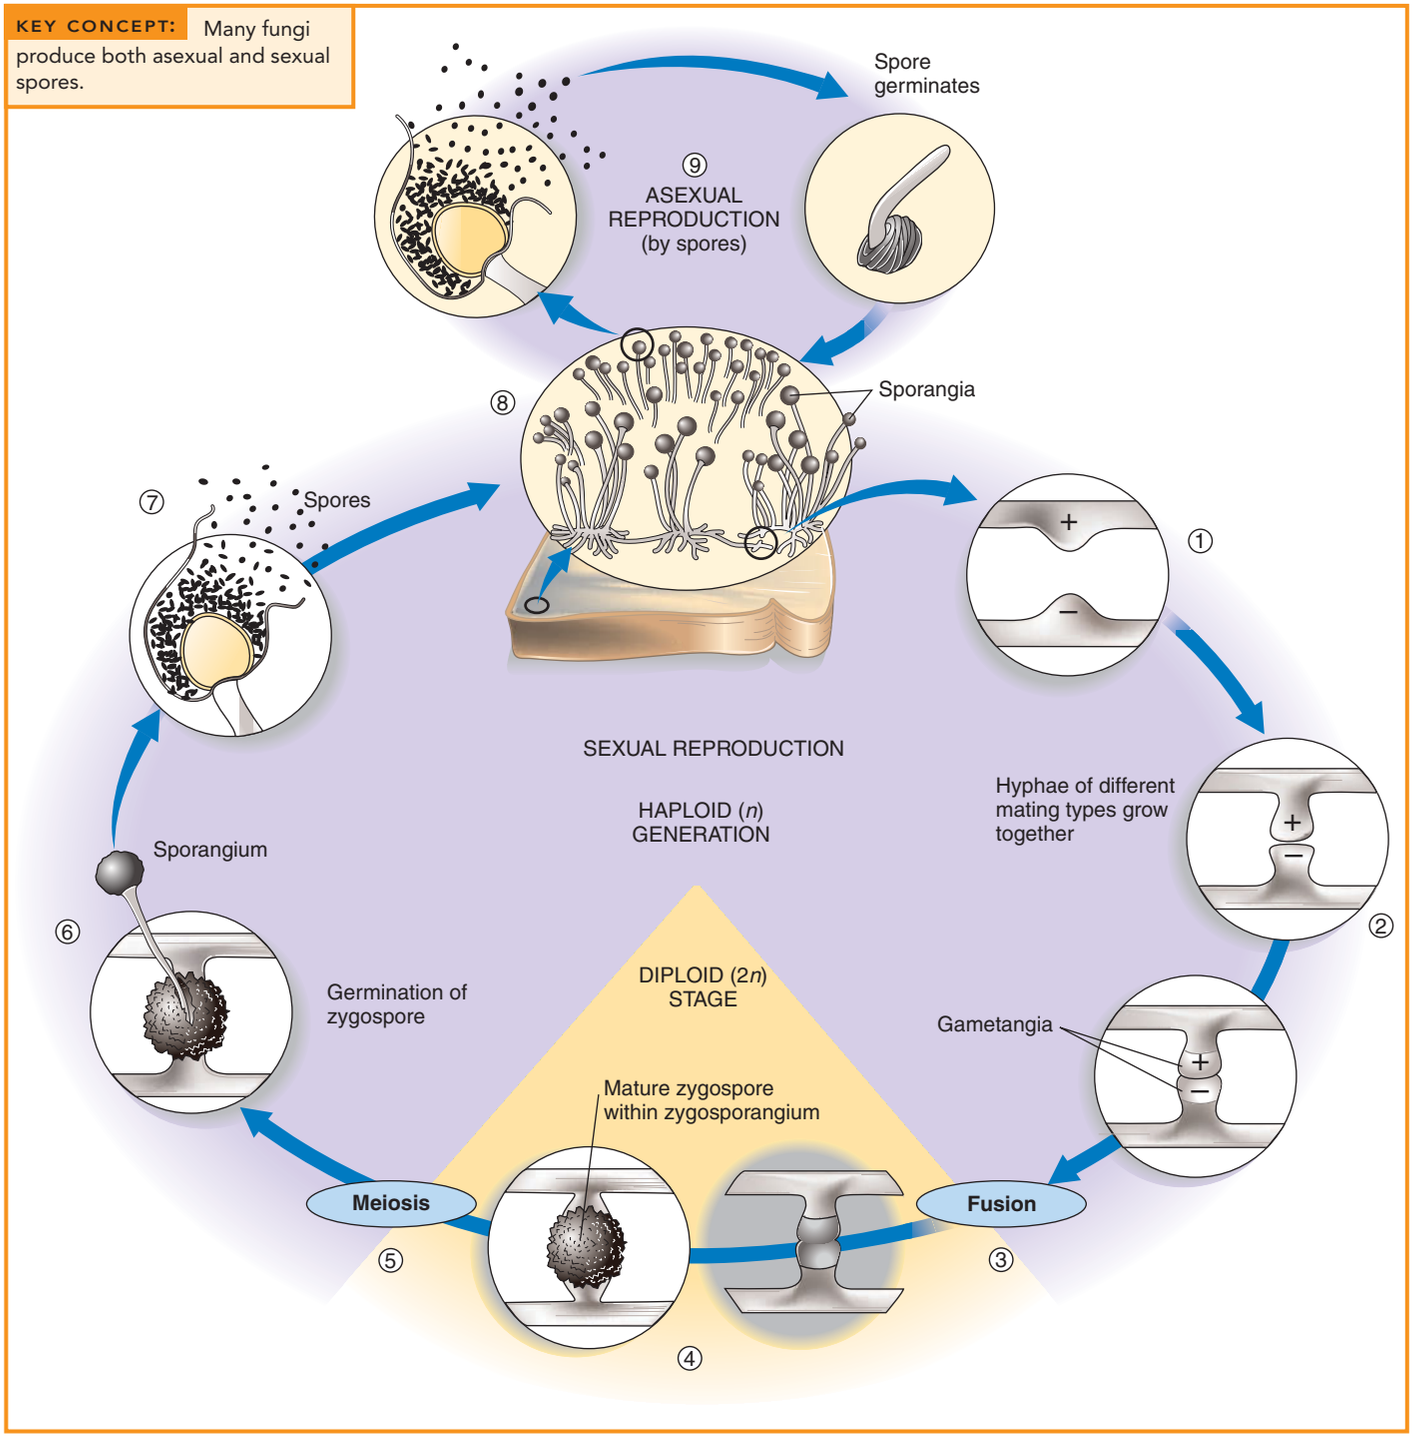


FIGURE **25-7** **Life cycle of the black bread mold (*Rhizopus stolonifer*), a zygomycete.**

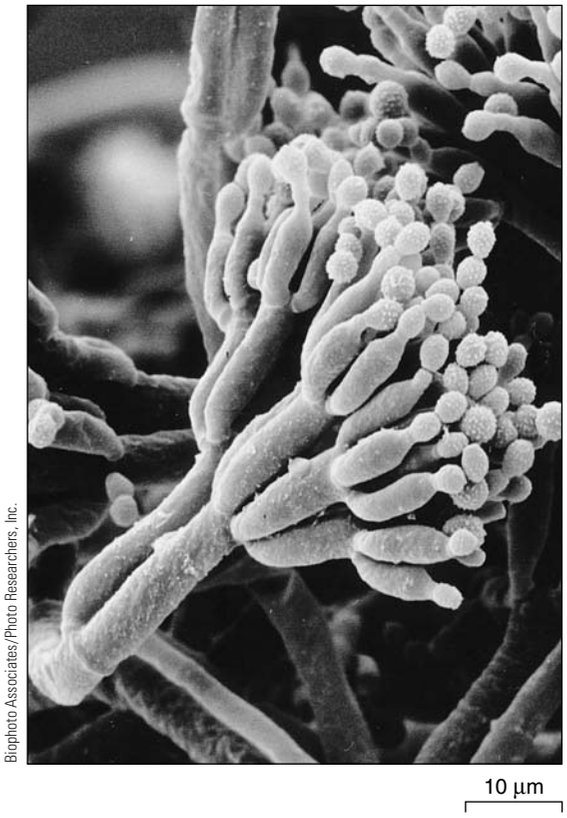
① Sexual reproduction takes place only between different mating types, designated (+) and (−). After their hyphae meet, ② they form gametangia. ③ The gametangia unite, and the nuclei fuse. ④ A single zygospore develops within a thick-walled, black zygosporangium. ⑤ Meiosis occurs, the zygospore germinates, and ⑥ the emerging hypha develops a sporangium at its tip. ⑦ Spores are released and may germinate, ⑧ giving rise to new hyphae. ⑨ In asexual reproduction, certain hyphae form sporangia in which clusters of black, asexual, haploid spores develop. When released, they give rise to new hyphae.

One common zygomycete is the black bread mold, *Rhizopus stolonifer*, a decomposer that breaks down bread and other foods (Fig. 25-7). If preservatives are not added, bread left at room temperature often becomes covered with a black, fuzzy growth in a few days. Bread becomes moldy when a spore falls on it and then germinates and grows into a mycelium. Hyphae penetrate

the bread and absorb nutrients. Eventually, certain hyphae grow upward and develop spore sacs called *sporangia* at their tips. Clusters of black asexual spores develop within each sporangium and are released when the delicate sporangium ruptures. The spores give the black bread mold its characteristic color.

Sexual reproduction in the black bread mold occurs when the hyphae of two different mating types, designated as plus (+) and minus (−), grow into contact with one another. The bread mold is **heterothallic,** meaning that an individual fungal hypha is self-sterile and mates only with a hypha of a different mating type. That is, sexual reproduction occurs only between a member of a (+) strain and one of a (−) strain, not between members of two (+) strains or members of two (−) strains. Because there are no physical differences between the two mating types, it is not appropriate to refer to them as "male" and "female."

When hyphae of opposite mating types grow in close proximity, hormones are produced that cause the tips of the hyphae to come together and form gametangia. The gametangia then unite, and the (+) and (−) nuclei fuse to form the zygote, which is a diploid nucleus. A zygospore develops from the zygote, surrounded by a thick protective covering known as a **zygosporangium.** The zygospore may lie dormant for several months and can survive desiccation and extreme temperatures. Meiosis probably occurs at or just before germination of the zygospore. When the zygospore germinates, an aerial hypha develops with a sporangium at the tip. Mitosis within the sporangium produces haploid spores. These spores may be all (+) spores, all (−) spores, or a mixture of (+) and (−) spores. When released, the spores may germinate to form new hyphae. Only the zygote and zygospore of a black bread mold are diploid; all the hyphae and the asexual spores are haploid.



Biophoto Associates/Photo Researchers, Inc.

FIGURE **25-8** **Conidia.**

Conidia are asexual reproductive cells produced by ascomycetes, some basidiomycetes, and most deuteromycetes. Biologists use the arrangement of conidia on conidiophores to identify species of these fungi. Shown is a SEM of *Penicillium* conidiophores, which resemble paintbrushes. Note the conidia pinching off the tips of the "brushes."

Ascomycetes reproduce sexually by forming ascospores

Ascomycetes (phylum Ascomycota) comprise a large group of fungi consisting of about 30,000 described species. Ascomycetes are sometimes referred to as *sac fungi* because their sexual spores are produced in microscopic sacs called **asci** (sing., *ascus*). Their hyphae usually have septa, but these cross walls have pores so that cytoplasm is continuous from one cell compartment to another.

The diverse ascomycetes include most yeasts; the powdery mildews; most of the blue-green, pink, and brown molds that cause food to spoil; decomposer cup fungi; and the edible morels and truffles. Some ascomycetes cause serious plant diseases such as Dutch elm disease, ergot disease on rye, powdery mildew on fruits and ornamental plants, and chestnut blight.

In most ascomycetes, asexual reproduction involves production of spores called *conidia* (sing., *conidium*). Conidia form at the tips of certain specialized hyphae known as *conidiophores* (Fig. 25-8). Production of these spores is a means of rapidly propagating new mycelia when environmental conditions are favorable. Conidia occur in various shapes, sizes, and colors in different species. The color of the conidia produces the characteristic brown, blue-green, pink, or other tints of many of these molds.

Some species of ascomycetes are heterothallic and have different mating strains. Others are **homothallic,** which means they are self-fertile and have the ability to mate with themselves. In both heterothallic and homothallic ascomycetes, sexual reproduction takes place after two gametangia come together and their cytoplasm mingles (Fig. 25-9). Within this fused structure, pairs of haploid nuclei, one from each parent hypha, associate but do not fuse. New hyphae, with dikaryotic cells, develop from the fused structure. The hyphae branch repeatedly until the hyphal tips reach the site where asci will be produced. As the many sac-shaped asci develop, each containing two dissimilar nuclei (one from each parent), they are surrounded by intertwining haploid (monokaryotic) hyphae. These hyphae develop into a fruiting body known as an **ascocarp** (Fig. 25-10a).

Within a cell that develops into an ascus, the two nuclei fuse and form a diploid nucleus, the zygote. The zygote then undergoes meiosis to form four haploid nuclei. One mitotic division of each of the four nuclei usually follows, resulting in eight haploid nuclei. Each haploid nucleus becomes incorporated into a heavy-walled **ascospore;** thus there are usually eight haploid ascospores within the ascus (Fig. 25-10b). The ascospores are usually released through a pore, slit, or hinged lid at the tip of the ascus. Air currents carry individual ascospores, often for long

distances. If one lands in a suitable location, it germinates and forms a new mycelium.

Phylum Ascomycota includes more than 300 species of unicellular yeasts (see Fig. 7-13a). Asexual reproduction of yeasts is mainly by **budding;** in this process a small protuberance (bud) grows and eventually separates from the parent cell. Each bud can grow into a new yeast cell. Some yeasts also reproduce asexually by **binary fission,** in which they undergo mitosis and then divide in half. Yeasts reproduce sexually by forming ascospores. During sexual reproduction, two haploid yeasts fuse, forming a diploid zygote. The zygote undergoes meiosis, and the resulting haploid nuclei are incorporated into ascospores. These spores remain enclosed for a time within the original cell wall, which corresponds to an ascus.

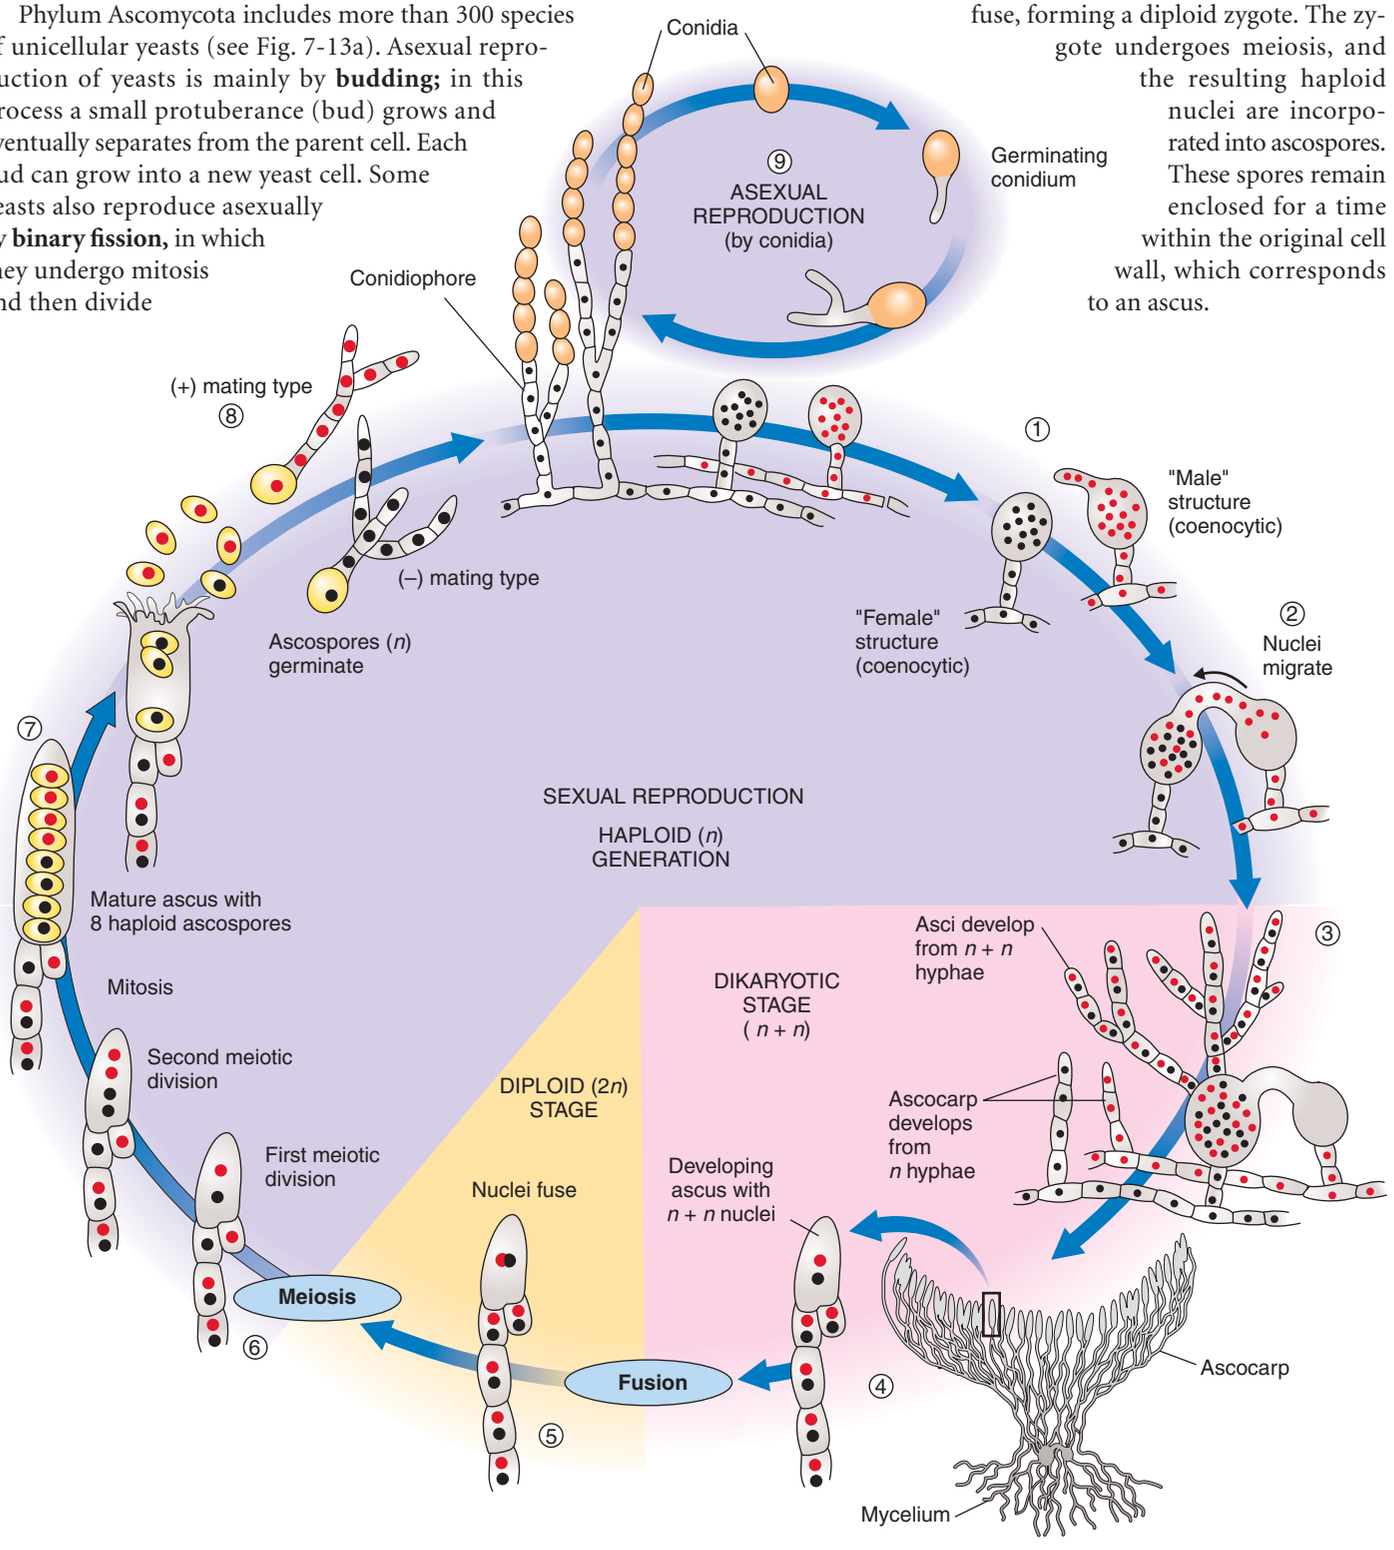


FIGURE **25-9** **Life cycle of a typical ascomycete.**

① Sexual reproduction involves haploid mycelia of opposite mating types. ② Gametangia of the two different mating types fuse, ③ forming dikaryotic ($n + n$) hyphae from which asci develop. ④ The asci are incorporated into an ascocarp (fruiting body). ⑤ In each ascus, the $n + n$ nuclei fuse forming a diploid nucleus, the zygote. ⑥ Meiosis occurs forming four haploid nuclei. Mitosis then takes place, producing eight haploid nuclei. ⑦ Each becomes incorporated into an ascospore. When ascospores are released, ⑧ they germinate and form new mycelia. ⑨ Asexual reproduction involves the formation of haploid conidia.

Photographed in Muskegon, Michigan. **(b)** Asci, each containing eight ascospores, line the inner portion of the saucer.

Basidiomycetes reproduce sexually by forming basidiospores

The 25,000 or more species of **basidiomycetes** (phylum Basidiomycota) include the most familiar of the fungi: the mushrooms, bracket fungi, and puffballs (Fig. 25-11). Some destructive plant parasites of important crops, such as wheat rust and corn smut, are also basidiomycetes. Sometimes called *club fungi,* Basidiomycetes derive their name from the fact that they develop microscopic club-shaped **basidia** (sing., *basidium*). Basidia are comparable in function to the asci of ascomycetes. Each basidium is an enlarged hyphal cell, on the tip of which develop four **basidiospores** (Fig. 25-12). Note that basidiospores develop on the *outside* of a basidium, whereas ascospores develop *within* an ascus.

Each individual fungus produces millions of basidiospores, and each basidiospore has the potential to give rise to a new **primary mycelium** (Fig. 25-13). Hyphae of a primary mycelium consist of monokaryotic cells. The mycelium of a basidiomycete such as the commonly cultivated mushroom *Agaricus brunnescens*[2] consists of a mass of white, branching, threadlike hyphae that live mostly below ground. Septa divide the hyphae into cells, but, as in ascomycetes, the perforated septa allow cytoplasmic streaming between cells.

When in the course of its growth a hypha of a primary mycelium encounters another monokaryotic hypha of a different mating type, the two hyphae fuse. As in the ascomycetes, the two haploid nuclei remain separate within each cell. In this way a **secondary mycelium** with dikaryotic hyphae is produced, in which each cell contains two haploid nuclei.

The $n + n$ hyphae of the secondary mycelium grow extensively. When environmental conditions are favorable, the hyphae form compact masses, called *buttons,* along the mycelium. Each button grows into a fruiting body that we call a *mushroom.* A mushroom, which consists of a stalk and a cap, is more formally referred to as a **basidiocarp.** Each basidiocarp consists of intertwined hyphae that are matted together. The lower surface of the cap usually consists of many thin, perpendicular plates called **gills** that radiate from the stalk to the edge of the cap.

Within the young basidia on the gills of the mushroom, haploid nuclei fuse in the dikaryotic cells, forming diploid zygotes. These are the only diploid cells that form during a basidiomycete's life history. Meiosis then takes place, forming four haploid nuclei that move to the outer edge of the basidium. Finger-like extensions of the basidium develop, into which the nuclei and some cytoplasm move; each of these extensions becomes a basidiospore. A septum forms that separates the basidiospore from the rest of the basidium by a delicate stalk that breaks when the basidiospore is forcibly discharged. Asexual reproduction is less common in basidiomycetes than in other groups.

Imperfect fungi have no known sexual stage

Mycologists have grouped about 25,000 species of fungi as **deuteromycetes** and assigned them to a *form phylum,* Deuteromycota. Members of a form phylum are similar to one another in certain respects but are probably **polyphyletic,** which means they do not share a common ancestor. Fungi classified as deuteromycetes do not have a common ancestor and are grouped together simply as a matter of convenience. Deuteromycetes are also known as **imperfect fungi,** because in most of them no sexual stage has been observed at any point during their life cycle. Some of these fungi have lost the ability to reproduce sexually, whereas others may reproduce sexually only rarely. Should further study reveal a sexual stage, mycologists will reassign the

[2] Also called *Agaricus bisporus.*

(a) Basidia line the gills of the Jack-o'lantern mushroom (*Omphalotus olearius*), a poisonous species whose gills produce a greenish glow in the dark. Each cap is about 15 cm (6 in) wide. Photographed at the base of an oak tree in Maryland, the Jack-o'lantern occurs throughout eastern North America and California. **(b)** The elegant stinkhorn (*Phallus ravenelii*) has a foul smell that attracts flies, which help disperse the slimy mass of basidiospores. Fruiting bodies of elegant stinkhorns grow to 18 cm (7 in) tall. Photographed in Pennsylvania. **(c)** Turkey-tail (*Trametes versicolor*) is a common bracket fungus. Bracket fungi grow on both dead and living trees, producing shelf-like fruiting bodies. Basidiospores are produced in pores located underneath each shelf. Photographed in Pennsylvania.

sexual state of these species to a different phylum. (By convention, the asexual stage is still identified as a deuteromycete.)

Increasingly, comparing DNA and/or RNA sequences among various species helps biologists find relationships between imperfect fungi and their sexually reproducing relatives. Most imperfect fungi reproduce only by means of conidia and are closely related to the ascomycetes. A few are more closely related to the basidiomycetes.

Review

LICHENS

Learning Objective

6 Characterize the unique nature of a lichen.

Although a **lichen** looks like a single organism, it is actually a dual organism. A lichen is a symbiotic association between two organisms: a *phototroph* (a photosynthetic organism) and a fungus (Fig. 25-14a). (A symbiotic association is an intimate relationship between organisms of different species.) Almost one fifth of all known fungal species form these symbiotic relationships; about 14,000 kinds of lichens have been described.

The phototrophic component of a lichen is either a green alga, a cyanobacterium, or both. The fungus is most often an ascomycete, although in some tropical lichens the fungal partner is a basidiomycete. Most phototrophic organisms found in lichens also occur as free-living species in nature, but the fungal components are generally found only as a part of the lichen.

In the laboratory, the fungal and phototrophic components of some lichens can be isolated and grown separately in appropriate culture media. The phototroph grows more rapidly when separated, whereas the fungus grows more slowly and requires many complex carbohydrates. Neither organism resembles a lichen in appearance when grown separately. The phototroph

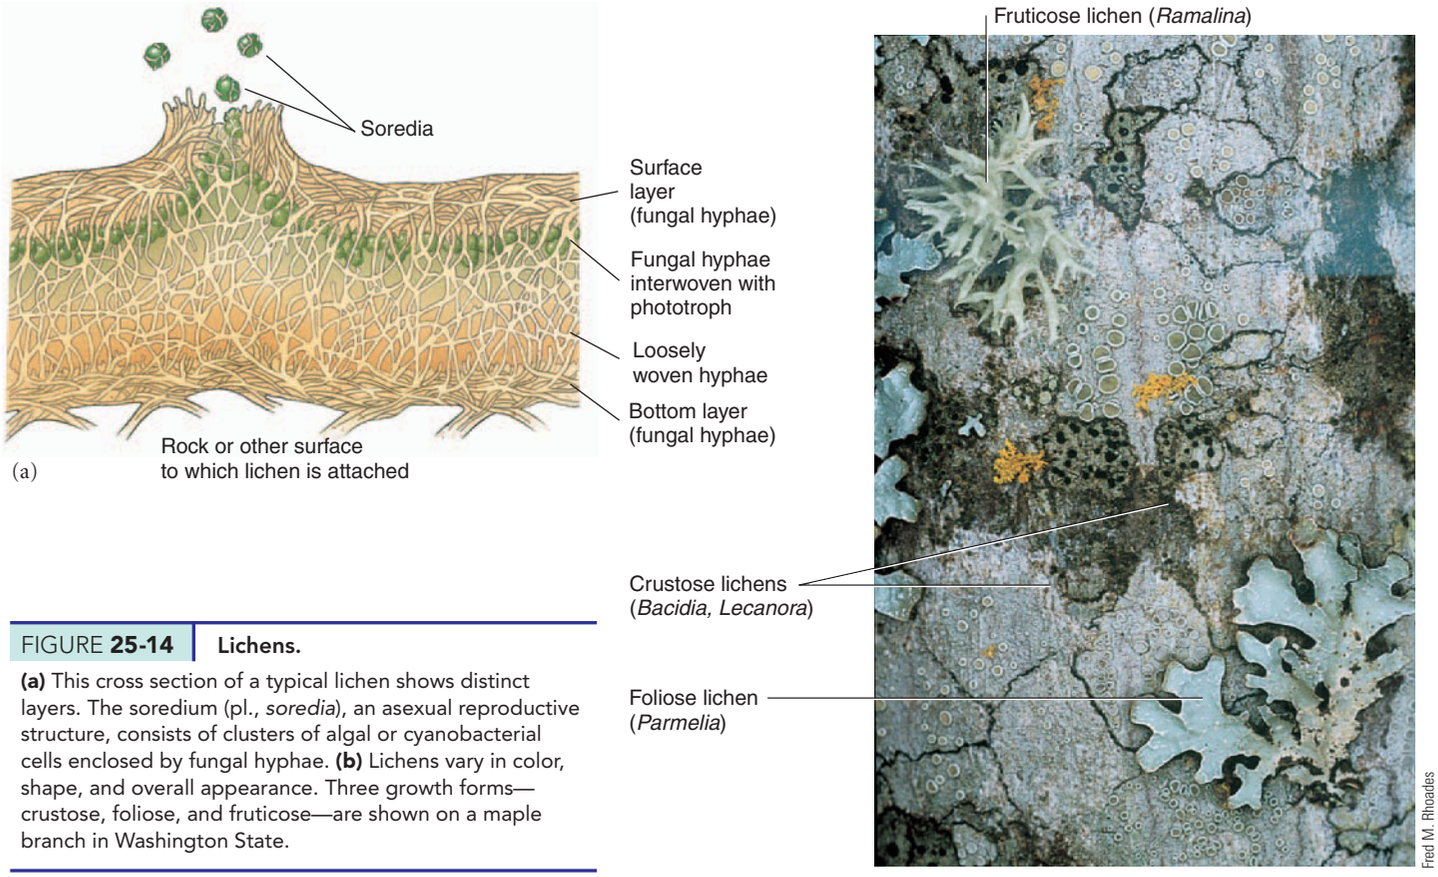

FIGURE **25-14** **Lichens.**

(a) This cross section of a typical lichen shows distinct layers. The soredium (pl., *soredia*), an asexual reproductive structure, consists of clusters of algal or cyanobacterial cells enclosed by fungal hyphae. **(b)** Lichens vary in color, shape, and overall appearance. Three growth forms—crustose, foliose, and fruticose—are shown on a maple branch in Washington State.

and fungus can be reassembled as a lichen thallus, but only if they are placed in a culture medium under conditions that cannot support either of them independently.

What is the nature of this partnership? The lichen was originally considered a definitive example of **mutualism,** a symbiotic relationship that is beneficial to both species. The phototroph carries on photosynthesis, producing food for both members of the lichen, but it is unclear how the phototroph benefits from the relationship. It has been suggested that the phototroph obtains water and nutrient minerals from the fungus as well as protection against desiccation. More recently some biologists have suggested that the lichen partnership is not really a case of mutualism but one of controlled parasitism of the phototroph by the fungus.

Lichens typically exhibit one of three different growth forms (Fig. 25-14b): *Crustose lichens* are flat and grow tightly against their substrate (the surface they are growing on); *foliose lichens* are also flat, but they have leaflike lobes and are not so tightly pressed to the substrate; and *fruticose lichens* grow erect and have many branches.

Able to tolerate extremes of temperature and moisture, lichens grow in almost all terrestrial environments except polluted cities. They exist farther north than any plants of the arctic region and are equally at home in the steaming equatorial rain forest. They grow on tree bark, leaves, and exposed rock surfaces, from solidified lava to tombstones. In fact, lichens are often the first organisms to inhabit rocky areas. Lichen growth in these areas plays an important role in forming soil from rock because they gradually etch tiny cracks in rock, which eventually breaks into particles of soil. This process sets the stage for further disintegration of the rock by wind and rain.

Reindeer mosses of the arctic region, which serve as the main source of food for migrating herds of caribou, are lichens, not mosses. Some lichens produce colored pigments. One of them, orchil, is used to dye woolens, and another, litmus, is widely used in chemistry laboratories as an acid–base (pH) indicator.

Lichens vary greatly in size. Some are almost invisible, whereas others, like the reindeer mosses, may cover many square kilometers of land with an ankle-deep growth. Growth proceeds slowly; the radius of a lichen may increase by less than 1 mm each year. Some mature lichens are thought to be thousands of years old.

Lichens absorb minerals from the air, rainwater, and the surface on which they grow. They cannot excrete the elements they absorb, and perhaps for this reason they are extremely sensitive to toxic compounds. This sensitivity was first reported in 1866 by a Finnish biologist who observed that lichens growing on tree trunks in Paris were poorly developed or sterile. He deduced that lichens could be used to measure air purity. Today, reduction in lichen growth is used as a sensitive indicator of air pollution, particularly from sulfur dioxide. In 1997, Italian researchers established a relationship between lung cancer and air pollution by comparing the locations of low lichen biodiversity (and therefore of air pollution) with the locations of

lung cancer deaths in young males. The return of lichens to an area indicates an improvement in air quality.

Lichens reproduce mainly by asexual means, usually by fragmentation, a process in which special dispersal units of the lichen, called **soredia,** break off and, if they land on a suitable surface, establish themselves as new lichens. Soredia contain cells of both partners. In some lichens, the fungus produces ascospores, which may be dispersed by wind and find an appropriate algal partner only by chance.

Review

ECOLOGICAL IMPORTANCE OF FUNGI

Learning Objectives

7 Explain the ecological significance of fungi as decomposers.

8 Describe the special ecological role of mycorrhizae.

Fungi make important contributions to the ecological balance of our planet. Like bacteria, most fungi are free-living decomposers (saprotrophs) that absorb nutrients from organic wastes and dead organisms. For example, many fungal decomposers degrade cellulose and lignin, the main components of plant cell walls. When fungi degrade wastes and dead organisms, they release water, carbon (as CO_2), and mineral components of organic compounds, and these elements are recycled (see biogeochemical cycles in Chapter 53). Without this continuous decomposition, essential nutrients would remain locked up in huge mounds of animal carcasses, feces, branches, logs, and leaves. The nutrients would be unavailable for use by new generations of organisms, and life would eventually cease.

Although most fungi are decomposers, others form symbiotic relationships of various kinds. Some fungi are **parasites,** organisms that live in or on other organisms and are harmful to their hosts. Parasitic fungi absorb food from the bodies of their hosts.

Mycorrhizae (from Greek words meaning "fungus roots") are mutualistic relationships between fungi and the roots of plants (see Fig. 34-10). Such relationships occur in more than 90% of all plant families. The mycorrhizal fungus decomposes organic material in the soil. It also benefits the plant by increasing its absorptive surface area, enabling it to take in more water and nutrient minerals such as phosphorus. At the same time, the roots supply the fungus with sugars, amino acids, and other organic substances (Fig. 25-15). Scientists have also measured the movement of organic materials from one tree species to another through shared mycorrhizal connections.

The importance of mycorrhizae first became evident when horticulturalists observed that orchids do not grow unless an appropriate fungus lives with them. Similarly, many forest trees such as pines decline and eventually die from mineral deficiencies when transplanted to mineral-rich grassland soils that lack the appropriate mycorrhizal fungi. When forest soil containing the appropriate fungi or their spores is added to the soil around these trees, they quickly resume normal growth.

Review

- What is the ecological importance of fungal decomposers?
- What is the importance of mycorrhizae?

ECONOMIC AND MEDICAL IMPORTANCE OF FUNGI

Learning Objectives

9 Summarize some of the ways humans use fungi.

10 Identify at least three fungal diseases of plants and three of animals.

The same powerful digestive enzymes that fungi use to decompose wastes and dead organisms can also be used to reduce wood, fiber, and food to their basic components with great efficiency. From the human perspective, various fungi cause incalculable damage to stored goods and building materials each year. Bracket fungi, for example, cause enormous losses by decaying wood, both in living trees and in stored lumber.

Fungi are more destructive to plants than any other disease-causing organism. Their activities cost billions of dollars in agricultural damage yearly. Some fungi cause diseases in humans and other animals. Yet fungi are responsible for economic gains as well as losses: People eat them and grow them to make various chemicals.

Fungi provide beverages and food

Humans exploit the capability of yeasts to produce ethyl alcohol and carbon dioxide from sugars such as glucose by fermentation (see Chapter 7) to make wine, beer, and other fermented beverages, and also to make bread. Wine is produced when yeasts ferment fruit sugars, and beer results when yeasts ferment sugars derived from starch in grains (usually barley). During the process of making bread, carbon dioxide produced by yeast becomes trapped in dough as bubbles, causing the dough to rise; this gives leavened bread its light texture. Both the carbon dioxide and the alcohol produced by the yeast escape during baking.

The unique flavor of cheeses such as Roquefort, Brie, Gorgonzola, and Camembert is produced by species of *Penicillium*. *Penicillium roquefortii,* for example, is found in caves near the French village of Roquefort; by French law, only cheeses produced in this area can be called Roquefort cheese. In Roquefort and certain other cheeses, the blue mycelium of the fungus is visible in the cheese.

Aspergillus tamarii and certain other imperfect fungi are used to produce soy sauce by fermenting soybeans with the fungi for three or more months.[3] Soy sauce enriches other foods with more than just its special flavor. It also adds vital amino acids from both the soybeans and the fungi themselves, which supplement a low-protein rice diet.

Among the basidiomycetes are some 200 kinds of edible mushrooms and about 70 species of poisonous ones, sometimes called toadstools. Some edible mushrooms are cultivated commercially. The mushroom *Agaricus brunnescens* is the principal fungal species grown extensively for food. About 30 other mushroom species, such as oyster, shiitake, portobello, and straw mushrooms, are available in supermarkets. Morels, which superficially resemble mushrooms, and truffles, which produce underground fruiting bodies, are ascomycetes (Fig. 25-16). These gourmet delights are now being cultivated as mycorrhizal fungi on the roots of tree seedlings.

Edible and poisonous mushrooms can look very much alike and may even belong to the same genus. There is no simple way to tell them apart; an expert must identify them. Some of the most poisonous mushrooms belong to the genus *Amanita* (Fig. 25-17).

[3] In the United States soy sauce is often made by adding flavoring to salt water rather than by soaking fermented soybeans.

(b)

FIGURE **25-16** **Edible ascomycetes.**

(a) The yellow morel (*Morchella esculenta*), which grows 6 to 10 cm (2.5 to 4 in) tall, is found throughout North America. Photographed in Michigan. **(b)** The Oregon white truffle (*Tuber gibbosum*), which is found underground near Douglas firs and possibly oak trees in British Columbia and Northern California, is 1 to 5 cm (0.4 to 2 in) wide. People find these subterranean ascocarps with the help of trained dogs or pigs. Here truffles are shown whole and sectioned to show the conspicuous white, marbled tissue.

James W. Richardson/CBR Images

FIGURE **25-17** **Poisonous mushrooms.**

The destroying angel (*Amanita virosa*) is an extremely poisonous mushroom that is distinguished, as are other amanitas, by the ring of tissue around its stalk and by the underground cup from which the stalk protrudes. About 50 g (2 oz) of this mushroom can kill an adult man. The destroying angel, which is 7.5 to 20 cm (3 to 8 in) tall, is found in grass or near trees throughout North America.

Toxic species of this genus have been appropriately called such names as "destroying angel" (*Amanita virosa*) and "death cap" (*Amanita phalloides*). Eating a single mushroom of either species can be fatal.

Ingesting certain species of mushrooms causes intoxication and hallucinations. The sacred mushrooms of the Aztecs—*Conocybe* and *Psilocybe*—are still used in religious ceremonies by Native Americans of Central America for their hallucinogenic properties. The chemical ingredient *psilocybin* is responsible for the trances and visions experienced by those who eat these mushrooms. Psilocybin is related to lysergic acid diethylamide (LSD). Ingestion of psychoactive mushrooms is dangerous because negative reactions vary considerably, from mild indigestion, sweating, and heart palpitations, to death. In addition, the possession and use of such mushrooms are illegal in the United States and some other countries.

Fungi produce useful drugs and chemicals

Discovered in 1928 by the British bacteriologist Alexander Fleming, penicillin, produced by the mold *Penicillium notatum,* is still among the most widely used and effective antibiotics (see Chapter 1). Other drugs derived from fungi include the cephalosporin antibiotics (produced by *Cephalosporium*), statins (used to lower blood cholesterol levels), and cyclosporine (used to suppress immune responses in patients who receive organ transplants). Fumagillin is a fungal chemical that inhibits the formation of new blood vessels; because solid tumors need a rich blood supply, fumagillin shows promise as an anticancer agent.

The ascomycete *Claviceps purpurea* infects the flowers of rye plants and other cereals. It produces a structure called an *ergot* where a seed would normally form in the grain head. When livestock eat this grain or when humans eat bread made from ergot-contaminated rye flour, they may be poisoned by the extremely toxic substances in the ergot. However, some ergot compounds are now used clinically in small quantities as drugs to induce labor, to stop uterine bleeding, to treat high blood pressure, and to relieve one type of migraine headache.

Some fungi are grown commercially to produce citric acid and other industrial chemicals. Also, biologists are using recombinant DNA techniques to manipulate yeasts and certain filamentous fungi to produce important biological molecules such as hormones.

Fungi cause many important plant diseases

Fungi are responsible for many serious plant diseases, including epidemic diseases that spread rapidly and often result in complete crop failure. All plants are apparently susceptible to some fungal infection. Damage may be localized in certain tissues or structures of the plant, or the disease may be systemic and spread throughout the entire plant. Fungal infections may cause stunting of plant parts or of the entire plant, may cause growths like warts, or may kill the plant.

A plant often becomes infected after hyphae enter through stomata (pores) in the leaf (Fig. 25-18) or stem or through wounds in the plant body. Alternatively, the fungus may produce *cutinase,* an enzyme that dissolves the waxy cuticle that covers the surface of leaves and stems. After dissolving the cuticle, the fungus easily invades the plant tissues. As the mycelium

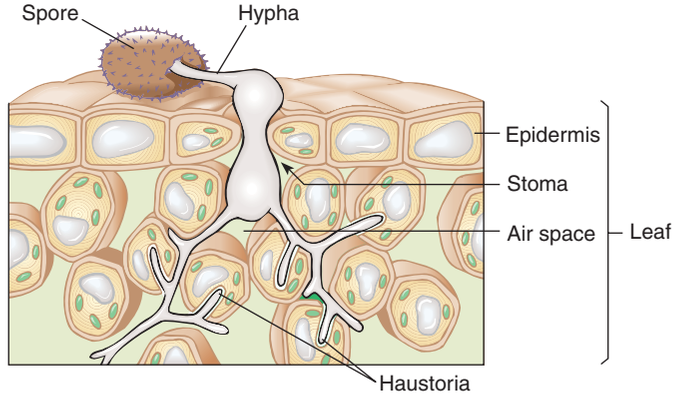

FIGURE **25-18** **How a fungus parasitizes a plant.**

In this example, the hypha enters the leaf through a stoma. It grows, branching extensively through the internal air spaces, and penetrates plant cells with specialized hyphal extensions called haustoria.

FIGURE **25-19**

Fungi that cause plant diseases.

Runk/Schoenberger, from Grant Heilman

(b)

grows, it may remain mainly between the plant cells or it may penetrate the cells. Parasitic fungi often produce special hyphal branches called **haustoria** (sing., *haustorium*) that penetrate the host cells and obtain nourishment from the cytoplasm.

Ascomycetes cause important plant diseases, including powdery mildew, chestnut blight, Dutch elm disease, apple scab, and brown rot, which attacks cherries, peaches, plums, and apricots (Fig. 25-19a). Early in the 20th century the chestnut blight fungus (*Cryphonectria parasitica*) was accidentally imported on diseased Asian chestnuts and quickly attacked native American chestnut trees, which had no resistance to the fungus. By the late 1940s, the blight had killed or damaged several billion mature trees—almost every North American chestnut tree throughout its entire natural range. Plant biologists are working to save the American chestnut tree from extinction. One approach has been to develop a disease-resistant variety by breeding the American chestnut with the Chinese chestnut, a related species that is resistant to chestnut blight. Other biologists are genetically engineering a virus that infects the chestnut blight fungus and reduces its virulence.

Basidiomycetes cause smuts and rusts that attack various plants, for example, corn, wheat, oats, and other grains (Fig. 25-19b). Certain imperfect fungi also cause plant diseases, including verticillium wilt on potatoes, which is caused by the deuteromycete *Verticillium,* and bean anthracnose, which is caused by the deuteromycete *Colletotrichum lindemuthianum.*

Some fungal parasites, such as the stem rust of wheat, have complex life cycles that involve two or more different host plants and the production of several kinds of spores. For example, wheat rust must infect a barberry plant at one stage in its life cycle. Since this fact was discovered, the eradication of barberry plants in wheat-growing regions has reduced infection with wheat rust. Eradication of the barberry has not eliminated wheat rust however, because the fungus overwinters on wheat at the southern end of the Grain Belt and forms asexual spores. During the spring, wind blows these spores for hundreds of kilometers, reinfecting northern areas of the United States and Canada.

Fungi cause certain animal diseases

Some fungi cause superficial infections in which only the skin, hair, or nails are infected. Ringworm and athlete's foot are examples of superficial fungal infections; both are caused by imperfect fungi. Candidiasis, a yeast infection of mucous membranes of the mouth, throat, or vagina, is also caused by an imperfect fungus.

Other fungi infect internal tissues and organs and may spread through many regions of the body. Histoplasmosis, for example, is a serious infection of the lungs caused by inhaling spores of a fungus common in soil contaminated with bird feces. Most people in the eastern and midwestern parts of the United States have been exposed to this fungus at some time, and an estimated 40 million Americans have had mild infections. Fortunately, the infection is usually confined to the lungs and is of short duration, but if the infection spreads through the blood to the heart, brain, or other parts of the body, it can be serious and sometimes fatal.

Most pathogenic fungi are opportunists that cause infections only when the body's immunity is lowered. For example, the deuteromycete *Aspergillus fumigatus* is usually harmless, but causes aspergillosis in people with defective immune systems, such as patients with AIDS. During the course of this disease, the fungus can invade the lungs, heart, brain, kidneys, and other vital organs and can cause death. Other patients at high risk of acquiring life-threatening fungal infections include those with organ transplants or cancer.

Some fungi produce poisonous compounds collectively called **mycotoxins.** A few species of *Aspergillus,* for example, produce potent mycotoxins called *aflatoxins* that harm the liver and are known carcinogens. Foods on which aflatoxin-producing fungi commonly grow include peanuts, pecans, corn, and other grains. Other foods that may contain traces of aflatoxins include animal products such as milk, eggs, and meat (from animals that consumed feed contaminated by aflatoxin). Avoiding aflatoxin in the diet is impossible, but exposure should be minimized as much as possible. Any human food or animal forage

product that has become moldy should be suspected of aflatoxin contamination and discarded.

Fungi contribute to sick building syndrome, a situation in which occupants of a building experience acute health effects linked to the time they spend in a given building. Mold-related insurance claims amount to hundreds of millions of dollars each year. When conditions are moist, molds can grow on carpets, leather, cloth, wood, sheet rock, and insulation, as well as food. Mold spores, fragments, and mold products make their way into the air, and people are exposed through inhalation as well as by skin contact. Exposure to molds and their toxins has been linked to depressed immune function, irritation of the throat and respiratory passageways, infection, and toxicity. The most common responses to mold exposure are allergic reactions that range from mild to severe illnesses, including hayfever, sinusitis, asthma, and dermatitis.

Review

- Some dictionaries erroneously define a morel as a type of mushroom. Why isn't a morel a mushroom?
- What are three important fungal diseases of plants?
- What are three important fungal diseases of humans?

BiologyNow™ Assess your understanding of **the economic and medical importance of fungi** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Describe the distinguishing characteristics of kingdom Fungi.

- **Fungi** are eukaryotic heterotrophs that secrete digestive enzymes onto their food source and then absorb the predigested food.
- Most fungi are decomposers, but many form mutualistic relationships with plants, and some are parasites of plants and animals.
- Fungi are characterized by their cell walls containing **chitin.**

2 Describe the body plan of a fungus.

- A fungus may be a unicellular **yeast** or a filamentous, multicellular **mold.** The vegetative body plan of most multicellular fungi consists of long, branched **hyphae** that form a tangled mass called a **mycelium.**
- In the **zygomycetes,** the hyphae are **coenocytic,** that is, they form an elongated, multinuclear cell. In other fungi, perforated **septa** divide the hyphae into individual cells.

3 Trace the fate of a fungal spore that lands in a favorable location, such as an overripe peach, and describe conditions that permit fungal growth.

- Most fungi reproduce both sexually and asexually by means of **spores.**
- When a fungal spore lands in a suitable spot, it germinates. Some hyphae infiltrate the substrate and digest its organic compounds. Spores are produced on aerial hyphae.

4 Give arguments to support the hypothesis that chytridiomycetes may have been the earliest fungal group to have evolved from the common ancestor of fungi.

- **Chytridiomycetes** are simple aquatic fungi that produce flagellate cells at some stage in their life cycle. No other fungi have flagella. Thus chytrids probably evolved from a flagellate protist, the common ancestor of all fungi.

5 List distinguishing characteristics, describe a typical life cycle, and give examples of each of the following fungal groups: chytridiomycetes, zygomycetes, ascomycetes, basidiomycetes, and imperfect fungi.

- *Allomyces,* a common chytridiomycete (chytrid), spends part of its life as a haploid **thallus** and part as a diploid thallus. The haploid thallus bears male and female **gametangia,** structures in which flagellate gametes form. The diploid thallus bears zoosporangia that produce diploid **zoospores** and resting sporangia in which haploid zoospores form by meiosis.
- **Zygomycetes** produce both asexual spores and sexual spores, called **zygospores.** *Pilobolus* and the black bread mold *Rhizopus* are representatives of this group.
- **Ascomycetes** produce asexual spores called **conidia;** sexual spores called **ascospores** are produced in **asci.** Ascomycetes include yeasts, cup fungi, morels, truffles, and pink, brown, and blue-green molds.
- **Basidiomycetes** produce sexual spores called **basidiospores** on the outside of a **basidium;** basidia develop on the surface of **gills** in mushrooms, a type of **basidiocarp.** Basidiomycetes include mushrooms, puffballs, bracket fungi, rusts, and smuts.
- **Imperfect fungi,** or **deuteromycetes,** are a polyphyletic group that lack a sexual stage. Most reproduce asexually by forming conidia. Members of this group include *Aspergillus tamarii* (used to produce soy sauce), some species of *Penicillium,* and fungi that cause certain human infections.

6 Characterize the unique nature of a lichen.

- A **lichen** is a symbiotic combination of a fungus and a phototroph (an alga or cyanobacterium.) Lichens have three main growth forms: crustose, foliose, and fruticose.

7 Explain the ecological significance of fungi as decomposers.

- Most fungi are decomposers that break down organic compounds into simpler nutrients that are recycled.

8 Describe the special ecological role of mycorrhizae.

- **Mycorrhizae** are mutualistic relationships between fungi and the roots of plants. The fungus supplies water and nutrient minerals to the plant, and the plant secretes organic compounds needed by the fungus.

9 Summarize some of the ways humans use fungi.

- Mushrooms, morels, and truffles are foods; yeasts are vital in the production of beer, wine, and bread; certain fungi are used to produce cheeses and soy sauce.
- Fungi are used to make penicillin and other antibiotics; ergot is used to produce certain drugs; other fungi make citric acid and other industrial chemicals.

10 Identify at least three fungal diseases of plants and three of animals.

- Fungi cause many plant diseases, including wheat rust, Dutch elm disease, and chestnut blight; they cause human diseases such as ringworm, athlete's foot, candidiasis, and histoplasmosis.

POST-TEST

1. Most fungi produce cell walls containing the polymer _____. (a) chitin (b) penicillin (c) cellulose (d) peptidoglycan (e) lysergic acid
2. Which of the following fungi does *not* have a mycelium? (a) black bread mold (b) yeast (c) decomposer cup fungus (d) cultivated mushroom (e) *Penicillium*
3. The condition described as $n + n$ is said to be (a) monokaryotic (b) diploid (c) a primary mycelium (d) coenocytic (e) dikaryotic
4. With the exception of chytridiomycetes, fungi are generally disseminated by (a) water currents (b) fragmentation of hyphae (c) soredia (d) airborne spores (e) flagellate zoospores
5. Which statement is *not* true of the chytridiomycetes? (a) they are simple aquatic fungi (b) they produce motile cells with single, posterior flagella (c) they have both sexual and asexual reproduction (d) the black bread mold is a representative of this group (e) they are the most primitive group of fungi
6. Which statement is *not* true of the zygomycetes? (a) they produce motile cells with single, posterior flagella (b) their sexual spores are called *zygospores* (c) they have both sexual and asexual reproduction (d) the black bread mold is a representative of this group (e) they have coenocytic hyphae
7. Which statement is *not* true of the ascomycetes? (a) their sexual spores are produced in asci (b) their asexual spores are produced in basidia (c) some species in this group are yeasts (d) their asexual spores are called *conidia* (e) some species cause serious plant diseases
8. The ascomycete life cycle typically includes (a) mainly diploid thalli (b) the formation of a thick zygosporangium (c) the production of eight haploid ascospores within an ascus (d) intertwined hyphae to form a basidiocarp (e) the production of ascospores, zoospores, and conidia at different stages
9. Which statement is *not* true of the basidiomycetes? (a) they have a diploid thallus that produces zoospores (b) their sexual spores are called *basidiospores* (c) they produce a secondary mycelium with $n + n$ hyphae (d) mushrooms and bracket fungi are examples of this group (e) this group includes both edible and poisonous species
10. The familiar portion of a mushroom is actually a large fruiting body called a(an) (a) ascocarp (b) basidium (c) basidiocarp (d) gametangium (e) ascus
11. Which statement is *not* true of deuteromycetes? (a) many are ascomycetes that lost the ability to reproduce by forming ascospores (b) they are also known as imperfect fungi (c) they have both sexual and asexual reproduction (d) their asexual spores are called *conidia* (e) some are important plant pathogens
12. A _____ is a symbiotic association between a phototroph and a fungus. (a) mycorrhizae (b) deuteromycete (c) lichen (d) haustorium (e) saprotroph
13. Which characteristic is true of *all* fungi? (a) saprotrophic (b) parasitic (c) nonflagellate (d) pathogenic (e) heterotrophic
14. Mutualistic relationships between fungi and the roots of plants are called (a) lichens (b) mycorrhizae (c) deuteromycetes (d) haustoria (e) conidiophores
15. *Amanita virosa* (a) is the mushroom commonly cultivated for food (b) is the yeast that ferments wine and beer (c) produces the unique flavor of many cheeses (d) is a highly toxic mushroom (e) has been ingested for its hallucinogenic properties
16. Which of the following describes how a fungus infects a plant? (a) infiltrates leaves with lichens (b) forms relationships by attaching mycorrhizae to stems (c) secretes powerful digestive juices onto the leaves (d) uses haustoria to penetrate stem tissue (e) hyphae enter leaves through a stoma
17. Mycotoxins are (a) released by most lichens (b) typically cause mild allergic reactions (c) can harm the liver (d) reduce the effects of sick building syndrome (e) are produced mainly by chytrids

CRITICAL THINKING

1. How are the life cycles of the marine alga *Ulva* (see Fig. 24-20) and *Allomyces* similar?
2. What measures can you suggest to prevent bread from becoming moldy?
3. Explain the statement: "Mushrooms are like the tips of icebergs." If you do not see toadstools in your lawn, can you conclude that no fungi live there? Why or why not?
4. Biologists have discovered that many mycorrhizal fungi are sensitive to a low pH. What human-caused environmental problem may prove catastrophic for these fungi? How may this problem affect their plant partners?

The Plant Kingdom: Seedless Plants

Sydney Karp/Photo/Nats, Inc.

Moss-covered rocks. Shown is Marron Creek in Snowmass Wilderness, Colorado.

CHAPTER OUTLINE

- Adaptations of Plants
- Bryophytes
- Seedless Vascular Plants

About 440 million years ago (mya), planet Earth would have seemed most inhospitable because, although life abounded in the oceans, it did not yet exist in abundance on land. The ocean was filled with vast numbers of fish, mollusks, and crustaceans as well as countless microscopic algae, and the water along rocky coastlines was home to large seaweeds. Occasionally, perhaps, an animal would crawl out of the water onto land, but it never stayed there permanently because there was little to eat on land—not a single blade of grass, no fruit, and no seeds.

During the next 30 million years, a time corresponding roughly to the Silurian period of the Paleozoic era in geological time (see Table 20-1), plants appeared in abundance and colonized the land. Where did they come from? Although plants living today exhibit great diversity in size, form, and habitat, botanists hypothesize they all evolved from a common ancestor that was an ancient green alga. Biologists infer this because modern green algae share many biochemical and metabolic traits with modern plants. Both green algae and plants contain the same photosynthetic pigments: chlorophylls *a* and *b* and accessory pigments, the yellow and orange carotenoids, including xanthophylls (yellow pigments) and carotenes (orange pigments). Also, both store excess carbohydrates as starch and have cellulose as a major component of their cell walls. In addition, plants and some green algae share certain details of cell division, including formation of a cell plate during cytokinesis (see Chapter 9).

Recent ultrastructural and molecular data indicate plants probably descended from a group of green algae called **charophytes** or **stoneworts** (see Fig. 24-18d). Molecular comparisons, particularly of DNA and RNA sequences, provide compelling evidence that charophytes are closely allied to plants. These data include comparisons among plants and various green algae, of chloroplast DNA sequences, of certain nuclear genes, and of ribosomal RNA sequences. In each case, the closest match occurs between charophytes and plants, indicating

modern charophytes and plants probably share a common charophyte ancestor.

Today the plant kingdom consists of hundreds of thousands of species that live in varied habitats, from frozen Arctic tundra to lush tropical rain forests to harsh deserts to moist stream banks, as shown in the photograph on the previous page. Plants are complex multicellular organisms that range in size from minute, almost microscopic duckweeds to massive giant sequoias, some of the largest organisms that have ever lived. ■

ADAPTATIONS OF PLANTS

Learning Objectives

1. Discuss some environmental challenges of living on land, and describe how several adaptations meet these challenges.
2. Name the protist group from which plants are hypothesized to have descended, and describe supporting evidence.

What are some features of plants that have let them colonize so many different environments? One important difference between plants and algae is that a waxy **cuticle** covers the aerial portion of a plant. Essential for existence on land, the cuticle helps prevent desiccation, or drying out, of plant tissues by evaporation. Most plants that are adapted to moister habitats may have a very thin layer of wax, whereas those adapted to drier environments often have a thick, crusty cuticle. (Many desert plants also have a reduced surface area, particularly of leaves, that minimizes water loss.)

Plants get the carbon they need for photosynthesis from the atmosphere as carbon dioxide (CO_2). To be fixed into organic molecules such as sugar, CO_2 must first diffuse into the chloroplasts that are inside green plant cells. Because a waxy cuticle covers the external surfaces of leaves and stems, however, gas exchange through the cuticle between the atmosphere and the insides of cells is negligible. Tiny pores called **stomata** (sing., *stoma*), which dot the surfaces of leaves and stems of almost all plants, facilitate gas exchange; algae lack stomata.

Most plants have multicellular sex organs called **gametangia** (sing., *gametangium*), whereas the gametangia of algae are unicellular (Fig. 26-1). Each plant gametangium has a layer of sterile (nonreproductive) cells that surrounds and protects the delicate gametes (eggs and sperm cells). In plants, the fertilized egg develops into a multicellular **embryo** (young plant) within the female gametangium. Thus the embryo is protected during its development. In algae, the fertilized egg develops away from its gametangium; in some algae, the gametes are released before fertilization, whereas in others the fertilized egg is released.

The plant life cycle alternates haploid and diploid generations

Plants have a clearly defined **alternation of generations** in which they spend part of their lives in a multicellular haploid stage and part in a multicellular diploid stage[1] (Fig. 26-2). The haploid portion of the life cycle is called the **gametophyte generation** because it gives rise to haploid gametes by mitosis. When two gametes fuse, the diploid portion of the life cycle, called the **sporophyte generation,** begins. The sporophyte generation produces haploid spores by the process of meiosis; these spores represent the first stage in the gametophyte generation.

[1] For convenience we limit our discussion to plants that are not polyploid, although polyploidy is very common in the plant kingdom. We therefore use the terms *diploid* and $2n$ (and *haploid* and n) interchangeably, although these terms are not actually synonymous.

FIGURE **26-1** **Generalized reproductive structures of algae and plants.**

(a, b) In algae, gametangia are generally unicellular. When the gametes are released, only the wall of the original cell remains. **(c, d)** In plants, the gametangia are multicellular, but only the inner cells become gametes. The gametes are surrounded by a protective layer of sterile (nonreproductive) cells.

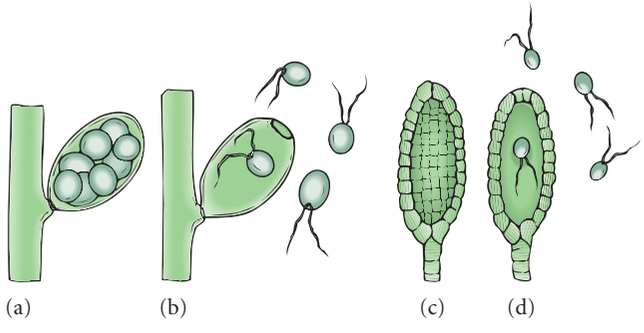

FIGURE **26-2** **The basic plant life cycle.**

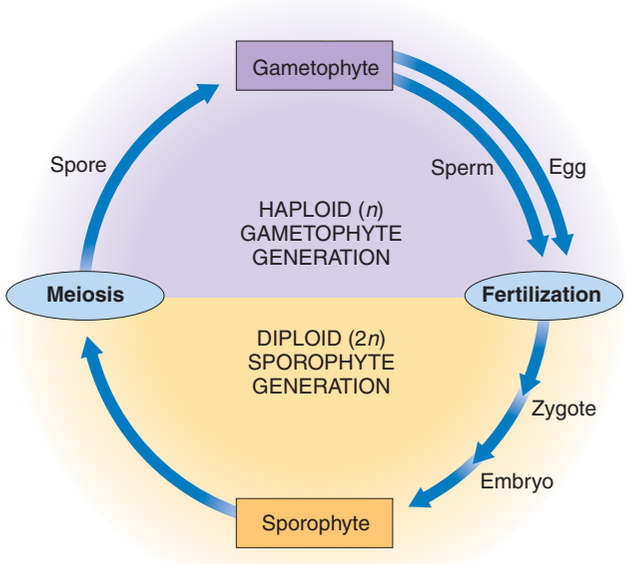
Plants have an alternation of generations, spending part of the cycle in a haploid gametophyte stage and part in a diploid sporophyte stage. Depending on the plant group, the haploid or the diploid stage may be greatly reduced.



Let's examine alternation of generations more closely. The haploid gametophytes produce **antheridia** (male gametangia), in which sperm cells form, and/or **archegonia** (female gametangia), each bearing a single egg (Fig. 26-3). Sperm cells reach the female gametangium in a variety of ways, and one sperm cell fertilizes the egg to form a **zygote,** or fertilized egg.

The diploid zygote is the first stage in the sporophyte generation. The zygote divides by mitosis and develops into a multicellular embryo, the young sporophyte plant. Embryo development takes place within the archegonium; thus, the embryo is protected as it develops. Eventually the embryo grows into a mature sporophyte plant. The mature sporophyte has special cells called *sporogenous cells* (spore-producing cells, also called *spore mother cells*) that divide by meiosis to form haploid **spores.**

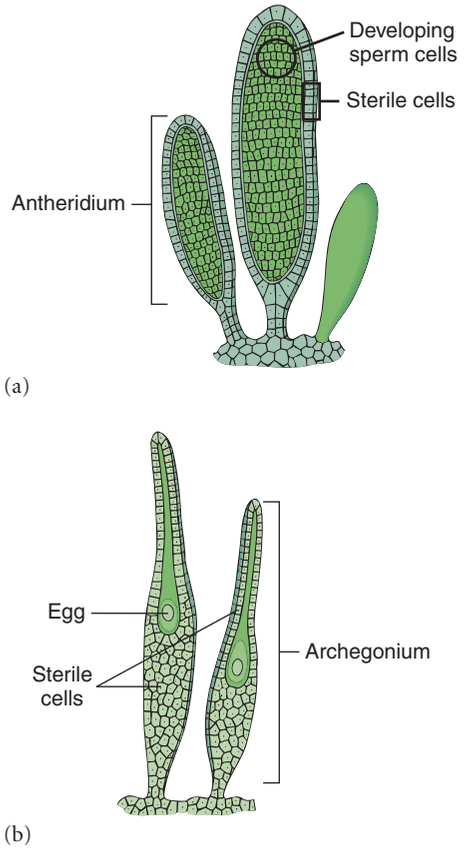
Fertilization of egg by sperm cell ⟶ zygote ⟶ embryo ⟶ mature sporophyte plant ⟶ sporogenous cells ⟶ meiosis ⟶ spores

All plants produce spores by meiosis, in contrast with algae and fungi, which may produce spores by meiosis or mitosis. The spores represent the first stage in the gametophyte generation. Each spore divides by mitosis to produce a multicellular gametophyte, and the cycle continues. Plants therefore alternate between a haploid gametophyte generation and a diploid sporophyte generation.

spores ⟶ mature gametophyte plants ⟶ archegonia ⟶ eggs; antheridia ⟶ sperm cells

FIGURE 26-3 Plant gametangia.

(a) Each antheridium, the male gametangium, produces numerous sperm cells. **(b)** Each archegonium, the female gametangium, produces a single egg. Shown are generalized moss gametangia.



Four major groups of plants evolved

The plant kingdom consists of four major groups: bryophytes, seedless vascular plants, gymnosperms, and flowering plants (Fig. 26-4; see also Table 26-1, which is an overview of living plant phyla discussed in Chapters 26 and 27). The mosses and other bryophytes are small nonvascular plants that lack a specialized vascular, or conducting, system to transport dissolved nutrients, water, and essential minerals throughout the plant body. In the absence of such a system, bryophytes rely on diffusion and osmosis to obtain needed materials. This reliance means bryophytes are restricted in size; if they were much larger, some

ACTIVE FIGURE 26-4 Plant evolution.

This cladogram shows hypothetical evolutionary relationships among living plants, based on current evidence. Although the arrangement of nonvascular, seedless vascular, and seed plant groupings is widely recognized, the exact positions of various phyla remain uncertain. The order in which the hornworts, liverworts, and mosses evolved is not yet resolved, and the exact position of the whisk ferns is still unclear.

Seeds enclosed within a fruit
- Phylum Magnoliophyta (angiosperms or flowering plants)
  - Class Magnoliopsida (dicots)
  - Class Liliopsida (monocots)

of their cells could not obtain enough necessary materials. Bryophytes are seedless plants; they do not form seeds, the reproductive structures discussed in Chapter 27. Bryophytes reproduce and disperse primarily via haploid spores. Recent molecular and fossil evidence, discussed later in the chapter, indicates bryophytes may have been some of the earliest plants to colonize land.

The other three groups of plants—ferns, gymnosperms, and flowering plants—have vascular tissues and are thus known as vascular plants. The two vascular tissues are **xylem,** for conducting water and minerals, and **phloem,** for conducting dissolved organic molecules such as sugar. A key step in the evolution of vascular plants was the ability to produce **lignin,** a strengthening polymer in the cell walls of cells that function for support and conduction (see Chapter 31 for a discussion of plant cell wall chemistry, including lignin). The stiffening property of lignin enabled plants to grow tall (which let them maximize light interception). The successful occupation of the land by plants in turn made the evolution of terrestrial animals possible by providing them with both habitat and food.

Ferns and their close relatives, or allies (whisk ferns, horsetails, and club mosses), are seedless vascular plants that, like the bryophytes, reproduce and disperse primarily via spores. Seedless vascular plants arose and diversified during the Silurian and Devonian periods of the Paleozoic era, between 420 and 360 mya (discussed later in the chapter). Ferns and fern allies extend back more than 420 million years and were of considerable importance as Earth's dominant plants in past ages. Fossil evidence indicates that many species of these plants were the size of immense trees. Many ferns and most fern allies are extinct today; a few, mostly small representatives of the ancient groups survive.

The gymnosperms are vascular plants that reproduce by forming seeds (see Chapter 27). Gymnosperms produce seeds borne exposed (unprotected) on a stem or in a cone. Plants with seeds as their primary means of reproduction and dispersal first appeared about 360 mya, at the end of the Devonian period. These early seed plants diversified into many varied species of gymnosperms.

The most recent plant group to appear is the flowering plants, or angiosperms, which arose during the early Cretaceous period of the Mesozoic era about 130 mya. Like gymnosperms, flowering plants reproduce by forming seeds. Flowering plants, however, produce seeds enclosed within a fruit.

Review

- What are the most important environmental challenges that plants face living on land?
- What adaptations do plants have to meet these environmental challenges?
- From which group of protists are plants hypothesized to have descended?
- What is alternation of generations in plants?

BiologyNow™ Assess your understanding of **adaptations of plants** by taking the pretest on your BiologyNow CD-ROM.

BRYOPHYTES

Learning Objectives

3 Summarize the features that distinguish bryophytes from green algae and from other plants.

4 Name and briefly describe the three phyla of bryophytes.

5 Describe the life cycle of mosses, and compare their gametophyte and sporophyte generations.

The **bryophytes** (from the Greek words meaning "moss plant") consist of more than 15,000 species of mosses, liverworts, and hornworts; bryophytes are the only living nonvascular plants (Table 26-2). Because they have no means for extensive internal transport of water, dissolved sugar, and essential nutrient minerals, bryophytes are typically quite small. They generally require a moist environment for active growth and reproduction, but some bryophytes tolerate dry areas.

The bryophytes are divided into three distinct phyla: mosses (phylum Bryophyta), liverworts (phylum Hepaticophyta), and hornworts (phylum Anthocerotophyta). These three groups differ in many ways and may or may not be closely related. They are usually studied together, because they lack vascular tissues and have similar life cycles.

Moss gametophytes are differentiated into "leaves" and "stems"

Mosses (phylum Bryophyta), with about 9000 species, usually live in dense colonies or beds (Fig. 26-5a). Each individual plant has tiny, hairlike absorptive structures called *rhizoids,* and an upright, stemlike structure that bears leaflike blades, each normally consisting of a single layer of undifferentiated cells except at the midrib. Because mosses lack vascular tissues, they do not

TABLE 26-2 A Comparison of Major Groups of Seedless Plants

Plant Group	Dominant Stage of Life Cycle	Representative Genera
Nonvascular; reproduce by spores (bryophytes)		
Mosses (phylum Bryophyta)	Gametophyte: leafy plant	*Polytrichum, Sphagnum, Physcomitrella*
Liverworts (phylum Hepaticophyta)	Gametophyte: thalloid or leafy plant	*Marchantia*
Hornworts (phylum Anthocerotophyta)	Gametophyte: thalloid plant	*Anthoceros*
Vascular; reproduce by spores		
Ferns (phylum Polypodiophyta)	Sporophyte: roots, rhizomes, and leaves (megaphylls)	*Pteridium, Polystichum, Azolla, Platycerium*
Whisk ferns (phylum Psilotophyta)	Sporophyte: rhizomes and erect stems; no true roots or leaves	*Psilotum*
Horsetails (phylum Equisetophyta)	Sporophyte: roots, rhizomes, erect stems, and leaves (reduced megaphylls)	*Equisetum*
Club mosses (phylum Lycophyta)	Sporophyte: roots, rhizomes, erect stems, and leaves (microphylls)	*Lycopodium, Selaginella*

have true roots, stems, or leaves; the moss structures are not homologous to roots, stems, or leaves in vascular plants. Some moss species have water-conducting cells and sugar-conducting cells, although these cells are not as specialized or as effective as the conducting cells of vascular plants.

Alternation of generations is clear in the life cycle of mosses (Fig. 26-6). In ① of the figure, the green moss gametophyte often bears its gametangia at the top of the plant. Many moss species have separate sexes: male plants that bear antheridia and female plants that bear archegonia. Other mosses produce antheridia and archegonia on the same plant.

In ②, fertilization occurs when one of the sperm cells fuses with the egg within the archegonium. Sperm cells, which have flagella, are transported from antheridium to archegonium by flowing water, such as splashing rain droplets. A raindrop lands on the top of a male gametophyte, and sperm cells are released into it from the antheridia. Another raindrop landing on the male plant may splash the sperm-laden droplet into the air and onto the top of a nearby female plant. Alternatively, insects may touch the sperm-laden fluid and inadvertently carry it for considerable distances. Once in a film of water on the female moss, a sperm cell swims into the archegonium, which secretes

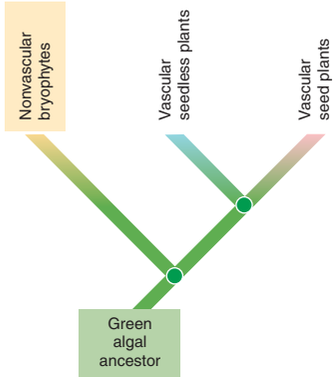

FIGURE 26-5 Mosses, liverworts, and hornworts.

FIGURE **26-6** **The life cycle of mosses.**

The gametophyte generation is dominant in the moss life cycle. After sexual reproduction, the sporophyte grows out of the gametophyte. See text for a detailed description.

chemicals to attract and guide the sperm cells, and fuses with the egg.

In ③, the diploid zygote, formed by fertilization, grows by mitosis into a multicellular embryo that ④ develops into a mature moss sporophyte. This sporophyte grows out of the top of the female gametophyte, remaining attached and nutritionally dependent on the gametophyte throughout its existence (Fig. 26-7). Initially green and photosynthetic, the sporophyte becomes a golden brown at maturity. It consists of three main parts: a *foot,* which anchors the sporophyte to the gametophyte and absorbs minerals and nutrients from it; a *seta,* or stalk; and a *capsule,* which contains sporogenous cells (spore mother cells). The capsule of some species is covered by a caplike structure, the *calyptra,* which is derived from the archegonium.

In ⑤, the sporogenous cells undergo meiosis to form haploid spores. When the spores are mature, the capsule opens and releases the spores, which are then transported by wind or rain. In ⑥, if a moss spore lands in a suitable spot, it germinates and grows into a filament of cells called a **protonema.** The protonema, which superficially resembles a filamentous green alga, forms buds, each of which grows into a green gametophyte, and the life cycle continues.

Biologists consider the haploid gametophyte generation the dominant generation in mosses, because it lives independently of the diploid sporophyte. In contrast, the moss sporophyte is attached to and nutritionally dependent on the gametophyte.

Mosses make up an inconspicuous but significant part of their environment. They play an important role in forming soil. Because they grow tightly packed together in dense colonies, mosses hold soil in place and help prevent erosion.

Commercially, the most important mosses are the peat mosses in the genus *Sphagnum.* One of the distinctive features of *Sphagnum* "leaves" is the presence of many large dead cells that absorb and hold water. This feature makes peat moss particularly beneficial as a soil conditioner. Added to sandy soils, for example, peat moss helps absorb and retain moisture. In some countries, such as Ireland and Scotland, people cut out layers of dead peat moss that have accumulated for hundreds of years from peat bogs, dry them and burn them for fuel.

The name "moss" is often misused to refer to plants that are not truly mosses. For example, reindeer "moss" is a lichen that is a dominant form of vegetation in the Arctic tundra, Spanish "moss" is a flowering plant, and club "moss" (discussed later in this chapter) is a relative of ferns.

Image not available due to copyright restrictions

Liverwort gametophytes are either thalloid or leafy

Liverworts (phylum Hepaticophyta) consist of about 6000 species of nonvascular plants with a dominant gametophyte generation, but the gametophytes of some liverworts are quite different from those of mosses. Their body form is often a flattened, lobed structure called a **thallus** (pl., *thalli*) that is not differentiated into leaves, stems, or roots. The common liverwort, *Marchantia polymorpha,* is thalloid (see Fig. 26-5b). Liverworts are so named because the lobes of their thalli superficially resemble the lobes of the human liver; *wort* is derived from the Old English word *wyrt,* meaning "plant." On the underside of the liverwort thallus are hairlike rhizoids that anchor the plant to the soil. Other liverworts, known as *leafy liverworts,* superficially resemble mosses, with leaflike blades, "stems," and rhizoids rather than a lobed thallus. As in the mosses, leafy liverwort "leaves" consist of a single layer of undifferentiated cells. Like other bryophytes, liverworts are small, generally inconspicuous plants that are largely restricted to damp environments. Unlike other plants, including mosses and hornworts, liverworts lack stomata (although some liverworts have surface pores thought to be analogous to stomata).

Liverworts reproduce both sexually and asexually (Fig. 26-8). In ①, their sexual reproduction involves production of archegonia and antheridia on the haploid gametophyte. In some liverworts, these gametangia are borne on stalked structures called *archegoniophores,* which bear archegonia, and *antheridiophores,* which bear antheridia. Their life cycle is basically the same as that of mosses, although some of the structures look quite different. In ②, splashing raindrops transport sperm cells to the archengonia, where fertilization takes place. The resulting zygote develops into a multicellular embryo that becomes a mature sporophyte, ③. The liverwort sporophyte, which is usually somewhat spherical, is attached to the gametophyte, as in mosses. In ④, sporogenous cells in the capsule of the sporophyte undergo meiosis, producing haploid spores. In ⑤, each spore has the potential to develop into a green gametophyte, and the cycle continues.

Some liverworts reproduce asexually by forming tiny balls of tissue called **gemmae** (sing., *gemma*), which are borne in a saucer-shaped structure, the gemmae cup, directly on the liverwort thallus. Splashing raindrops and small animals help disperse gemmae. When a gemma lands in a suitable place, it grows into a new liverwort thallus. Liverworts may also reproduce asexually by thallus branching and growth. The individual thallus lobes elongate, and each becomes a separate plant when the older part of the thallus that originally connected the individual lobes dies.

Hornwort gametophytes are inconspicuous thalloid plants

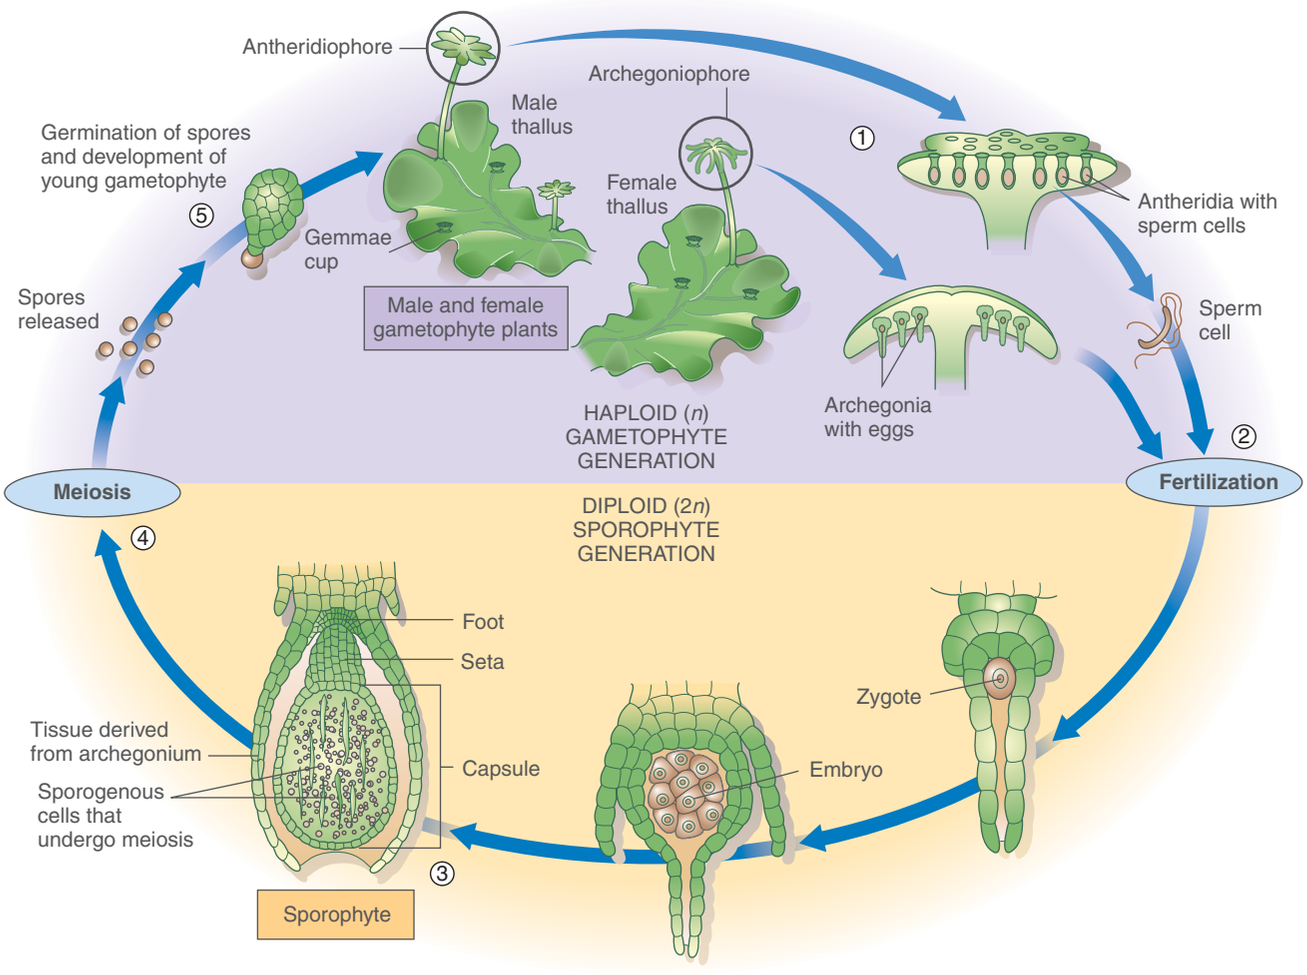
Hornworts (phylum Anthocerotophyta) are a small group of about 100 species of bryophytes whose gametophytes superficially resemble those of the thalloid liverworts. Hornworts live in disturbed habitats such as fallow fields and roadsides.

Hornworts may or may not be closely related to other bryophytes. For example, their cell structure, particularly the presence of a single large chloroplast in each cell, resembles certain algal cells more than plant cells. In contrast, mosses, liverworts, and other plants have many disk-shaped chloroplasts per cell.

In the common hornwort (*Anthoceros natans*), archegonia and antheridia are embedded in the gametophyte thallus rather than on archegoniophores and antheridiophores. After fertilization and development, the needle-like sporophyte projects out of the gametophyte thallus, forming a spike or "horn"—hence the name *hornwort.* A single gametophyte often produces multiple sporophytes (see Fig. 26-5c). Meiosis occurs, forming spores within each **sporangium** (pl., *sporangia*), or spore case. The sporangium splits open from the top to release the spores; each spore can give rise to a new gametophyte thallus. A unique feature of hornworts is that the sporophytes, unlike those of mosses and liverworts, continue to grow from their bases for the remainder of the gametophyte's life.

Bryophytes are used for experimental studies

Botanists use certain bryophytes as experimental models to study many fundamental aspects of plant biology, including genetics, growth and development, plant ecology, plant hormones, and **photoperiodism,** which is plant responses to varying periods



ACTIVE FIGURE **26-8** **The life cycle of the common liverwort (*Marchantia polymorpha*).**

The dominant generation is the gametophyte, represented by separate male and female thalli. The stalked, umbrella-shaped structures are the antheridiophores, with antheridia that produce sperm cells, and the archegoniophores, with archegonia that each bear an egg cell. See text for a detailed description.

BiologyNow™ Watch **the life cycle of the liverwort** by clicking on this figure on your BiologyNow CD-ROM.

of night and day length (see Chapter 36). As experimental organisms, bryophytes are easy to grow on artificial media and do not require much space, because they are so small (Fig. 26-9).

Bryophyte evolution is based on fossils and on structural and molecular evidence

PROCESS OF SCIENCE

Plants are a **monophyletic group**—that is, all plants probably evolved from a common ancestral green alga. Fossil evidence indicates the bryophytes are ancient plants, probably the first group of plants to arise from the common plant ancestor. The fossil record of ancient bryophytes is incomplete, consisting mostly of spores and small tissue fragments, and can be inter-

FIGURE **26-9** **Mosses as research organisms.**

Researchers inoculated this petri dish with offspring from a genetic cross in the moss *Physcomitrella patens*.They will test the cultures for their phenotypes with respect to vitamin requirements. (The culture medium in which the mosses are currently growing is supplemented with all the vitamins required by the parental strains.)

preted in different ways. As a result, it does not provide a definite answer on bryophyte evolution.

The oldest known complete fossil plant, dated at about 400 million years old, was reported in 1995. This fossil, from a coal deposit in the United Kingdom, resembles modern liverworts in many respects, but its spores are virtually identical to those in 460-million-year-old rocks. This discovery suggests liverwort-like plants may have been the earliest plants to colonize land.

Structural and molecular evidence, however, supports the hypothesis that *hornworts* may be the most ancient group of plants alive today. A 1998 cladistic analysis using structural data was the first to strongly support this hypothesis, which was reinforced in 2000 by DNA evidence. The study of nuclear, chloroplast, and mitochondrial genes from numerous plant species, from bryophytes to flowering plants, suggests an early plant ancestor gave rise to two lineages, one from which the hornworts descended and the other from which all other plants descended.

Review

- Which of the following are parts of the gametophyte generation in mosses: antheridia, zygote, embryo, capsule, archegonia, sperm cells, egg cell, spore mother cells, spores, and protonema?
- How are mosses, liverworts, and hornworts similar? How is each group distinctive?
- What adaptations do bryophytes have that algae lack?

SEEDLESS VASCULAR PLANTS

Learning Objectives

6 Discuss the features that distinguish ferns and other seedless vascular plants from algae and bryophytes.

7 Name and briefly describe the four phyla of seedless vascular plants.

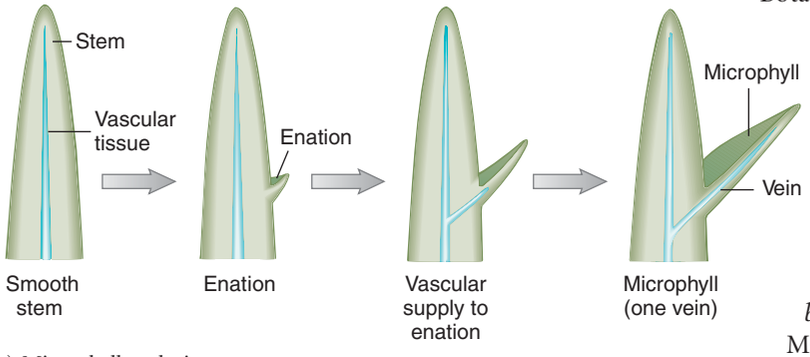
8 Describe the life cycle of ferns, and compare their sporophyte and gametophyte generations.

9 Compare the generalized life cycles of homosporous and heterosporous plants.

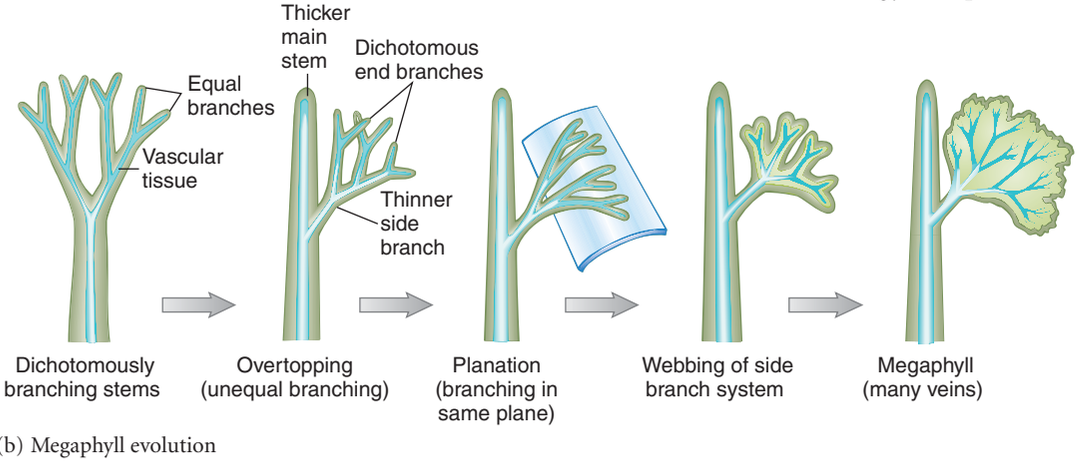
About 11,000 species of ferns exist today. Ferns are especially common in temperate woodlands and tropical rain forests, where they are most varied. Three groups of vascular plants—whisk ferns (about 12 species), horsetails (15 species), and club mosses (about 1000 species)—are considered fern allies because their life cycles are similar to those of ferns (Table 26-2). As shown in Figure 26-4, horsetails and ferns are a monophyletic group and the closest living relatives of seed plants.

The most important adaptation found in ferns and their allies, though absent in algae and bryophytes, is specialized vascular tissues—xylem and phloem—for support and conduction. This system of conduction lets vascular plants grow larger than the bryophytes because water, dissolved minerals, and dissolved sugar are transported to all parts of the plant. Although ferns in temperate environments are relatively small, tree ferns in the tropics may grow to heights of 18 m (60 ft). All ferns and fern allies have true stems with vascular tissues, and most also have true roots and leaves.

Botanists have extensively studied the evolution of the leaf as the main organ of photosynthesis. There are two basic types of leaves: microphylls and megaphylls (Fig. 26-10). The **microphyll,** which is usually small and has a single vascular strand, probably evolved from small, projecting extensions of stem tissue *(enations)*. Only one group of living plants, the club mosses, has microphylls. In contrast, **megaphylls** probably evolved from stem branches that gradually filled in with additional tissue *(webbing)* to form most leaves as we know them today. Megaphylls have more than one vascular strand, as we would expect if they evolved from branch systems. Ferns, horsetails, gymnosperms, and flowering plants have mega-



(a) Microphyll evolution



(b) Megaphyll evolution

FIGURE **26-10**

Evolution of microphylls and megaphylls.

Webbing (in **b**) is the evolutionary process in which the spaces between close branches become filled with chlorophyll-containing cells.

phylls. (Note that whisk ferns lack leaves and so are not included in this discussion.)

Recent evidence suggests megaphylls evolved over a 40-million-year period in the late Paleozoic era, in response to a gradual decline in the level of atmospheric CO_2. As CO_2 declined, plants developed a flattened blade with more stomata for gas exchange. (More stomata allowed cells inside the leaf to get enough CO_2.)

Ferns have a dominant sporophyte generation

Most of the 11,000 species of **ferns** (phylum Polypodiophyta) are terrestrial, although a few have adapted to aquatic habitats (Fig. 26-11a, b). Ferns range from the tropics to the Arctic Circle, with most species living in tropical rain forests, where they perch high in the branches of trees (Fig. 26-11c). In temperate regions, ferns commonly inhabit swamps, marshes, moist woodlands, and stream banks. Some species grow in fields, rocky crevices on cliffs or mountains, or even deserts.

The life cycle of ferns involves a clearly defined alternation of generations. The ferns grown as houseplants (such as the Boston fern, maidenhair fern, and staghorn fern) represent the larger, more conspicuous sporophyte generation. As shown in Figure 26-12, number ①, the fern sporophyte consists of a horizontal underground stem, or *rhizome,* that bears leaves, called *fronds,* and true roots. As each young frond first emerges from the ground, it is tightly coiled and resembles the top of a violin, hence the name *fiddlehead* (Fig. 26-13). As fiddleheads grow, they unroll and expand to form fronds. Fern fronds are usually compound (the blade is divided into several leaflets), with the leaflets forming beautifully complex leaves. Fronds, roots, and rhizomes all contain vascular tissues.

Spore production usually occurs in certain areas on the fronds, which develop sporangia. Many species bear the sporangia in clusters, called **sori** (sing., *sorus*). ② Within sporangia, sporogenous cells (spore mother cells) undergo meiosis to form haploid spores. In ③, the sporangia burst open and discharge spores that may germinate and grow by mitosis into mature gametophytes.

In ④, the mature fern gametophyte, which bears no resemblance to the sporophyte, is a tiny (less than half the size of one of your fingernails), green, often heart-shaped structure that grows flat against the ground. Called a **prothallus** (pl., *prothalli*), the fern gametophyte lacks vascular tissues and has tiny, hairlike absorptive rhizoids to anchor it (Fig. 26-14). In ⑤, the prothallus usually produces both archegonia and antheridia on its underside. Each archegonium contains a single egg, whereas numerous sperm cells are produced in each antheridium.

Ferns use water as a transport medium. The flagellate sperm cells swim, usually from a nearby prothallus, to the neck of an archegonium through a thin film of water on the ground

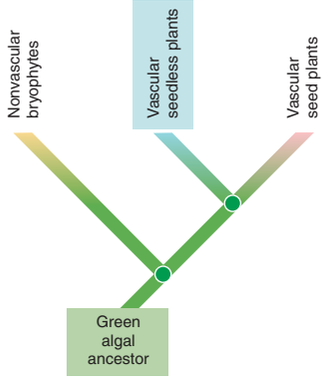


FIGURE **26-11** **Ferns.**

(a) The Christmas fern (*Polystichum acrostichoides*) is green at Christmas, making it a popular decoration. This fern, photographed in the Great Smoky Mountains in Tennessee, has fronds that grow to 0.6 m (2 ft) in length. **(b)** The tiny mosquito fern (*Azolla caroliniana*) is a free-floating aquatic fern that does not resemble "typical" ferns. Although each individual plant grows to only about 1.3 cm (0.5 in) in length, *Azolla* populations sometimes grow so densely across ponds that they reportedly smother mosquito larvae. Photographed in Massachusetts. **(c)** The staghorn fern (*Platycerium bifurcatum*) is native to Australian rain forests and is widely cultivated elsewhere. In nature the staghorn fern is an epiphyte, a plant that grows attached to another organism (in this case, a tree trunk) but derives no nourishment from it. The individual leaves grow to 0.9 m (3 ft) in length.

FOCUS ON ANCIENT PLANTS AND COAL FORMATION

Industrial society depends on energy from fossil fuels that formed from the remains of ancient organisms. One of the most important fossil fuels is coal, which people burn to produce electricity and to manufacture items of steel and iron. Although mined, coal is not an inorganic mineral like gold or aluminum, but an organic material formed from the remains of ancient vascular plants, particularly those of the Carboniferous period, approximately 300 mya. Five main groups of plants contributed to coal formation. Three were seedless vascular plants: the club mosses, horsetails, and ferns. The other two important groups were seed plants: seed ferns (now extinct) and early gymnosperms.

It is hard to imagine that relatives of the small, relatively inconspicuous club mosses, ferns, and horsetails of today were so significant in forming vast beds of coal. However, many members of these groups that existed during the Carboniferous period were giants compared with their modern counterparts and formed immense forests (see Fig. 20-11).

The climate during the Carboniferous period was warm, moist, and mild. Plants in most locations could grow year-round because of the favorable conditions. Forests of these plants often grew in low-lying, swampy areas that periodically flooded when the sea level rose. As the sea level receded, these plants would re-establish.

When these large plants died or were blown over in storms, they decomposed incompletely, because they were covered by swamp water. (The anaerobic conditions of the water prevented wood-rotting fungi from decomposing the plants, and anaerobic bacteria do not decompose wood rapidly.) Thus, over time the partially decomposed plant material accumulated and consolidated.

Layers of sediment formed over the plant material each time the water level rose and flooded the low-lying swamps. With time, heat and pressure built up in these accumulated layers and converted the plant material to coal and the sediment layers to sedimentary rock. Much later, geological upheavals raised the layers of coal and sedimentary rock. Coal is usually found in seams, underground layers that vary in thickness from 2.5 cm (1 in) to more than 30 m (100 ft).

The various grades of coal (lignite, sub-bituminous, bituminous, and anthracite) formed as a result of the different temperatures and pressures to which the layers were exposed. Coal exposed to high heat and pressure during its formation is drier, is more compact (and therefore harder), and has a higher heating value (that is, a higher energy content).

underneath the prothallus. In ⑥, after one of the sperm cells fertilizes the egg, a diploid zygote grows by mitosis into a multicellular embryo (an immature sporophyte). At this stage, the sporophyte embryo is attached to and dependent on the gametophyte, but as the embryo matures, the prothallus withers and dies, and the sporophyte becomes free-living.

The fern life cycle alternates between the dominant, diploid sporophyte with its rhizome, roots, and fronds, and the haploid gametophyte (prothallus). The sporophyte generation is dominant not only because it is larger than the gametophyte but also because it persists for an extended period (most fern sporophytes are perennials), whereas the gametophyte dies soon after reproducing.

Whisk ferns are the simplest vascular plants

Only about 12 species of **whisk ferns** (phylum Psilotophyta) exist today, and the fossil record contains several extinct species. All are relatively simple in structure and lack true roots and leaves but have vascularized stems. *Psilotum nudum,* a representative whisk fern, has both a horizontal underground rhizome and vertical aerial stems (Fig. 26-15a). Whenever the stem forks or branches, it always divides into two equal halves. Botanists consider this **dichotomous branching** a primitive characteristic. In contrast, when most plant stems branch, one stem is more vigorous and becomes the main trunk.

The upright stems of *Psilotum* are green and are the main organs of photosynthesis. Tiny, round sporangia, borne directly on the erect, aerial stems, contain sporogenous cells that undergo meiosis to form haploid spores. After dispersal, the spores germinate to form haploid prothalli. Because they grow underground, the prothalli of whisk ferns are difficult to study. They are nonphotosynthetic, owing to their subterranean location, and they apparently have a symbiotic relationship with mycorrhizal fungi that provides them with sugar and essential minerals (see Chapter 25).

Most species of whisk ferns are extinct, and the few surviving species live mainly in the tropics and subtropics. Although whisk ferns do not closely resemble ferns in appearance, they are considered fern allies because of similarities in their life cycles.

Botanists have carefully studied whisk ferns in recent years but disagree about how to interpret their structures. Some botanists consider whisk ferns to be surviving representatives of extinct vascular plants (see discussion of rhyniophytes later in the chapter). Other botanists hypothesize that whisk ferns are highly modified relatives of ferns. Recent molecular data, including comparisons of nucleotide sequences of ribosomal RNA, chloroplast DNA, and mitochondrial DNA in living species, support the hypothesis that the whisk ferns are more closely related to ferns than to other seedless vascular plants.

Horsetails have hollow, jointed stems

About 300 mya the **horsetails** (phylum Equisetophyta) were among the dominant plants and grew as large as modern trees (Fig 26-16). Because they contributed to Earth's vast coal deposits, these ancient horsetails are still significant today (see

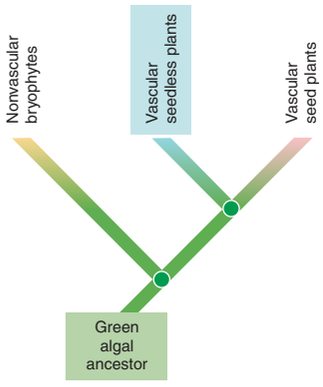

Image not available due to copyright restrictions

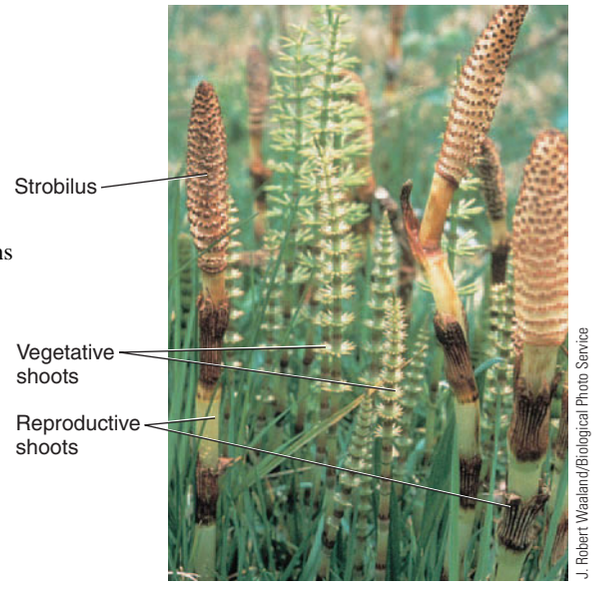
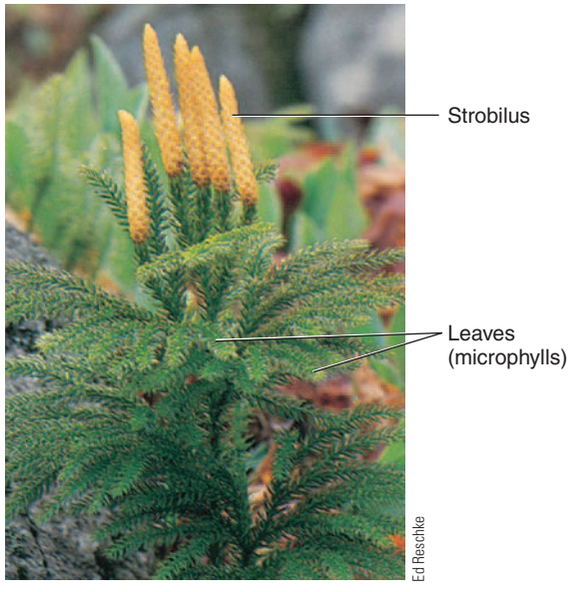


(b)



(c)

FIGURE 26-15 Fern allies.

(b) *Equisetum telematia,* a horsetail with a wide distribution in Eurasia, Africa, and North America, has unbranched reproductive shoots bearing conelike strobili and separate, highly branched vegetative (nonreproductive) shoots. In some horsetail species, both reproductive and vegetative shoots are unbranched. **(c)** The sporophyte of *Lycopodium,* a club moss, has small, scalelike leaves (microphylls) that are evergreen. Spores are produced in sporangia on reproductive leaves clustered in a conelike strobilus *(as shown)* or, in other species, scattered along the stem.

FIGURE 26-16

Reconstruction of *Calamites*.

This ancient horsetail was as tall as many modern trees—to 20 m (about 65 ft). *Calamites* had an underground rhizome where roots and aerial shoots originated. *(Redrawn from L. Emberger,* Les Plantes Fossiles, *Masson et Cie, Paris, 1968)*

Focus On: Ancient Plants and Coal Formation on page 510). The few surviving horsetails, about 15 species in the genus *Equisetum,* grow mostly in wet, marshy habitats and are less than 1.3 m (4 ft) tall but extremely distinctive (see Fig. 26-15b). They are widely distributed on every continent except Australia.

Horsetails have true roots, stems (both rhizomes and erect aerial stems), and small leaves. The hollow, jointed stems are impregnated with silica, which gives them a gritty texture. Small leaves, interpreted as reduced megaphylls, are fused in whorls at each node (the area on the stem where leaves attach). The green stem is the main organ of photosynthesis. Horsetails are so named because certain vegetative (nonreproductive) stems have whorls of branches that give the appearance of a bushy horse's tail. In the past horsetails were called "scouring rushes" and were used to scrub pots and pans along stream banks.

(a)

FIGURE **26-17** ***Lepidodendron.***

(a) Reconstruction of *Lepidodendron*. This ancient club moss was the size of a large tree—to 40 m (about 130 ft). Numerous fossils of *Lepidodendron* were preserved in coal deposits, particularly in Great Britain and the central United States.

Image not available due to copyright restrictions

Each reproductive branch of a horsetail bears a terminal conelike **strobilus** (pl., *strobili*). The strobilus consists of several stalked, umbrella-like structures, each of which bears 5 to 10 sporangia in a circle around a common axis.

The horsetail life cycle is similar in many respects to the fern life cycle. In horsetails, as in ferns, the sporophyte is the conspicuous plant, whereas the gametophyte is a minute, lobed thallus ranging in width from the size of a pinhead to about 1 cm (less than 0.5 in) across. The sporophyte and gametophyte are both photosynthetic and nutritionally independent at maturity. Like ferns, horsetails require water as a medium for flagellate sperm cells to swim to the egg.

Club mosses are small plants with rhizomes and short, erect branches

Like horsetails, **club mosses** (phylum Lycophyta) were important plants millions of years ago, when species that are now extinct often reached great size (Fig. 26-17). These large, treelike plants, like the ancient horsetails, were major contributors to our present-day coal deposits. The 1000 or so species of club mosses living today, such as *Lycopodium* (see Fig. 26-15c), are small (less than 25 cm [10 in] tall), attractive plants common in temperate woodlands. They possess true roots; both rhizomes and erect aerial stems; and small, scale-like leaves (microphylls). Sporangia are borne on reproductive leaves that are either clustered in conelike strobili at the tips of stems or scattered in reproductive areas along the stem. Club mosses are evergreen and often fashioned into Christmas wreaths and other decorations. In some areas overharvesting endangers them.

That common names are sometimes misleading in biology is vividly evident in this group of plants. The most common names for the phylum Lycophyta are "club mosses" and "ground pines," yet these plants are neither mosses nor pines and are most closely allied to the ferns.

Some ferns and club mosses are heterosporous

In the life cycles examined thus far, plants produce only one type of spore as a result of meiosis. This condition, known as **homospory,** is characteristic of bryophytes, horsetails, whisk ferns, and most ferns and club mosses. However, certain ferns and club mosses exhibit **heterospory,** in which they produce two different types of spores: microspores and megaspores. Figure 26-18 illustrates the generalized life cycle of a heterosporous plant.

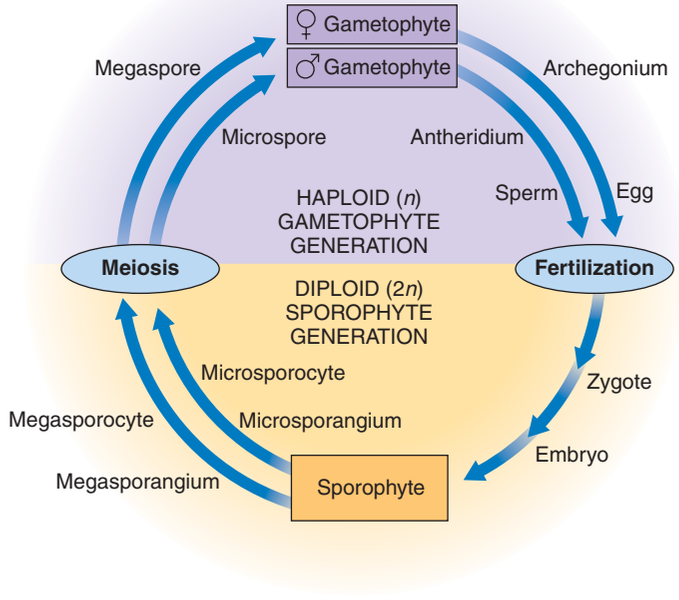


FIGURE **26-18** **The basic life cycle of heterosporous plants.**

Two types of spores, microspores and megaspores, are produced during the life cycle of heterosporous plants.

Spike moss (*Selaginella*), a small, delicate club moss, is an example of a heterosporous plant (Fig. 26-19). Beginning at ①, the sporophyte plant produces sporangia within a conelike strobilus. Each strobilus usually bears two kinds of sporangia: microsporangia and megasporangia. In ②, *microsporangia* are sporangia that produce *microsporocytes* (also called *microspore mother cells*), which undergo meiosis to form microscopic, haploid **microspores.** In ③, each microspore develops into a male gametophyte that produces sperm cells within antheridia. In ④, *megasporangia* in the *Selaginella* strobilus produce *megasporocytes* (also called *megaspore mother cells*). When megasporocytes undergo meiosis, they form haploid **megaspores,** each of which develops into a female gametophyte that produces eggs in archegonia, ⑤. In *Selaginella,* the development of male gametophytes from microspores and of female gametophytes from megaspores occurs within their respective spore walls, using stored food provided by the sporophyte. As a result, the male and female gametophytes are not truly free-living, unlike the gametophytes of other seedless vascular plants. In ⑥, fertilization is followed by the development of a new sporophyte.

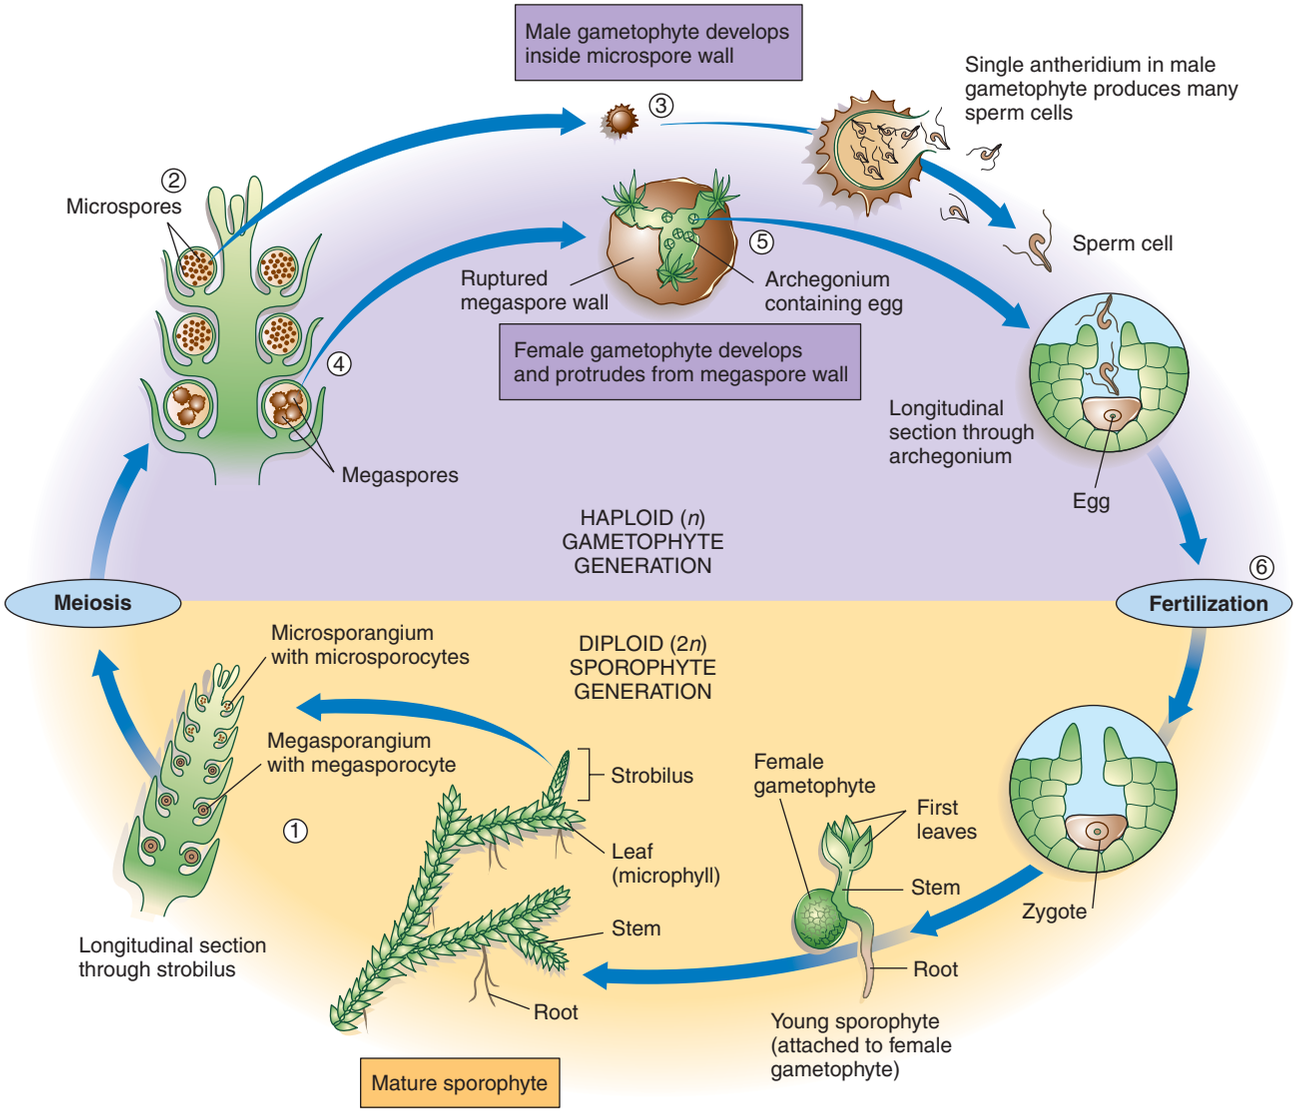
Heterospory was a significant development in plant evolution because it was the forerunner of the evolution of seeds. Heterospory characterizes the two most successful groups of plants existing today, the gymnosperms and the flowering plants, both of which produce seeds (see Chapter 27).

FIGURE **26-19** **The life cycle of spike moss (*Selaginella*).**

Spike moss is heterosporous, producing two types of spores in one strobilus. The megaspores develop into female gametophytes, and the microspores become male gametophytes. See text for a detailed description.

Seedless vascular plants are used for experimental studies

Botanists use many seedless vascular plants as experimental models to study certain aspects of plant biology, such as physiology, growth, and development. Ferns and other seedless vascular plants are useful in studying how apical meristems give rise to plant tissues. As discussed in Chapter 31, an **apical meristem** is the area at the tip (apex) of a root or shoot where growth—cell division, elongation, and differentiation—occurs.



Ferns and other seedless vascular plants have a single large *apical cell* located at the center tip of the apical meristem. This apical cell is the source, by mitosis, of all the cells that eventually make up the root or shoot. The apical cell divides in an orderly fashion, and the smaller daughter cells produced by the apical cell in turn divide, giving rise to different parts of the root or shoot. It is possible to trace mature cells in the root or shoot back to their origin from the single apical cell.

Ferns are interesting research plants for studies in genetics because they are **polyploids** and have multiple sets of chromosomes. (Many ferns have hundreds of chromosomes.) However, gene expression in ferns is exactly what one would expect of a *diploid* plant. Apparently, genes in the extra sets of chromosomes are gradually silenced and therefore not expressed.

Seedless vascular plants arose more than 420 mya

Currently, the oldest known megafossils of early vascular plants are from mid-Silurian (420 mya) deposits in Europe. (Plant *megafossils* are fossilized roots, stems, leaves, and reproductive structures.) Megafossils of several kinds of small, seedless vascular plants were also discovered in Silurian deposits in Bolivia, Australia, and northwestern China. Microscopic spores of early vascular plants appear in the fossil record earlier than megafossils, suggesting that even older megafossils of simple vascular plants may be discovered.

Botanists assign the oldest known vascular plants to phylum Rhyniophyta which, according to the fossil record, arose some 420 mya and became extinct about 380 mya. The rhyniophytes are so named because many fossils of these extinct plants were found in fossil beds near the village of Rhynie, Scotland. *Rhynia gwynne-vaughanii* is an example of an early vascular plant that superficially resembled whisk ferns in that it consisted of leafless upright stems that branched dichotomously from an underground rhizome (Fig. 26-20). *Rhynia* lacked roots, although it had absorptive rhizoids. Sporangia formed at the ends of short branches. The internal structure of its rhizome contained a central core of xylem cells for conducting water and dissolved nutrient minerals.

PROCESS OF SCIENCE

For more than 60 years, botanists considered *Rhynia major,* a plant that grew about 50 cm (20 in) tall and probably lived in marshes, a classic example of a rhyniophyte. Fossils indicate this plant had rhizoids, dichotomously branching rhizomes and upright stems that terminated in sporangia. However, recent microscopic studies of fossil rhizomes indicate that the central core of tissue lacked the xylem cells characteristic of vascular plants. For that reason, *R. major* was reclassified into a new genus, *Aglaophyton,* and is no longer considered a rhyniophyte (Fig. 26-21). Science is an ongoing enterprise, and over time, existing knowledge is re-evaluated in light of newly discovered evidence. *Aglaophyton major* is an excellent example of

FIGURE **26-20** **Reconstruction of *Rhynia gwynne-vaughanii.***

This leafless plant, one of Earth's earliest vascular plants, is now extinct. It grew about 18 cm (7 in) tall. *(Redrawn from D. Edwards, "Evidence for the Sporophytic Status of the Lower Devonian Plant* Rhynia gwynne-vaughanii*," Rev. Palaeobot. Palynol., Vol. 29, 1980)*

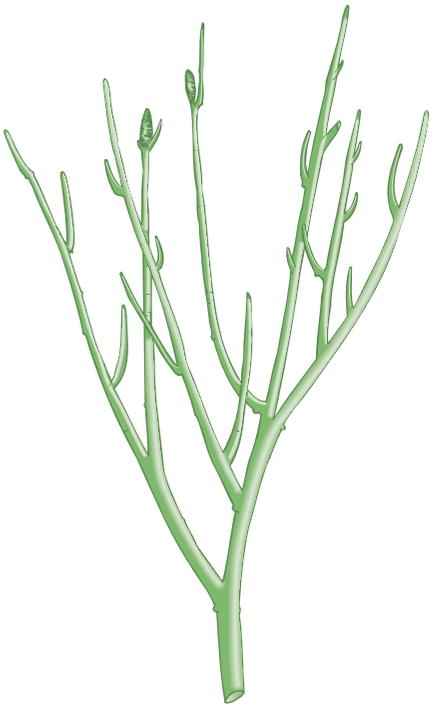


FIGURE **26-21** **Reconstruction of *Aglaophyton major.***

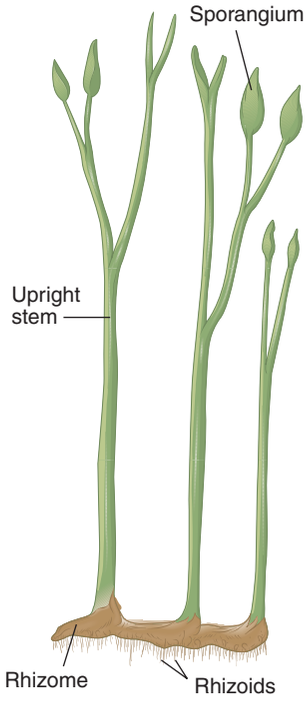
Recent evidence indicates that this plant, although superficially similar to other early vascular plants, lacked conducting tissues that are characteristic of vascular plants. For that reason, it was reclassified into a new genus and is no longer considered a rhyniophyte. *(Redrawn from J.D. Mauseth,* Botany: An Introduction to Plant Biology, *2nd ed., Saunders College Publishing, Philadelphia, 1995)*



the self-correcting nature of science, which is in a perpetually dynamic state and changes in response to newly available techniques and data.

Review

- What adaptations do ferns have that both algae and bryophytes lack?
- How does one distinguish between megaphylls and microphylls?
- Which of the following are parts of the sporophyte generation in ferns: frond, sperm cells, egg cell, roots, sorus, sporangium, spores, prothallus, rhizome, antheridium, archegonium, and zygote?
- What three groups of plants are known as fern allies?
- How does heterospory modify the life cycle?

BiologyNow™ Assess your understanding of **seedless vascular plants** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Discuss some environmental challenges of living on land, and describe how several adaptations meet these challenges.

- The colonization of land by plants required the evolution of many anatomical, physiological, and reproductive adaptations. Plants have a waxy **cuticle** to protect against water loss and **stomata** for gas exchange needed for photosynthesis.
- Plant life cycles have an **alternation of generations** in which they spend part of their life cycle in a haploid **gametophyte generation** and part in a diploid **sporophyte generation.** The gametophyte plant produces gametes by mitosis. During fertilization these gametes fuse to form a **zygote,** the first stage of the sporophyte generation. The zygote develops into a multicellular **embryo** that the gametophyte protects and nourishes. The mature sporophyte plant develops from the embryo and produces sporogenous cells (spore mother cells). These undergo meiosis to form **spores,** the first stage in the gametophyte generation.
- Most plants produce multicellular **gametangia** with a protective jacket of sterile cells surrounding the gametes. **Antheridia** are gametangia that produce sperm cells, and **archegonia** are gametangia that produce eggs.
- Mosses and ferns, although adapted to life on land, have motile sperm cells and require water as a transport medium for fertilization. Ferns and other vascular plants have **xylem** to conduct water and dissolved nutrient minerals, and have **phloem** to conduct dissolved sugar.

2 Name the protist group from which plants are hypothesized to have descended, and describe supporting evidence.

- Recent ultrastructural and molecular data indicate plants probably arose from a group of green algae called **charophytes.** Plants and green algae have similar biochemical characteristics: the same photosynthetic pigments, cell wall components, and carbohydrate storage material. Plants and green algae share similarities in certain fundamental processes such as cell division.

3 Summarize the features that distinguish bryophytes from green algae and from other plants.

- **Mosses** and other **bryophytes** have several adaptations that green algae lack, including a cuticle, stomata, and multicellular gametangia. Unlike other land plants, bryophytes are nonvascular and lack xylem and phloem.
- Bryophytes are the only plants with a dominant gametophyte generation. Their sporophytes remain permanently attached and nutritionally dependent on the gametophyte.

4 Name and briefly describe the three phyla of bryophytes.

- Mosses (phylum Bryophyta) have gametophytes that are green plants that grow from a filamentous **protonema.**
- Many **liverworts** (phylum Hepaticophyta) have gametophytes that are flattened, lobelike **thalli;** others are leafy.
- **Hornworts** (phylum Anthocerotophyta) have thalloid gametophytes.

5 Describe the life cycle of mosses, and compare their gametophyte and sporophyte generations.

- The green moss gametophyte bears archegonia and/or antheridia at the top of the plant. During fertilization, a sperm cell fuses with an egg cell in the archegonium. The zygote grows into an embryo that develops into a moss sporophyte, which is attached to the gametophyte. Meiosis occurs within the capsule of the sporophyte to produce spores. When a spore germinates, it grows into a protonema that forms buds.

6 Discuss the features that distinguish ferns and other seedless vascular plants from algae and bryophytes.

- **Ferns** and fern allies have several adaptations that algae and bryophytes lack, including vascular tissues and a dominant sporophyte generation. As in bryophytes, reproduction in ferns depends on water as a transport medium for their motile sperm cells.

7 Name and briefly describe the four phyla of seedless vascular plants.

- Ferns (phylum Polypodiophyta) are the largest and most diverse group of seedless vascular plants.
- Sporophytes of **whisk ferns** (phylum Psilotophyta) consist of **dichotomously branching** rhizomes and erect stems; they lack true roots and leaves.
- **Horsetail** (phylum Equisetophyta) sporophytes have roots, rhizomes, aerial stems that are hollow and jointed, and leaves that are reduced **megaphylls.**
- Sporophytes of **club mosses** (phylum Lycophyta) consist of roots, rhizomes, erect branches, and leaves that are **microphylls.**

8 Describe the life cycle of ferns, and compare their sporophyte and gametophyte generations.

- Fern sporophytes have roots, rhizomes, and leaves that are megaphylls. Their leaves, or fronds, bear sporangia in clusters called **sori.** Meiosis in sporangia produces haploid spores. The fern gametophyte, called a **prothallus,** develops from a haploid spore and bears both archegonia and antheridia.

9 Compare the generalized life cycles of homosporous and heterosporous plants.

- **Homospory,** the production of one kind of spore, is characteristic of bryophytes, whisk ferns, horsetails, most club mosses, and most ferns. In homospory, spores give rise to gametophyte plants that produce both egg cells and sperm cells.
- **Heterospory,** the production of two kinds of spores (microspores and megaspores), occurs in certain club mosses, certain ferns, and all seed plants. The evolution of heterospory was an essential step in the evolution of seeds. **Microspores** give rise to male gametophytes that produce sperm cells. **Megaspores** give rise to female gametophytes that produce eggs.

POST-TEST

1. The bryophytes (a) include mosses, liverworts, and hornworts (b) include whisk ferns, horsetails, and club mosses (c) are small plants that lack a vascular system (d) both a and c (e) both b and c
2. The waxy layer that covers aerial parts of plants is the (a) cuticle (b) archegonium (c) protonema (d) stoma (e) thallus
3. A strengthening compound found in cell walls of vascular plants is (a) xanthophyll (b) lignin (c) cutin (d) cellulose (e) carotenoid
4. Stomata (a) help prevent desiccation of plant tissues (b) transport water and minerals through plant tissues (c) allow gas exchange for photosynthesis (d) strengthen cell walls (e) produce male gametes
5. The female gametangium, or _____, produces an egg; the male gametangium, or _____, produces sperm cells. (a) antheridium; archegonium (b) archegonium; megaphyll (c) megasporangium; antheridium (d) archegonium; antheridium (e) megasporangium; megaphyll
6. Liverworts and hornworts share life cycle similarities with (a) ferns (b) mosses (c) horsetails (d) club mosses (e) whisk ferns
7. The green, gametangia-bearing moss plant (a) is the gametophyte generation (b) is the sporophyte generation (c) is called a protonema (d) contains cells with single large chloroplasts (e) both b and c
8. Seedless vascular plants have _____ to conduct water and dissolved minerals and _____ to conduct dissolved sugar. (a) cuticle; xylem (b) phloem; stoma (c) phloem; xylem (d) stoma; cuticle (e) xylem; phloem
9. Whisk ferns, horsetails, and club mosses share life cycle similarities with (a) ferns (b) mosses (c) hornworts (d) liverworts (e) b, c, and d
10. A(an) _____ is a leaf that arose from a branch system. (a) antheridium (b) microphyll (c) megaphyll (d) sorus (e) microspore
11. These plants have vascularized stems but lack true roots and leaves. (a) mosses (b) club mosses (c) horsetails (d) whisk ferns (e) hornworts
12. These plants have hollow, jointed stems that are impregnated with silica. (a) mosses (b) club mosses (c) horsetails (d) whisk ferns (e) hornworts
13. Spike moss (*Selaginella*) is a (a) homosporous fern (b) homosporous horsetail (c) heterosporous fern (d) heterosporous horsetail (e) heterosporous club moss
14. Which of the following statements about ferns is *not* true? (a) Ferns have motile sperm cells that swim through water to the egg-containing archegonium. (b) Ferns are vascular plants. (c) Ferns are the most economically important group of bryophytes. (d) The fern sporophyte consists of a rhizome, roots, and fronds. (e) The diversity of ferns is greatest in the tropics.
15. Plants probably descended from a group of green algae called (a) rhyniophytes (b) *Calamites* (c) epiphytes (d) charophytes (e) club mosses
16. Which of the following is *not* a characteristic of plants? (a) cuticle (b) unicellular gametangia (c) stomata (d) multicellular embryo (e) alternation of generations
17. In plant life cycles (a) the first products of meiosis are gametes (b) spores are part of the diploid sporophyte generation (c) the embryo gives rise to a zygote (d) the first stage in the diploid sporophyte generation is the zygote (e) the first stage in the haploid gametophyte generation is the prothallus
18. Ferns are (a) seedless, vascular plants (b) vascular plants with seeds (c) seedless, nonvascular plants (d) nonvascular plants with seeds (e) seedless plants with a dominant gametophyte generation
19. Microphylls (a) probably evolved from stem branches that gradually filled in with additional tissues (b) are usually small and have a single vascular strand (c) are characteristics of club mosses (d) both a and c (e) both b and c

CRITICAL THINKING

1. Which group probably colonized the land first, plants or animals? Explain.
2. How may the following trends in plant evolution be adaptive to living on land?
   a. Dependence on water for fertilization ⟶ no need for water as a transport medium
   b. Dominant gametophyte generation ⟶ dominant sporophyte generation
   c. Homospory ⟶ heterospory

The Plant Kingdom: Seed Plants

Holt Studies Intl./Silvestra Silva/Photo Researchers, Inc.

Guava fruit. Guava (*Psidium guajava*) is a flowering plant, and its seeds are enclosed within a fruit.

CHAPTER OUTLINE

- Seed Plants
- Gymnosperms
- Flowering Plants
- The Evolution of Seed Plants

Chapter 26 focused on plants that reproduce by means of *spores,* haploid reproductive units that give rise to gametophytes. Although the most successful and widespread plants also produce spores, their primary means of reproduction and dispersal is by **seeds,** each of which consists of an embryonic sporophyte, nutritive tissue, and a protective coat. Seeds develop from the fertilized egg cell, the female gametophyte, and its associated tissues. The two groups of seed plants, gymnosperms and angiosperms (flowering plants), exhibit the greatest evolutionary complexity in the plant kingdom and are the dominant plants in most terrestrial environments.

Seeds, such as the guava seeds shown in the photograph, are reproductively superior to spores for three main reasons. First, development is further advanced in seeds than in spores. A seed contains a multicellular young plant with embryonic root, stem, and one or more leaves already formed, whereas a spore is a single cell. Second, a seed contains an abundant food supply. After germination, food stored in the seed nourishes the plant embryo until it becomes self-sufficient. Because a spore is a single cell, few food reserves exist for the plant that develops from a spore. Third, a seed is protected by a multicellular **seed coat** that is very thick and hard in some plants, as for example, in lima beans. Like spores, seeds live for extended periods at reduced rates of metabolism, germinating when conditions become favorable.

Seeds and seed plants are intimately connected with the development of human civilization. From prehistoric times, early humans collected and used seeds for food. The food stored in seeds is a concentrated source of proteins, oils, carbohydrates, and vitamins, which are nourishing for humans as well as for germinating plants. Also, seeds are easy to store (if kept dry); this has allowed humans to collect them during times of plenty and save them for times of need. Few other foods are stored as conveniently or for as long. Although flowering plants produce most seeds that humans consume, the seeds of certain gymnosperms—the piñon pine, for example—are edible. They are usually sold as "pine nuts." ■

SEED PLANTS

Learning Objective

1 Compare the features of seeds with those of spores, and discuss the advantages of plants that reproduce primarily by seeds rather than by spores.

Following fertilization in seed plants, an **ovule,** which is a *megasporangium* and its enclosed structures, develops into a seed. Seed plants also have **integuments,** layers of sporophyte tissue that surround and enclose the megasporangium. After fertilization takes place, the seed coat develops from the integuments.

Botanists divide seed plants into two groups based on whether or not an ovary wall surrounds their ovules (an *ovary* is a structure that contains one or more ovules). The two groups of seed plants are the **gymnosperms** and the **angiosperms** (Table 27-1). The word *gymnosperm* is adapted from the Greek for "naked seed." Gymnosperms produce seeds that are totally exposed or borne on the scales of cones. In other words, an ovary wall does not surround the ovules of gymnosperms. Pine, spruce, fir, hemlock, and *Ginkgo* are examples of gymnosperms.

The Greek expression from which the term *angiosperm* is derived translates as "seed enclosed in a vessel or case." Angiosperms are flowering plants that produce their seeds within a fruit (a mature ovary). Thus the ovules of angiosperms are protected. Flowering plants, which are extremely diverse, include corn, oaks, water lilies, cacti, apples, grasses, palms, and buttercups.

Both gymnosperms and flowering plants have vascular tissues: **xylem** for conducting water and dissolved nutrient minerals, and **phloem** for conducting dissolved sugar. Both have life cycles with an **alternation of generations,** that is, they spend part of their lives in the diploid sporophyte stage and part in the haploid gametophyte stage. The sporophyte generation is the dominant stage in each group, and the gametophyte generation is significantly reduced in size and entirely dependent on the sporophyte generation. Unlike the plants we have considered so far (bryophytes, ferns, and most of their allies; see Chapter 26), gymnosperms and flowering plants do not have free-living gametophytes. Instead, the female gametophyte is attached to and nutritionally dependent on the sporophyte generation. All gymnosperms and flowering plants are *heterosporous* and produce two types of spores: microspores and megaspores.

Review

- Why are seeds such a significant evolutionary innovation?
- What is an ovule?

GYMNOSPERMS

Learning Objectives

2 Trace the steps in the life cycle of a pine, and compare its sporophyte and gametophyte generations.

3 Summarize the features that distinguish gymnosperms from bryophytes and ferns.

4 Name and briefly describe the four phyla of gymnosperms.

The gymnosperms include some of the most interesting members of the plant kingdom, including a number of record holders. For example, a giant sequoia (*Sequoiadendron giganteum*) known as the General Sherman Tree, in Sequoia National Park in California, is one of the world's most massive organisms. It is 82 m (267 ft) tall and has a girth of 23.7 m (77 ft) measured 1.5 m (5 ft) above ground level. Another gymnosperm, a coast redwood (*Sequoia sempervirens*) known as the Mendocino tree, is among the world's tallest trees, measuring 112 m (364 ft) in the year 2000. Botanists using tree ring analysis determined that one of the oldest living trees, a bristlecone pine (*Pinus aristata*) in the White Mountains of California, is 4900 years old!

Gymnosperms are usually classified into four phyla, which represent four different evolutionary lines (Fig. 27-1). Numbering 550 species, the largest phylum of gymnosperms is the phylum Pinophyta, commonly called *conifers.* Two phyla of gymnosperms, the ginkgo (phylum Ginkgophyta) and the cycads (phylum Cycadophyta), represent evolutionary remnants of groups that were more significant in the past. The fourth phylum of gymnosperms, the gnetophytes (phylum Gnetophyta), is a collection of some unusual plants that share certain traits not found in other gymnosperms.

Conifers are woody plants that produce seeds in cones

The **conifers** (phylum Pinophyta), which include pines, spruces, hemlocks, and firs, are the most familiar group of gymnosperms (Fig. 27-2a). These woody trees or shrubs produce annual additions of secondary tissues (wood and bark; see Chapter 33); there are no herbaceous (nonwoody) conifers. The wood *(sec-*

TABLE **27-1** A Comparison of Gymnosperms and Angiosperms

Characteristic	Gymnosperms	Angiosperms
Growth habit	Woody trees and shrubs	Woody or herbaceous
Conducting cells in xylem	Tracheids	Vessel elements and tracheids
Reproductive structures	Cones (usually)	Flowers
Pollen grain transfer	Wind (usually)	Animals or wind
Fertilization	Egg and sperm ⟶ zygote; double fertilization fertilization in gnetophytes	Double fertilization: egg and sperm ⟶ zygote; Two polar nuclei and sperm ⟶ endosperm
Seeds	Exposed or borne on scales of cones	Enclosed within fruit
Number of species	About 760	More than 235,000
Geographical distribution	Worldwide	Worldwide

KEY CONCEPT: The arrangement of the phyla shown here may change as future analyses help clarify relationships.

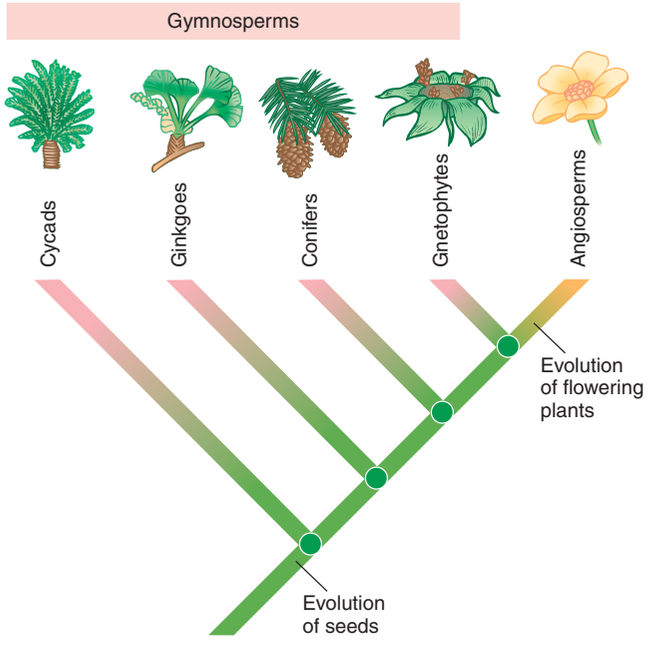

FIGURE **27-1** **Gymnosperm and angiosperm evolution.**

This cladogram shows one hypothesis of phylogenetic relationships among living seed plants. It is based on structural evidence and molecular comparisons. The exact relationships of certain seed plant phyla remain unclear. Some DNA analyses suggest gnetophytes are more closely related to other gymnosperms than to the angiosperms, unlike the depiction shown here.

ondary xylem) consists of **tracheids,** which are long, tapering cells with pits through which water and dissolved nutrient minerals move from one cell to another.

Many conifers produce **resin,** a viscous, clear or translucent substance consisting of several organic compounds that may protect the plant from attack by fungi or insects. The resin collects in resin ducts, tubelike cavities that extend throughout the roots, stems, and leaves. Resin is produced and secreted by cells lining the resin ducts.

Most conifers have leaves called **needles** that are commonly long and narrow, tough, and leathery (Fig. 27-2b). Pines bear clusters of two to five needles, depending on the species. In a few conifers such as American arborvitae, the leaves are scalelike and cover the stem (Fig. 27-2c). Most conifers are evergreen and bear their leaves throughout the year. Only a few, such as the dawn redwood, larch, and bald cypress, are deciduous and shed their needles at the end of each growing season.

Most conifers are **monoecious:** They have separate male and female reproductive parts in different locations on the same plant. These reproductive parts are generally borne in *strobili* (commonly called *cones*), hence the name *conifer,* which means "cone-bearing."

Conifers occupy extensive areas, ranging from the Arctic to the tropics, and are the dominant vegetation in the forested regions of Alaska, Canada, northern Europe, and Siberia. In addition, they are important in the Southern Hemisphere, particularly in wet, mountainous areas of temperate and tropical regions in South America, Australia, New Zealand, and Malaysia. Southwestern China, with more than 60 species of conifers, has the greatest regional diversity of conifer species on Earth. California, New Caledonia (an island east of Australia), southeastern China, and Japan also have considerable diversity of conifer species.

FIGURE **27-3** **Life cycle of pine.**

One major advantage of gymnosperms over the seedless vascular plants is the production of wind-borne pollen grains. See text for a detailed description.

Ecologically, conifers contribute food and shelter to animals and other organisms, and their roots hold the soil in place and help prevent soil erosion. Humans use conifers for their wood (for building materials as well as paper products), medicine (such as the anticancer drug taxol from the Pacific yew), turpentine, and resins. Because of their attractive appearance, conifers such as firs, spruces, pines, and cedars are grown for landscape design and decorative holiday trees and wreaths.

Pines represent a typical conifer life cycle

The genus *Pinus,* by far the largest genus in the conifers, consists of about 100 species. As shown in ① of Fig. 27-3, a pine tree is a mature sporophyte. Pine is heterosporous and therefore produces microspores and megaspores in separate cones.[1] Male cones, usually 1 cm or less in length, are smaller than female cones and are generally produced on the lower branches each spring (Fig. 27-4). The more familiar, woody female cones, which are on the tree year-round, are usually found on the upper branches of the tree and bear seeds after reproduction. Female cones vary considerably in size. The sugar pine (*Pinus lambertiana*) of California produces the world's longest female cones, which reach lengths of 60 cm (2 ft).

Each male cone, also called a *pollen cone,* consists of **sporophylls,** leaflike structures that bear sporangia on the underside. At the base of each sporophyll are two **microsporangia,** which contain numerous **microsporocytes,** also called *microspore mother cells.* In ② of Fig. 27-3, each microsporocyte undergoes meiosis to form four haploid microspores. **Microspores** then develop into extremely reduced male gametophytes. Each

[1] It may be helpful to review alternation of generations in Chapter 26, including Figure 26-18, which depicts a heterosporous life cycle, before studying the pine life cycle.

Walt Anderson/Visuals Unlimited

FIGURE **27-4** **Male and female cones in lodgepole pine (*Pinus contorta*).**

(Top) Mature female cones have opened to shed their seeds. *(Bottom)* Clusters of male cones produce copious amounts of pollen grains in the spring.

immature male gametophyte, also called a **pollen grain,** consists of four cells, two of which—a *generative cell* and a *tube cell*—are involved in reproduction. The other two cells soon degenerate. Two large air sacs on each pollen grain provide buoyancy for wind dissemination. In ③, male cones shed pollen grains in great numbers, and wind currents carry some to the immature female cones.

Many botanists think the female cones (also called *seed cones*) are modified branch systems. As shown in ④, each cone scale bears two ovules, or **megasporangia,** on its upper surface. Within each megasporangium, meiosis of a **megasporocyte,** or *megaspore mother cell,* produces four haploid **megaspores.** One of these divides mitotically, developing into the female gametophyte, which produces an egg within each of several archegonia. The other three megaspores are nonfunctional and soon degenerate.

When the ovule is ready to receive pollen, it produces a sticky droplet at the opening where the pollen grains land. **Pollination,** the transfer of pollen to the female cones, occurs in the spring during a period of a week or 10 days, after which the pollen cones wither and drop off the tree. One of the many pollen grains that adhere to the sticky female cone grows a **pollen tube,** an outgrowth that digests its way through the megasporangium to the egg within the archegonium. The germinated pollen grain with its pollen tube is the mature male gametophyte. The tube cell, which is involved in the growth of the pollen tube, and the generative cell enter the pollen tube.

The generative cell divides and forms a *stalk cell* and a *body cell;* the body cell later divides and forms two nonmotile sperm cells. When the pollen tube reaches the female gametophyte, it discharges the two sperm cells near the egg. In ⑤, one of these sperm cells fuses with the egg, in the process of **fertilization,** to form a zygote, or fertilized egg, which subsequently grows into a young pine embryo in the seed. The other sperm cell degenerates.

In ⑥ the developing embryo, which consists of an embryonic root and an embryonic shoot with several cotyledons (embryonic leaves), is embedded in haploid female gametophyte tissue that becomes the nutritive tissue in the mature pine seed. A tough, protective seed coat derived from the integuments surrounds the embryo and nutritive tissue. The seed coat forms a thin, papery wing at one end that enables dispersal by air currents.

A long time elapses between the appearance of female cones on a tree and the maturation of seeds in those cones. When pollination occurs during the first spring, the female cone is still immature, and meiosis of the megasporocytes (megaspore mother cells) has not yet occurred. After the megaspore has formed, it takes more than a year for eggs to form within archegonia. Meanwhile, the pollen tube grows slowly through the megasporangium to the archegonia. Fertilization occurs about 15 months after pollination, and the embryo begins to develop. Seed maturation takes several additional months, although some seeds remain within the female cones for several years before being shed.

In the pine life cycle, the sporophyte generation is dominant, and the gametophyte generation is restricted in size to microscopic structures in the cones. Although the female gametophyte produces archegonia, the male gametophyte is so reduced that it does not produce antheridia. The gametophyte generation in pines, as in all seed plants, depends totally on the sporophyte generation for nourishment.

A major adaptation in the pine life cycle is elimination of the need for external water as a sperm transport medium. Instead, air currents carry pine pollen grains to female cones and nonmotile sperm cells accomplish fertilization by moving through a pollen tube to the egg. Pine and other conifers are plants whose reproduction is totally adapted for life on land.

Cycads have seed cones and compound leaves

Cycads (phylum Cycadophyta) were very important during the Triassic period, which began approximately 248 million years ago (mya) and is sometimes referred to as the "Age of Cycads." Most species are now extinct, and the few surviving cycads, about 140 species, are tropical and subtropical plants with stout, trunklike stems and compound leaves that resemble those of palms or tree ferns (Fig. 27-5). Many cycads are endangered, primarily because they are popular as ornamentals and are gathered from the wild and sold to collectors.

Cycad reproduction is similar to that in pines except that cycads are **dioecious** and therefore have seed cones on female plants and pollen cones on male plants. Their seed structure is most like that of the earliest seeds found in the fossil record. Cycads have also retained motile sperm cells, each of which has many hairlike flagella. Motile sperm cells are a vestige retained from the ancestors of cycads, in which sperm cells swam from antheridia to archegonia. In cycads, air or insects carry pollen grains to the female plants and their cones; there the pollen

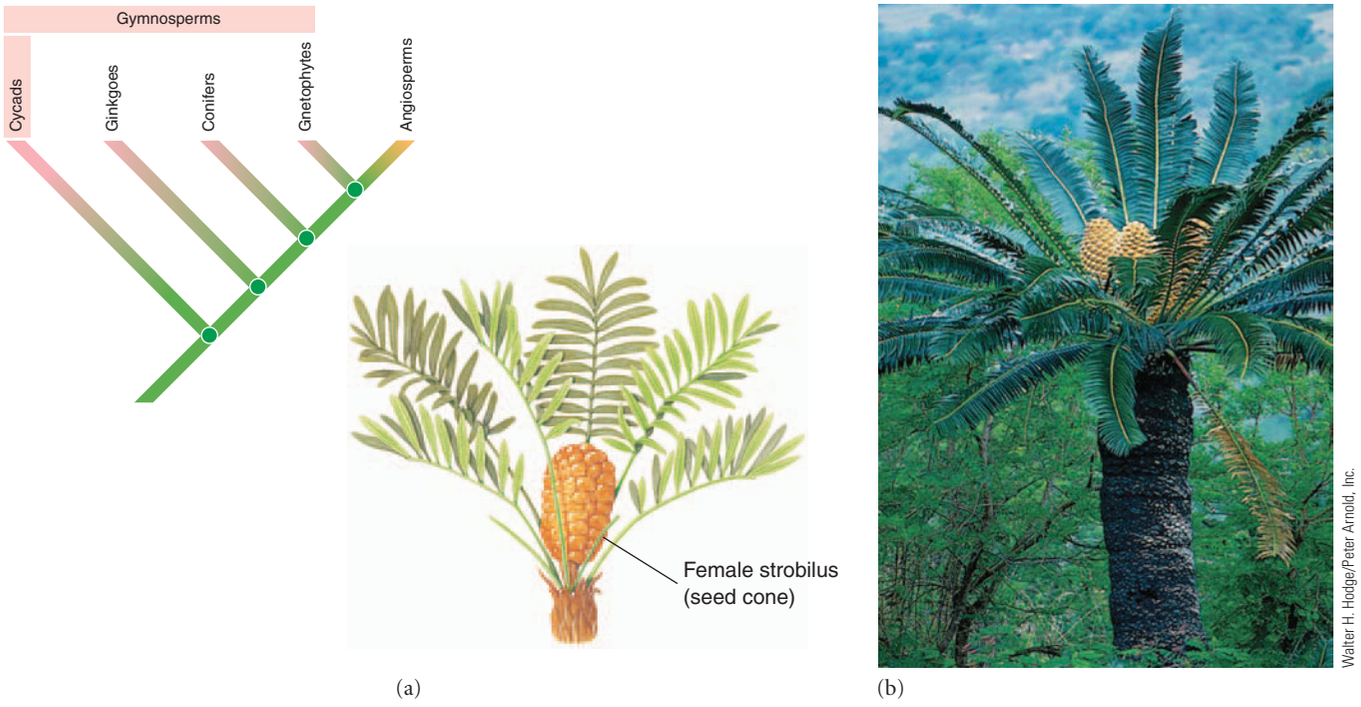

FIGURE **27-5** **Cycads.**

(a) A female coontie (*Zamia integrifolia*) produces seed cones. This plant is the only cycad native to the United States. Like *Zamia,* most cycads are short plants, less than 2 m tall. **(b)** This female cycad (*Encephalartos transvenosus*) in South Africa has a trunk that reaches a height of about 9 m (30 ft) and resembles a palm. Note its immense seed cones, to 0.8 m (30 in) in length.

grain germinates and grows a pollen tube. The sperm cells are released at the top of this tube and swim to get to the egg.

Ginkgo biloba is the only living species in its phylum

Ginkgo (phylum Ginkgophyta) is represented by a single living species, the maidenhair tree, *Ginkgo biloba* (Fig. 27-6). This native of eastern China grew in the wild in only two locations, although people had cultivated it for its edible seeds in China and Japan for centuries. *Ginkgo* is the oldest genus (and species) of living trees. Fossil ginkgoes 200 million years old have been discovered that are similar to the modern ginkgo.

People often plant ginkgo in North America and Europe today, particularly in parks and along city streets, because it is hardy and somewhat resistant to air pollution. Its leaves are deciduous and turn a beautiful yellow before being shed in the fall.

Like cycads, ginkgo is dioecious, with separate male and female trees. It has flagellate sperm cells—an evolutionary vestige that is not required, because ginkgo produces airborne pollen grains. Ginkgo seeds are completely exposed rather than occur-

Robert and Linda Mitchell

(c)

ring within cones. Male trees are typically planted, because the female trees bear seeds whose fleshy outer coverings give off a foul odor that smells like rancid butter. In China and Japan, where people eat the seeds, the female trees are more common.

Ginkgo has been an important medicinal plant for centuries. Extracts from the leaves may enhance neurological functioning by increasing blood flow to the brain. Several studies are underway to determine if ginkgo improves memory in elderly people.

Gnetophytes include three unusual genera

The **gnetophytes** (phylum Gnetophyta) consist of about 70 species in three diverse genera (*Gnetum, Ephedra,* and *Welwitschia*). Gnetophytes share certain features that make them unique among the gymnosperms. For example, gnetophytes have more efficient water-conducting cells, called *vessel elements,* in their xylem (see Chapter 31). Flowering plants also have vessel elements in their xylem, but no gymnosperms do except the gnetophytes. Also, the cone clusters that some gnetophytes produce resemble flower clusters, and certain details in their life cycles resemble those of flowering plants.

The genus *Gnetum* contains tropical vines, shrubs, and trees with broad leaves that resemble those of flowering plants (Fig. 27-7a). Species in the genus *Ephedra* include many shrubs and vines that grow in deserts and other dry temperate and tropical regions. Some *Ephedra* species resemble horsetails in that they have jointed green stems with tiny leaves (Fig. 27-7b). Commonly called *joint fir, Ephedra* has been used medicinally for centuries. An Asiatic *Ephedra* is the source of ephedrine, which stimulates the heart and raises blood pressure. Ephedrine is sold over the counter in weight control medications and herbal energy-boosters; several deaths have been reported from chronic use or overdose of products containing ephedrine.

The third gnetophyte genus, *Welwitschia,* contains a single species found in deserts of southwestern Africa (Fig. 27-7c). Most of *Welwitschia's* body—a long taproot—grows underground. Its short, wide stem forms a shallow disk, up to 0.9 m (3 ft) in diameter, from which two ribbon-like leaves extend. These two leaves continue to grow from the stem throughout the plant's life, but their ends are usually broken and torn by the wind, giving the appearance of numerous leaves. Each leaf grows to about 2 m (6.5 ft) in length. When *Welwitschia* reproduces, it forms cones around the edge of its disclike stem.

Review

- What is the dominant generation in the pine life cycle? How does pollination occur in gymnosperms?

- What features distinguish gymnosperms from other plants?
- What are the four groups of gymnosperms?
- What features distinguish cycads from ginkgo? From gnetophytes?

Biology Now™ Assess your understanding of **gymnosperms** by taking the pretest on your BiologyNow CD-ROM.

FLOWERING PLANTS

Learning Objectives

5 Summarize the features that distinguish flowering plants from other plants.
6 Briefly explain the life cycle of a flowering plant, and describe double fertilization.
7 Contrast dicots and monocots, the two classes of flowering plants.
8 Discuss the evolutionary adaptations of flowering plants.

Flowering plants or **angiosperms** (phylum Magnoliophyta) are the most successful plants today, surpassing even the gymnosperms in importance. They have adapted to almost every habitat and, with at least 235,000 species, are Earth's dominant plants. Flowering plants come in a wide variety of sizes and forms, from herbaceous violets to massive eucalyptus trees. Some flowering plants—tulips and roses, for example—have large, conspicuous flowers, whereas others, such as grasses and oaks, produce small and inconspicuous flowers.

Flowering plants are vascular plants that reproduce sexually by forming flowers, and, after a unique double fertilization process that is discussed later, seeds within fruits. The fruit protects the developing seeds and often aids in their dispersal (see Chapter 35). Flowering plants have efficient water-conducting cells called **vessel elements** in their xylem, and efficient sugar-conducting cells called **sieve tube elements** in their phloem (see Chapter 31).

Flowering plants are extremely important to humans because our survival as a species literally depends on them. All our major food crops are flowering plants, including cereal crops such as rice, wheat, corn, and barley. Woody flowering plants such as oak, cherry, and walnut provide valuable lumber. Flowering plants give us fibers such as cotton and linen and medicines such as digitalis and codeine. Products as diverse as rubber, tobacco, coffee, chocolate, and aromatic oils for perfumes come from flowering plants. Economic botany is the subdiscipline of botany that deals with plants of economic importance.

Monocots and dicots are the two classes of flowering plants

Traditionally, phylum Magnoliophyta is divided into two classes: the monocots (class Liliopsida) and the dicots (class Magnoliopsida) (Fig. 27-8). Monocots include palms, grasses, orchids, irises, onions, and lilies. The dicot class includes oaks, roses, mustards, cacti, blueberries, and sunflowers. Dicots are more diverse and include many more species (at least 170,000) than the monocots (at least 65,000). Table 27-2 provides a comparison of some of the general features of the two classes.

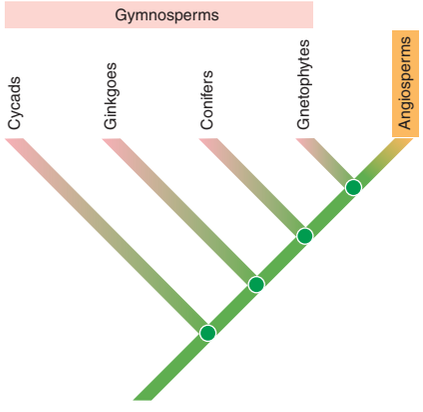

FIGURE **27-8** **Flowering plants.**

(a) *Trillium erectum,* like most monocots, has floral parts in threes. Note the three green sepals, three red petals, six stamens, and three stigmas (the compound pistil consists of three fused carpels). **(b)** Most dicots such as this *Tacitus* have their floral parts in fours or fives. Note the five petals, 10 stamens, and five separate pistils. Five sepals are present but barely visible against the background.

John Gerlach/Tom Stack & Associates

(a)

Richard H. Gross

(b)

Monocots are mostly herbaceous plants with long, narrow leaves that have parallel veins (the main leaf veins run parallel to one another). The parts of monocot flowers usually occur in threes or multiples of 3. For example, a flower may have three sepals, three petals, six stamens, and a compound pistil consisting of three fused carpels (these flower parts are discussed shortly). Monocot seeds have a single **cotyledon,** or embryonic seed leaf, and **endosperm,** a nutritive tissue, is usually present in the mature seed.

TABLE **27-2** Distinguishing Features of Dicots and Monocots

Feature	Dicots	Monocots
Flower parts	Usually in fours or fives	Usually in threes
Pollen grains	Three furrows or pores	One furrow or pore
Leaf venation	Usually netted	Usually parallel
Vascular bundles in stem cross section	Arranged in a circle (ring)	Usually scattered or more complex arrangement
Roots	Taproot system	Fibrous root system
Seeds	Embryo with two cotyledons	Embryo with one cotyledon
Secondary growth (wood and bark)	Often present	Absent

Dicots are either herbaceous (such as a tomato plant) or woody (such as a hickory tree). Their leaves vary in shape but usually are broader than monocot leaves, with netted veins (branched veins resembling a net). Flower parts usually occur in fours or fives or multiples thereof. Two cotyledons are present in dicot seeds, and endosperm is usually absent in the mature seed, having been absorbed by the two cotyledons.

Flowers are involved in sexual reproduction

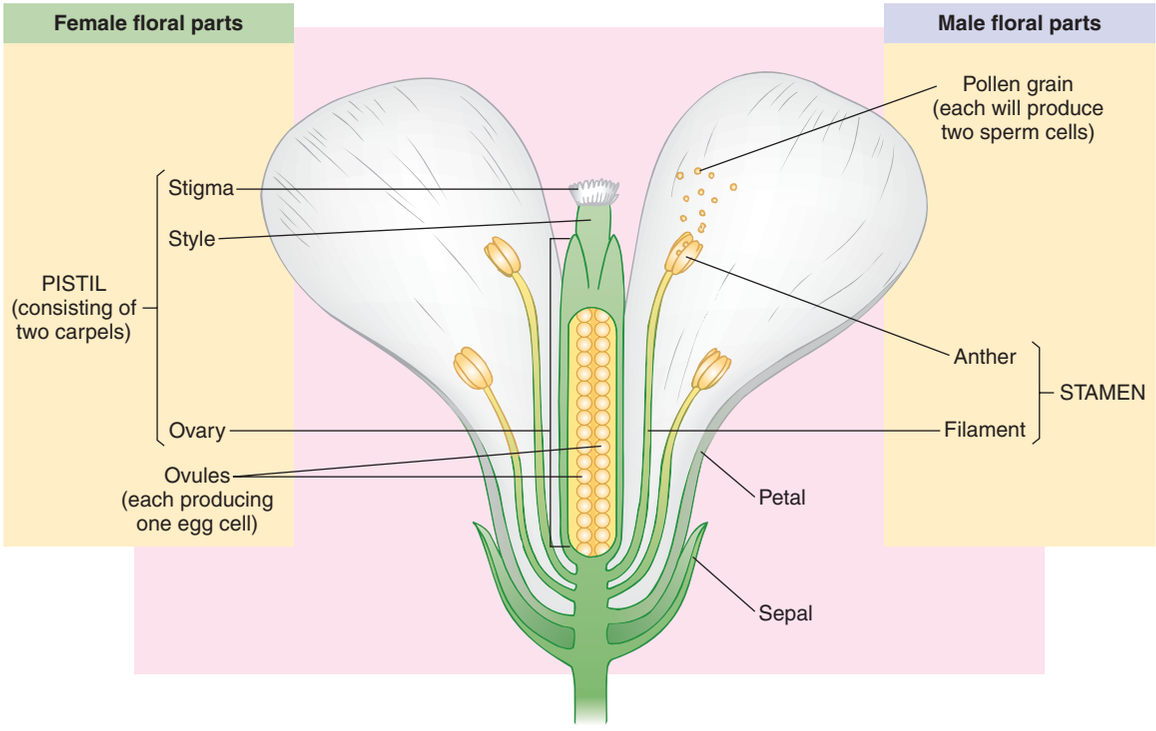
Flowers are reproductive shoots usually composed of four parts—sepals, petals, stamens, and carpels—arranged in whorls (circles) on the end of a flower stalk, or **peduncle** (Fig. 27-9). The peduncle may terminate in a single flower or a cluster of flowers known as an **inflorescence.** The tip of the peduncle enlarges to form a **receptacle** that bears some or all of the flower parts.

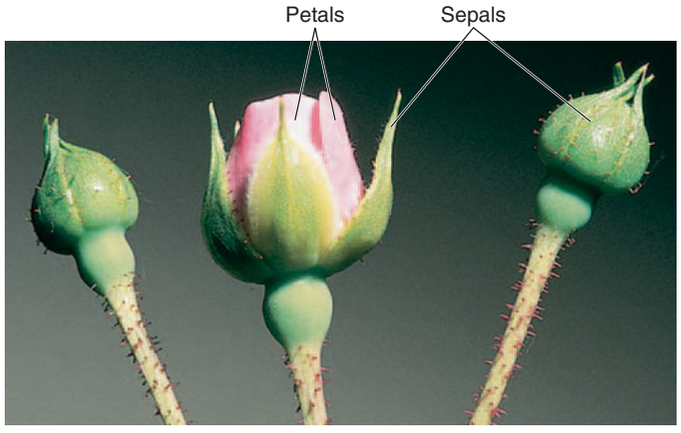
All four floral parts are important in the reproductive process, but only the stamens (the "male" organs) and carpels (the "female" organs) produce gametes. A flower that has all four parts is **complete,** whereas an **incomplete** flower lacks one or more of these four parts. A flower with both stamens and carpels is **perfect,** whereas an **imperfect** flower has stamens or carpels, but not both.

Sepals, which make up the lowermost and outermost whorl on a floral shoot, are leaflike in appearance and often green (Fig. 27-10a). Sepals cover and protect the other flower parts when the flower is a bud. As the blossom opens, the sepals fold

FIGURE **27-9** Floral structure.

This cutaway view of a "typical" flower shows the details of basic floral structure. This flower is both a complete and a perfect flower. Not all flowers have all these structures. (Pistils each consist of one or more carpels. In this example, the pistil consists of two carpels.)





(a)

FIGURE **27-10** **Parts of a flower.**

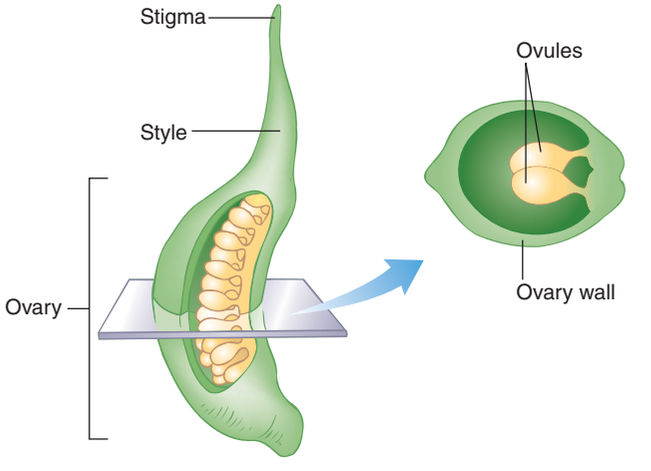
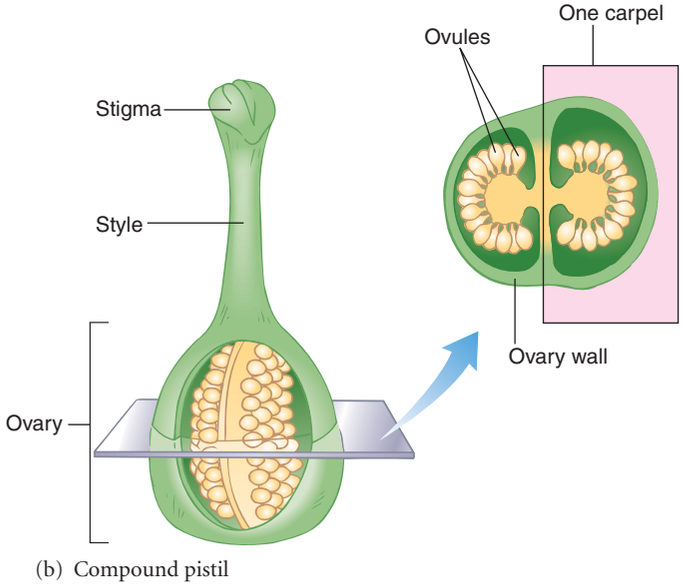
Image not available due to copyright restrictions



(a) Simple pistil



(b) Compound pistil

back to reveal the more conspicuous petals. The collective term for all the sepals of a flower is the **calyx.**

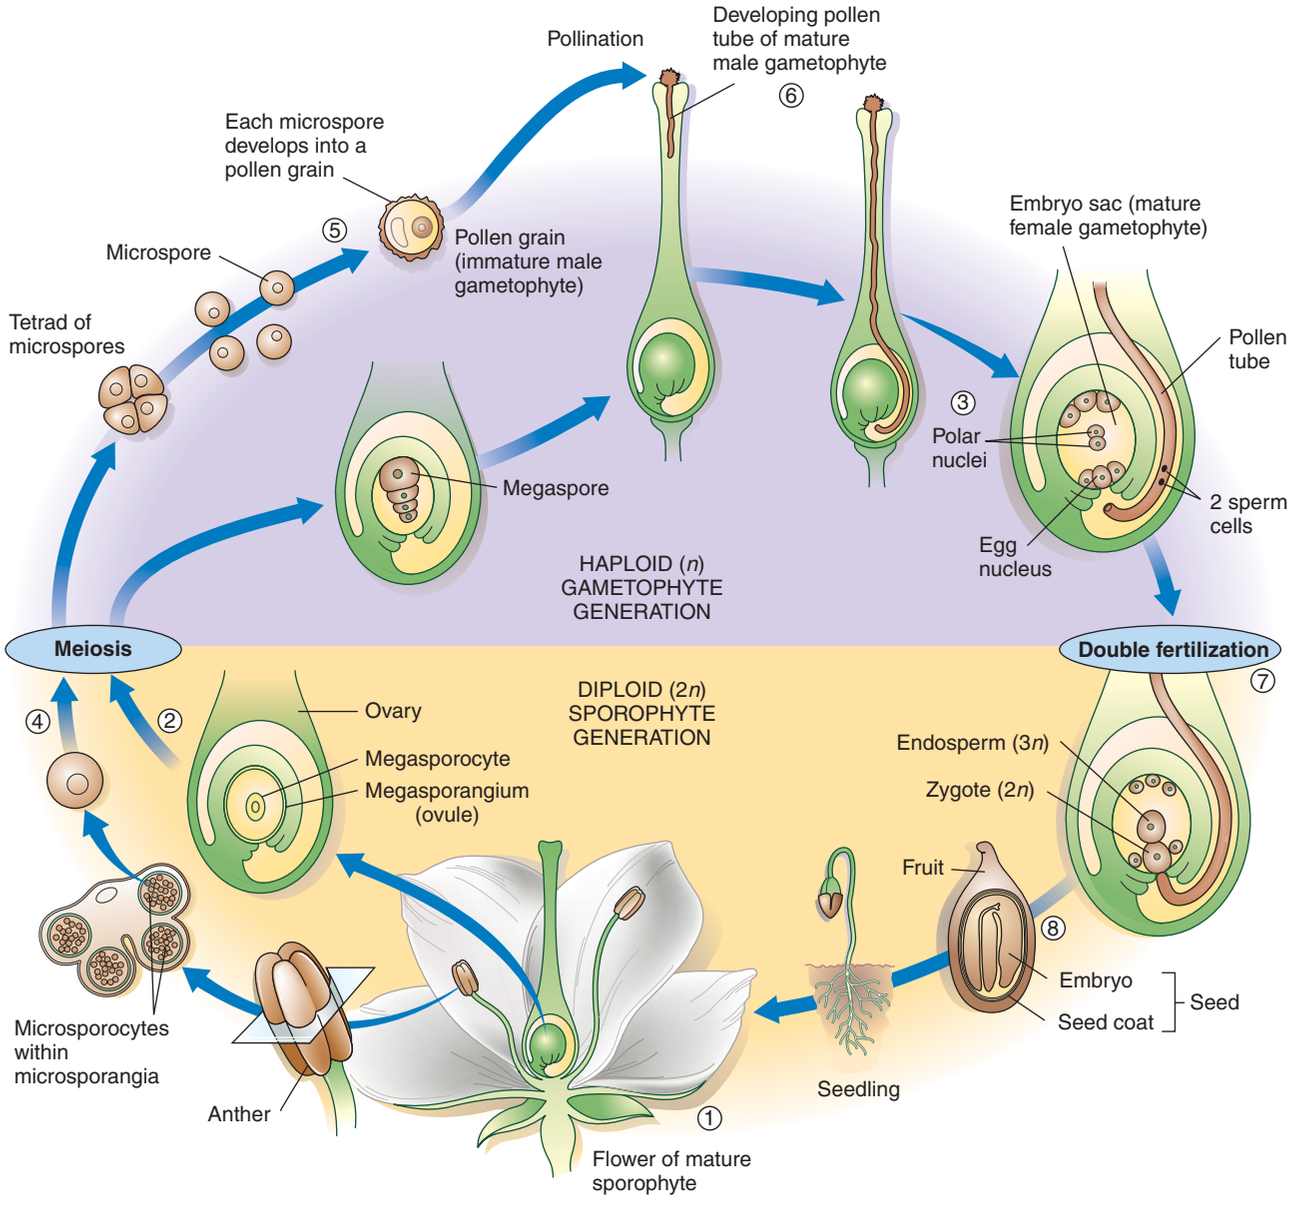
The whorl just above the sepals consists of **petals,** which are broad, flat, and thin (like sepals and leaves) but vary in shape and are frequently brightly colored. Petals play an important role in attracting animal pollinators to the flower (see Chapter 35). Sometimes petals are fused to form a tube (such as trumpet honeysuckle flowers) or other floral shape (such as snapdragons). The petals of a flower are referred to collectively as the **corolla.**

Just inside the petals is a whorl of **stamens** (Fig. 27-10b). Each stamen is composed of a thin stalk, called a **filament,** and a sac-like **anther,** where meiosis occurs to form microspores that develop into pollen grains. Each pollen grain produces two cells surrounded by a tough outer wall. One cell eventually divides to form two male gametes, or sperm cells, and the other produces a pollen tube through which the sperm cells travel to reach the ovule.

In the center of most flowers is one or more closed **carpels,** the "female" reproductive organs. Carpels bear ovules, which, as you may recall, are structures with the potential to develop into seeds. The carpels of a flower are separate or fused into a single structure. The female part of the flower is also called a **pistil** (see Fig. 27-10b). A pistil may consist of a single carpel (a simple pistil) or a group of fused carpels (a compound pistil) (Fig. 27-11). Each pistil generally has three sections: a **stigma,** on which the pollen grain lands; a **style,** a necklike structure

FIGURE **27-11** **Simple and compound pistils.**

(a) This simple pistil consists of a single carpel. **(b)** This compound pistil has two united carpels. In most flowers with single pistils, the pistils are compound, consisting of two or more fused carpels.



through which the pollen tube grows; and an **ovary,** an enlarged structure that contains one or more ovules. Each young ovule contains a female gametophyte that forms one female gamete (an egg), two *polar nuclei,* and several other haploid cells. After fertilization, the ovule develops into a seed and the ovary into a fruit.

ACTIVE FIGURE **27-12** **Life cycle of flowering plants.**

A significant feature of the flowering plant life cycle is double fertilization, in which one sperm cell unites with the egg, forming a zygote, and the other sperm cell unites with the two polar nuclei, forming a triploid cell that gives rise to endosperm. See text for a detailed description.

BiologyNow™ Explore **plant life-cycles** by clicking on this figure on your BiologyNow CD-ROM.

The life cycle of flowering plants includes double fertilization

Flowering plants have an alternation of generations in which the sporophyte generation is larger and nutritionally independent. The gametophyte generation in flowering plants is microscopic and nutritionally dependent on the sporophyte. Flowering plants, like gymnosperms and certain other vascular plants, are heterosporous and produce two kinds of spores: microspores and megaspores. As shown in ① of Fig. 27-12, sexual reproduction occurs in the flower.

In ② each young ovule within an ovary contains a megasporocyte (megaspore mother cell) that undergoes meiosis to produce four haploid megaspores. Three of these usually disintegrate, and one divides mitotically and ③ develops into a mature female gametophyte, also called an **embryo sac.** The most widely studied type of embryo sac contains seven cells with eight haploid nuclei. Six of these cells, including the egg cell, contain a single nucleus each, and a central cell has two nuclei, called **polar nuclei.** The egg and the central cell with two polar

nuclei are directly involved in fertilization; the other five cells in the embryo sac apparently have no direct role in the fertilization process and disintegrate. As the *synergids* (the two cells closely associated with the egg) disintegrate, however, they release chemicals that may affect the direction of pollen tube growth.

Each pollen sac, or microsporangium, of the anther contains numerous microsporocytes (microspore mother cells) ④, each of which undergoes meiosis to form four haploid microspores. Every microspore develops into ⑤ an immature male gametophyte, also called a *pollen grain.* Pollen grains are extremely small; each consists of two cells: the *tube cell* and the *generative cell.*

The anthers split open and begin to shed pollen. Pollen grains are transferred to the stigma by a variety of agents, including wind, water, insects, and other animal pollinators (see Chapter 35). As shown in ⑥, if compatible with the stigma, the pollen grain germinates; that is, the tube cell forms a pollen tube that grows down the style and into the ovary. The germinated pollen grain with its pollen tube is the mature male gametophyte. Next, the generative cell divides to form two nonmotile sperm cells. The sperm cells move down the pollen tube and are discharged into the embryo sac. Both sperm cells are involved in fertilization.

Something happens during sexual reproduction in flowering plants that does not occur anywhere else in the living world. In ⑦, when the two sperm cells enter the embryo sac, *both* participate in fertilization. One sperm cell fuses with the egg, forming a zygote that grows by mitosis and develops into a multicellular embryo in the seed. The second sperm cell fuses with the two haploid polar nuclei of the central cell to form a triploid ($3n$) cell that grows by mitosis and develops into **endosperm,** a nutrient tissue rich in lipids, proteins, and carbohydrates that nourishes the growing embryo. This fertilization process, which involves two separate nuclear fusions, is called **double fertilization** and is, with two exceptions, unique to flowering plants. (Double fertilization was reported in the gymnosperms *Ephedra nevadensis* [in 1990] and *Gnetum gnemon* [in 1996]. This process differs from double fertilization in flowering plants in that an additional zygote, rather than endosperm, is produced. The second zygote later disintegrates.)

Seeds and fruits develop after fertilization

As a result of double fertilization and subsequent growth and development, each seed contains a young plant embryo and nutritive tissue (the endosperm), both of which are surrounded by a protective seed coat. In monocots the endosperm persists and is the main source of food in the mature seed. In most dicots the endosperm nourishes the developing embryo, which subsequently stores food in its cotyledons.

As a seed develops from an ovule following fertilization, ⑧ the ovary wall surrounding it enlarges dramatically and develops into a **fruit.** In some instances, other tissues associated with the ovary also enlarge to form the fruit. Fruits serve two purposes: to protect the developing seeds from desiccation as they grow and mature and to aid in the dispersal of seeds (see Chapter 35). For example, dandelion fruits have feathery plumes that are lifted and carried by air currents. Once a seed lands in a suitable place, it may germinate and develop into a mature sporophyte that produces flowers, and the life cycle continues as described.

Flowering plants have many adaptations that account for their success

The evolutionary adaptations of flowering plants account for their success in terms of their ecological dominance and their great number of species. Seed production as the primary means of reproduction and dispersal, an adaptation shared with the gymnosperms, is clearly significant and provides a definite advantage over seedless vascular plants. Closed carpels, which give rise to fruits surrounding the seeds, and the process of double fertilization increase the likelihood of reproductive success. The evolution of a variety of interdependencies with many types of insects, birds, and bats, which disperse pollen from one flower to another of the same species, is another reason for angiosperm success. Pollen transfer results in cross-fertilization, which mixes the genetic material and promotes genetic variation among the offspring.

In addition to their highly successful reproduction involving flowers, fruits, and seeds, several distinctive features have contributed to the success of flowering plants. Recall that most flowering plants have very efficient water-conducting vessel elements in their xylem, in addition to tracheids. In contrast, the xylem of almost all seedless vascular plants and gymnosperms consists exclusively of tracheids. Most flowering plants also have efficient carbohydrate-conducting sieve tube elements in their phloem. Vascular plants other than flowering plants and gnetophytes lack vessel elements and sieve tube elements.

The leaves of flowering plants, with their broad, expanded blades, are very efficient at absorbing light for photosynthesis. Abscission (shedding) of these leaves during cold or dry spells reduces water loss and has enabled some flowering plants to expand into habitats that would otherwise be too harsh for survival. The stems and roots of flowering plants are often modified for food or water storage, another feature that helps flowering plants survive in severe environments.

Probably most crucial to the evolutionary success of flowering plants, however, is the overall adaptability of the sporophyte generation. As a group, flowering plants readily adapt to new habitats and changing environments. This adaptability is evident in the great diversity exhibited by the various species of flowering plants. For example, the cactus is remarkably well adapted to desert environments. Its stem stores water; its leaves (spines) have a reduced surface area available for transpiration (loss of water vapor; see Chapter 32) and may also protect against thirsty herbivorous animals; and its thick, waxy cuticle reduces water loss. In contrast, the water lily is well adapted for wet environments, in part because it has air channels that provide adequate oxygen to stems and roots living in oxygen-deficient water and mud.

Studying how flowers evolved provides insights into the evolutionary process

In evolution, new structures or organs often originate by modification of previously existing structures or organs (see Chapter 19). Much evidence supports the classical interpretation that the four organs of a flower—sepals, petals, stamens, and carpels—arose from highly modified leaves. This evidence includes comparisons of the arrangement of vascular tissues in both flowers and leafy stems and of the developmental stages of floral parts and leaves.

Sepals are the most leaflike of the four floral organs, and botanists generally agree that sepals are specialized leaves. Although petals of many flowering plant species are leaflike in appearance, botanists generally view petals as modified stamens that became sterile and leaflike. Cultivated roses and camellias provide evidence supporting this hypothesis; in some varieties the stamens have been transformed into petals, forming showy flowers with large numbers of petals.

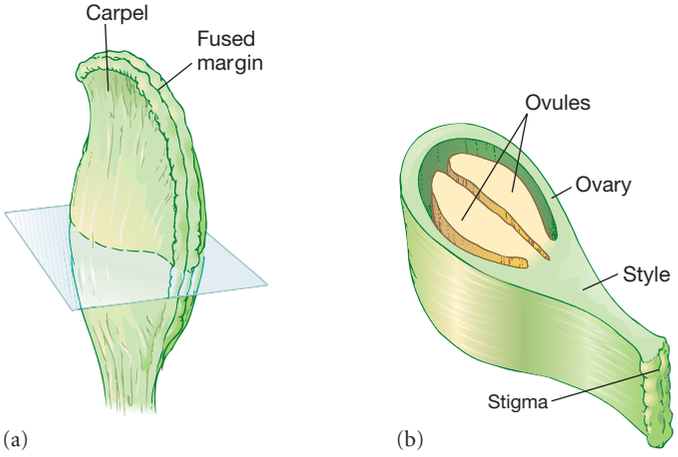
PROCESS OF SCIENCE

The remarkably leaflike stamens and carpels of certain tropical trees and other species support the origin of stamens and carpels from leaves or leaflike organs. Consider, for example, the carpel of *Drimys,* a genus of evergreen trees and shrubs native to Southeast Asia, Australia, and South America. This carpel resembles a leaf that is folded inward along the midrib, thereby enclosing the ovules, and joined along the entire length of the leaf's margin (Fig. 27-13).

The fundamental question is whether these leaflike stamens and carpels are early organs that were conserved (retained) during the course of evolution or are highly specialized organs that do not resemble early stamens and carpels. Many botanists who have studied this question have concluded that stamens and carpels are probably derived from leaves. Not all botanists accept the origin of stamens and carpels from highly modified leaves, however. As we noted in Chapter 1, uncertainty and debate are part of the scientific process and scientists can never claim to know a final answer.

FIGURE **27-13** **Carpel of *Drimys piperita*.**

(a) The carpel resembles a folded leaf in which the ovules borne on its upper surface are enclosed. **(b)** A cross section of the carpel, cut along the dashed line in **(a).**



During the course of more than 130 million years of angiosperm evolution, flower structure diversified as floral organs fused together or became reduced in size or number. These changes led to greater complexity in floral structure in some species and to greater simplicity in other species. Interpreting the floral structures of so many different angiosperm species is sometimes difficult, but it is important because correct interpretations are essential to devising a classification scheme that is phylogenetic.

Review

- How do nonreproductive adaptations of flowering plants differ from those of gymnosperms?
- How does the flowering plant life cycle differ from that of the gymnosperms?
- What are the two classes of flowering plants, and how can one distinguish between them?
- How does pollination occur in flowering plants?
- How does fertilization differ in gymnosperms and flowering plants?

THE EVOLUTION OF SEED PLANTS

Learning Objective

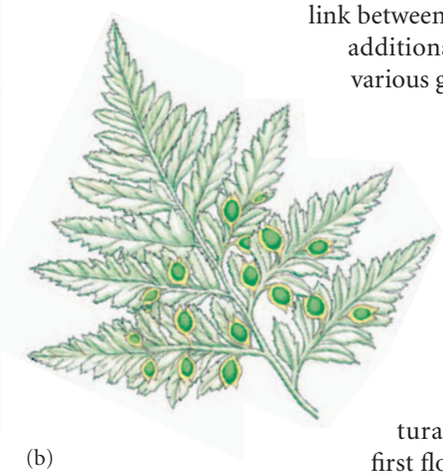
9 Summarize the evolution of gymnosperms from seedless vascular plants, and trace the evolution of flowering plants from gymnosperms.

One group that descended from ancestral seedless vascular plants was the **progymnosperms,** all of which are now extinct. Progymnosperms had two derived features absent in their immediate ancestors: leaves with branching veins (*megaphylls*), and woody tissue (*secondary xylem*) similar to that of modern gymnosperms. Progymnosperms, however, reproduced by spores, not seeds. *Archaeopteris* was a progymnosperm that lived about 370 mya (Fig. 27-14a). In 1999, the discovery and evaluation of 150 fossils of Archaeopteris in southeast Morocco confirmed that this progymnosperm is the earliest known tree with "modern" woody tissue.

Fossils of several progymnosperms with reproductive structures intermediate between those of spore plants and seed plants have been discovered. For example, the evolution of microspores into pollen grains and of megasporangia into ovules (seed-producing structures) can be traced in fossil progymnosperms. Plants producing seeds appeared during the late Devonian period, more than 360 mya. The fossil record indicates different groups of seed plants apparently arose independently several times.

As mentioned previously, fossilized remains of ginkgo are found in 200-million-year-old rocks, and other groups of gymnosperms were well established by 160 to 100 mya. Although the gymnosperms are an ancient group, some questions persist about the exact pathways of gymnosperm evolution. The fossil

(a)



(b)

FIGURE **27-14** **Evolution of seed plants.**

(a) *Archaeopteris,* a progymnosperm that existed about 370 mya, had some features in common with modern seed plants but did not produce seeds. **(b)** *Emplectopteris,* a seed fern, produced seeds on fernlike leaves. Seed ferns existed from about 360 to 250 mya. *(a, Redrawn from C.B. Beck, "Reconstructions of* Archaeopteris *and Further Consideration of Its Phylogenetic Position,"* American Journal of Botany, *Vol. 49, 1962; b, Redrawn from H.N. Andrews,* Ancient Plants and the World They Lived In, *Comstock, New York, 1947)*

record indicates progymnosperms probably gave rise to conifers and to another group of extinct plants called **seed ferns,** which were seed-bearing woody plants with fernlike leaves (Fig. 27-14b). The seed ferns in turn probably gave rise to cycads and possibly ginkgo, as well as to several gymnosperm groups now extinct. The origin of gnetophytes remains unclear, although molecular data indicate they are closely related to conifers.

Flowering plants are the most recent group of plants to evolve. The fossil record, although incomplete, indicates flowering plants probably descended from gymnosperms. By the middle of the Jurassic period, approximately 180 mya, several gymnosperm lines existed with features resembling those of flowering plants. Among other traits, these derived gymnosperms possessed leaves with broad, expanded blades and the first modified seed-bearing leaves, which nearly enclose the ovules. It is also evident beetles were visiting these plants, and biologists have suggested that perhaps this relationship was the beginning of **coevolution,** a mutual adaptation between plants and their animal pollinators (see Chapter 35).

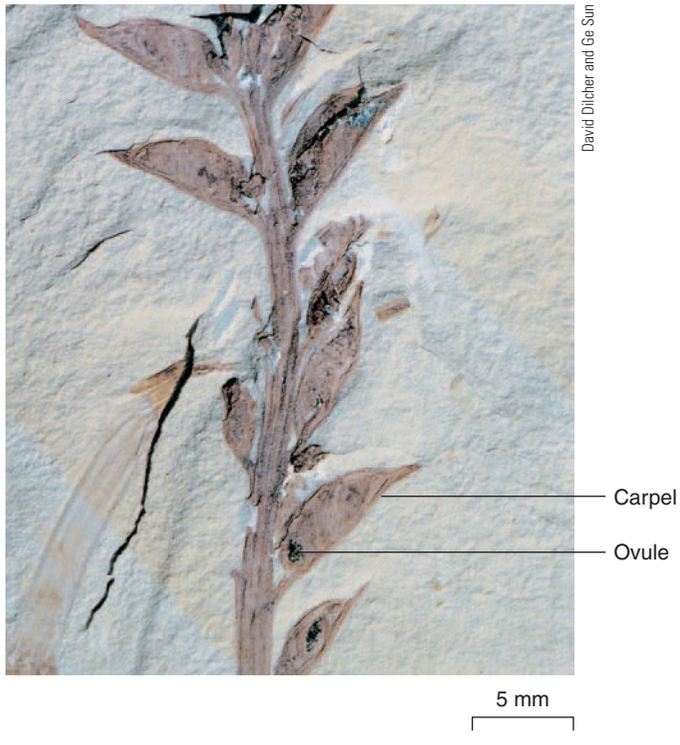
One important task facing paleobotanists (biologists who study fossil plants) is determining which of the ancient gymnosperms are in the direct line of evolution leading to the flowering plants. Given the structural data, most botanists hypothesize flowering plants arose only once, that is, there is only one line of evolution from the gymnosperms to the flowering plants. The gnetophytes are the gymnosperm group some botanists consider the closest living relatives of flowering plants; both structural similarities and certain comparative molecular data support this conclusion. Like angiosperms, gnetophytes have vessels, lack archegonia, have flower-like compound strobili, and undergo double fertilization. However, other molecular data refute a close link between the gnetophytes and flowering plants. It is hoped additional studies will clarify the relationships among the various gymnosperm phyla and the flowering plants.

The oldest definitive trace of flowering plants in the fossil record is of ovules enclosed in tiny pod-like fruits interpreted as carpels in Jurassic and Lower Cretaceous rocks some 125 to 145 million years old (Fig. 27-15). In 1998 Chinese botanists Ge Sun and David Dilcher of the University of Florida discovered the fossil fruits in northeast China. The oldest fossilized flowers are about 118 to 120 million years old.

Based on the fossil record as well as both structural and molecular data of living angiosperms, the first flowering plants were probably small, weedy shrubs or herbaceous plants adapted to disturbed habitats. They may have been fragile plants that were not easily preserved. If so, it explains why there are few fossils of early angiosperms: The environment in which they evolved was repeatedly disturbed and not favorable for their preservation as fossils.

FIGURE **27-15** **The oldest known fossil angiosperm.**

This fossil of *Archaefructus* shows a carpel-bearing stem. It was discovered in northeast China in 1998.



Botanists hypothesize the rapid diversification of angiosperms did not occur until early flowering plants had invaded lowland regions. By 90 mya, during the Cretaceous period, flowering plants had diversified and had begun to replace gymnosperms as Earth's dominant plants. Fossils of flowering plant leaves, stems, flowers, fruits, and seeds are numerous and diverse. They outnumber fossils of gymnosperms and ferns in late Cretaceous deposits, indicating the rapid success of flowering plants once they appeared (Fig. 27-16). Many angiosperm species apparently arose from changes in chromosome number (see discussion of sympatric evolution in Chapter 19).

Within the angiosperms, current evidence suggests the dicots evolved before the monocots and are therefore an older group. The monocots probably evolved from certain ancient dicots (Fig. 27-17). The cladistic analysis of molecular comparisons suggests the monocots are a monophyletic group but the dicots are not. Instead, the dicots are paraphyletic. Recall from Chapter 22 that a **paraphyletic** group contains a common ancestor and some, but not all, of its descendants. According to molecular evidence such as DNA sequence comparisons, some dicots—the magnolias and laurels—are more closely related to the monocots than to other dicots. Despite these data, many botanists currently recognize the classes Liliopsida and Magnoliopsida for convenience.

Review

- What features distinguish progymnosperms from seed ferns?
- What is the oldest known fossil angiosperm?
- Are monocots a monophyletic or paraphyletic group? Why?

FIGURE **27-17** **Evolution of flowering plants.**

(a) One hypothesis of relationships among the flowering plants, based on fossil and molecular evidence. *Amborella*, water lilies (*Nymphaea*), and star anise (*Illicium verum*) are living dicots whose ancestors apparently branched off the angiosperm family tree early. These early dicot taxa were followed by the monocot branch and then by all other dicots (the Eudicots). **(b)** *Amborella trichopoda*, which is native to New Caledonia, an island in the South Pacific, may be the nearest living relative to the ancestor of all flowering plants. Photographed in the National Tropical Botanical Garden World Collection Greenhouse in Kauai, Hawaii.

SUMMARY WITH KEY TERMS

1 Compare the features of seeds with those of spores, and discuss the advantages of plants that reproduce primarily by seeds rather than by spores.

- **Seeds** are the primary means of reproduction and dispersal of gymnosperms and angiosperms (flowering plants). Seeds are reproductively superior to spores because embryonic development is further advanced in seeds, seeds contain an abundant food supply, and each seed has a protective **seed coat.**

2 Trace the steps in the life cycle of a pine, and compare its sporophyte and gametophyte generations.

- A pine tree is a mature sporophyte; pine gametophytes are extremely small and nutritionally dependent on the sporophyte generation. Pine is heterosporous and produces microspores and megaspores in separate cones.
- Male cones produce **microspores** that develop into **pollen grains** (immature male gametophytes) that are carried by air currents to female cones.
- Female cones produce **megaspores.** One of each four megaspores produced by meiosis develops into a female gametophyte within an **ovule (megasporangium).**
- After **pollination,** the transfer of pollen to the female cones, a **pollen tube** grows through the megasporangium to the egg within the archegonium.
- After **fertilization,** the zygote develops into an embryo encased inside a seed adapted for wind dispersal.

3 Summarize the features that distinguish gymnosperms from bryophytes and ferns.

- **Gymnosperms** are vascular plants with seeds that are totally exposed or borne on the scales of cones. Gymnosperms produce wind-borne **pollen grains,** a feature seedless vascular plants lack.

4 Name and briefly describe the four phyla of gymnosperms.

- **Conifers** (phylum Pinophyta) are the largest phylum of gymnosperms. Conifers are woody plants that bear **needles** (leaves that are usually evergreen) and produce seeds in cones. Most conifers are **monoecious** and have male and female reproductive parts in separate cones on the same plant.
- **Cycads** (phylum Cycadophyta) are palmlike or fernlike in appearance. They are **dioecious**—they have male and female reproductive structures on separate plants—but reproduce with pollen and seeds in conelike structures. There are relatively few living members of this once large phylum.
- *Ginkgo biloba,* the only surviving species in phylum Ginkgophyta, is a deciduous, dioecious tree. The female **ginkgo** produces fleshy seeds directly on branches.
- **Gnetophytes** (phylum Gnetophyta) share a number of traits with angiosperms.

5 Summarize the features that distinguish flowering plants from other plants.

- **Flowering plants,** or **angiosperms** (phylum Magnoliophyta) constitute the phylum of vascular plants that produce flowers and seeds enclosed within a **fruit.** They are the most diverse and most successful group of plants.
- The flower, which may contain **sepals, petals, stamens,** and **carpels,** functions in sexual reproduction. Unlike those of gymnosperms, the ovules of flowering plants are enclosed within an **ovary.** After fertilization, the ovules become seeds, and the ovary develops into a fruit.

6 Briefly explain the life cycle of a flowering plant, and describe double fertilization.

- The sporophyte generation is dominant in flowering plants; gametophytes are extremely reduced in size and nutritionally dependent on the sporophyte generation. Flowering plants are heterosporous and produce microspores and megaspores within the flower.
- Each microspore develops into a pollen grain (immature male gametophyte). One of each four megaspores produced by meiosis develops into an **embryo sac** (female gametophyte). The embryo sac contains seven cells with eight nuclei; the egg cell and the central cell with two **polar nuclei** participate in fertilization.
- **Double fertilization,** which results in the formation of a diploid zygote and triploid **endosperm,** is characteristic of flowering plants.

7 Contrast dicots and monocots, the two classes of flowering plants.

- Most **monocots** (class Liliopsida) have floral parts in multiples of 3, and their seeds each contain one **cotyledon.** The nutritive tissue in their mature seeds is endosperm.
- **Dicots** (class Magnoliopsida) usually have floral parts in multiples of 4 or 5, and their seeds each contain two cotyledons. The nutritive organs in their mature seeds are usually the cotyledons, which have absorbed the nutrients in the endosperm.

8 Discuss the evolutionary adaptations of flowering plants.

- Flowering plants reproduce sexually by forming flowers. After double fertilization, seeds are formed within fruits.
- Flowering plants have efficient water-conducting **vessel elements** in their xylem and efficient carbohydrate-conducting **sieve tube elements** in their phloem.
- Wind, water, insects, or other animals transfer pollen grains in various flowering plants.

9 Summarize the evolution of gymnosperms from seedless vascular plants, and trace the evolution of flowering plants from gymnosperms.

- Seed plants arose from seedless vascular plants.
- **Progymnosperms** were seedless vascular plants that had megaphylls and "modern" woody tissue. Progymnosperms probably gave rise to conifers. Progymnosperms probably gave rise to **seed ferns** as well, which in turn probably gave rise to cycads and possibly ginkgo.
- The evolution of the gnetophytes, particularly their relationship to flowering plants, is unclear.
- Flowering plants probably descended from ancient gymnosperms that had specialized features, such as leaves with broad, expanded blades and closed carpels. Flowering plants probably arose only once. The first flowering plants were probably dicots that were weedy shrubs or small herbaceous plants. *Amborella* is a dicot that may be the nearest living relative to the ancestor of all flowering plants.

POST-TEST

1. Seed plants *lack* which of the following structures? (a) ovules surrounded by integuments (b) microspores and megaspores (c) vascular tissues (d) a large, nutritionally independent sporophyte (e) a large, nutritionally independent gametophyte
2. Conifers, cycads, ginkgo, and gnetophytes are collectively called (a) fern allies (b) gymnosperms (c) angiosperms (d) dicots (e) seedless vascular plants
3. Most conifers are _____, having male and female reproductive parts at different locations on the same plant. (a) incomplete (b) imperfect (c) monoecious (d) dioecious (e) perfect
4. The immature male gametophytes of pine are called (a) ovules (b) stamens (c) seed cones (d) pollen grains (e) polar nuclei
5. The transfer of pollen grains from the male to the female reproductive structure is known as (a) pollination (b) fertilization (c) embryo sac development (d) seed development (e) fruit development
6. Motile sperm cells are found as vestiges in these two gymnosperm groups: (a) monocots, dicots (b) gnetophytes, conifers (c) gnetophytes, flowering plants (d) cycads, conifers (e) cycads, ginkgo
7. More than _____ species of flowering plants have been identified. (a) 235 (b) 2350 (c) 23,500 (d) 235,000 (e) 2,350,000
8. This class of flowering plants includes the palms, grasses, and orchids. (a) dicots (b) gnetophytes (c) cycads (d) monocots (e) conifers
9. The pistil has three sections: (a) stigma, style, and anther (b) anther, filament, and ovule (c) stigma, style, and ovary (d) ovary, ovule, and sepal (e) corolla, stamen, and sepal
10. A simple pistil consists of a single (a) calyx (b) carpel (c) ovule (d) filament (e) petal
11. A flower that lacks stamens is both _____ and _____. (a) complete; imperfect (b) incomplete; perfect (c) complete; perfect (d) incomplete; imperfect
12. After fertilization, the _____ develop(s) into a fruit and the _____ develop(s) into a seed. (a) ovary; ovule (b) polar nuclei; ovule (c) ovary; endosperm (d) ovule; ovary (e) ovule; polar nuclei
13. The female gametophyte in flowering plants is also called the (a) polar nuclei (b) anther (c) embryo sac (d) endosperm (e) sporophyll
14. This living dicot may be the nearest living relative to the ancestor of all flowering plants (a) *Amborella* (b) *Archaeopteris* (c) *Gnetum* (d) water lily (e) *Archaeanthus*
15. This cross section through an ovary reveals that the pistil is (a) simple, with one carpel (b) compound, with two fused carpels (c) compound, with three fused carpels (d) compound, with six separate carpels (e) compound, with six fused carpels

CRITICAL THINKING

1. How are cones and flowers alike? How are they different? (*Hint:* Your answer should consider microspores/megaspores and seeds.)
2. How do the life cycles of seedless plants (see Chapter 26) and seed plants differ? In what fundamental way are they alike?
3. In contrast with the cones of gymnosperms, which are either male or female, most flowers contain both male and female reproductive structures. Explain how bisexual flowers might be advantageous to flowering plants.
4. Contrast the algae, mosses, ferns, gymnosperms, and angiosperms with respect to their dependence on water as a transport medium for reproductive cells. Suggest a hypothesis to explain the differences.

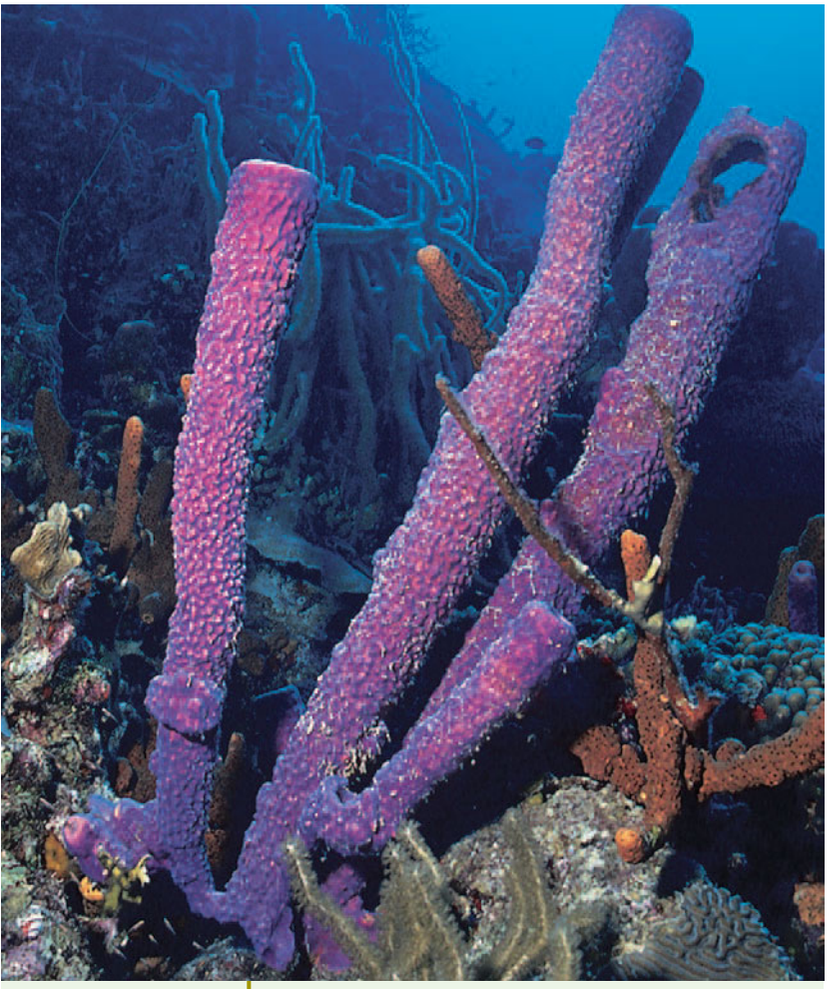
The Animal Kingdom: An Introduction to Animal Diversity



Charles V. Angelo/Photo Researchers, Inc.

The tube sponge (*Callyspongia vaginalis*). This animal, which ranges in color from purple to blue to gray, is common on coral reefs in the Caribbean, from Florida to Mexico.

CHAPTER OUTLINE

- Animal Characteristics
- Animal Habitats
- Reconstructing Phylogeny
- The Parazoa
- The Radiata

Biologists have described and named more than a million species of animals, and millions more may remain to be discovered and classified. Although most animal species are readily recognizable as animals, the identity of some others is less obvious. Early naturalists thought sponges were plants, because they did not move from place to place. Some people still mistake certain marine animals, such as sponges and corals, for plants (see photograph). Locomotion is not a requirement for being classified as an animal.

Animal phylogeny has become an exciting and rapidly changing field of study. Biologists have assigned the extant (living) members of **kingdom Animalia** to about 35 phyla, but the relative positions of phyla and classes are a work in progress. As they consider new data, systematists redraw the tree of animal life.

Early animals were soft-bodied forms that left few fossils. The scarcity of fossils has made it difficult to determine the age, rate of divergence, and number of branches of animal groups. Animals belonging to most extant phyla first appeared in the fossil record during a geologically brief 40-million-year span (about 565–525 mya) during the late Precambrian period and early Cambrian period. The rapid appearance of diverse body plans of extant animals and of an amazing variety of extinct animals during this time is known as the **Cambrian explosion** (see Chapter 20). (The term **body plan** refers to the basic structure of the body.) Based on the fossil record, the many major modifications in body plan that occurred during this time account for many of the branches in the animal tree.

Recently, researchers have presented molecular data indicating that animal clades diverged over a much longer period of time during the Proterozoic eon (which preceded the Cambrian period). Analysts of the molecular data estimate that certain groups are about twice as old as the oldest fossils found to date. According to this view, most animal groups diverged several hundred million years before they appear in the fossil record. Later, during the Cambrian explosion, a reorganization of the animal genome led to new body plans. Perhaps fossils of early animals remain to be discovered in Proterozoic rocks.

Systematists are using recently developed molecular tools to clarify the evolutionary relationships among animal groups. For example, biologists historically viewed roundworms and ribbon worms as members of simple groups that appeared early in animal evolution. Analysis of molecular data suggests these worms evolved from more complex animals and then became structurally simpler over time. Given these data, systematists have repositioned these groups.

In this chapter we discuss some of the criteria biologists use to determine evolutionary relationships and classify animals. Then we describe three phyla that diverged early in the evolutionary history of this kingdom. In Chapters 29 and 30 we discuss two major clades of animals: the protostomes and the deuterostomes. Many current hypotheses are presented in these chapters; keep in mind that biologists continually respond to new data by redrawing branches of the animal phylogenetic tree. ■

ANIMAL CHARACTERISTICS

Learning Objective

1 List several characteristics common to most animals.

Animals are so diverse that for almost any definition, we can find exceptions. Still, the following characteristics describe most animals:

1. Animals are multicellular eukaryotes.
2. Animals are **heterotrophs.** As consumers, they depend on producers for their raw materials and energy. Most animals ingest their food first and then digest it inside the body, usually within a digestive system.
3. Cells that make up the animal body are specialized to perform specific functions. In all but the simplest animals, cells are organized to form tissues, and tissues are organized to form organs. In many animals with simple body plans, life processes such as gas exchange, circulation of materials, and waste disposal take place by diffusion directly to and from the environment. In large, complex animals, specialized organ systems and mechanisms have evolved that perform these life processes.
4. Most animals have nervous systems and muscle systems that enable them to respond rapidly to stimuli in their environment.
5. Most animals are capable of locomotion at some time during their life cycle. Some animals (such as sponges and corals) move about as larvae (immature forms) but are **sessile** (firmly attached to the ground or some other surface) as adults (see chapter opening photograph).
6. Most animals are diploid organisms that reproduce sexually, with large, nonmotile eggs and small, flagellated sperm. A haploid sperm unites with a haploid egg, forming a **zygote** (fertilized egg) that undergoes **cleavage,** a series of mitotic cell divisions. During cleavage the zygote develops into a hollow ball of cells called a **blastula.** Cells of the blastula undergo **gastrulation,** a process of forming and segregating specific layers of tissue, called *germ layers.*

Some animals develop directly into adults. Others develop into a **larva,** a sexually immature form that may look very different from the adult. Larvae undergo **metamorphosis,** a developmental process that converts the immature animal into a juvenile form that can then grow into an adult.

ANIMAL HABITATS

Learning Objective

2 Compare the advantages and disadvantages of life in the ocean, in fresh water, and on land.

Fossil evidence suggests animals evolved during Precambrian time in shallow, marine environments (see Chapter 20). Although animals are now distributed in virtually every environment, members of most animal phyla still inhabit marine environments.

Marine environments offer many advantages. The buoyancy of sea water provides support, and the temperature is relatively stable owing to the large volume of water. The body fluids of most invertebrates have about the same osmotic concentration as sea water, so fluid and salt balance are more easily maintained than in fresh water. **Plankton,** which consists of the mainly microscopic animals and protists that are suspended in water and float with its movement, provides a ready source of food for many aquatic animals.

Life in the ocean also presents some challenges. Although the continuous motion of water brings nutrients to animals and washes their wastes away, they must be able to cope with the water's movements and the currents that could sweep them away. Squids, fishes, and marine mammals are strong swimmers and can usually direct their movements and maintain their location. However, most invertebrates and young vertebrates cannot swim strongly, and they have adapted in many different ways to the tides and currents. Some sessile animals attach permanently to a stable structure such as a rock. Others burrow in the sand and silt that cover the sea bottom. Many invertebrates have adapted by maintaining a small body size and becoming part of the plankton. As they are tossed about, their food supply continues to surround them.

Far fewer kinds of animals make their homes in fresh water than in the ocean. Fresh water is hypotonic to the tissue fluids of animals, so water tends to move into the animal by osmosis. Freshwater species must have mechanisms for removing excess water while retaining salts. This *osmoregulation* requires an expenditure of energy. Fresh water offers a much less constant environment than sea water and generally contains less food. Oxygen content and temperature vary, and turbidity (owing to

sediments suspended in the water) and even water volumes fluctuate.

Living on land is even more difficult than living in fresh water and requires many adaptations. Analyzing the fossil record, many biologists hypothesize that the first air-breathing terrestrial animals were scorpion-like arthropods that came ashore in the Silurian period about 450 million years ago (mya). The first vertebrates to inhabit terrestrial environments, the amphibians, did not appear until the latter part of the Devonian period, about 30 million years later.

The chief problem facing all terrestrial organisms is desiccation (drying out). Water is constantly lost by evaporation and is often difficult to replace. A body covering adapted to minimize fluid loss helps solve this problem in many terrestrial animals. Location of the respiratory surface deep within the animal also helps prevent fluid loss. Thus the gills of aquatic animals are typically located externally, but lungs and tracheal tubes of terrestrial animals are internal.

Reproduction on land also poses challenges to protect gametes and the developing offspring from desiccation. Aquatic animals typically shed their gametes in the water, where fertilization occurs. The surrounding water also serves as an effective shock absorber, protecting the delicate embryos as they develop. Some land animals, including most amphibians, return to the water for reproduction, and their larval forms develop in the water.

The evolution of internal fertilization has permitted many terrestrial animals, including earthworms, land snails, insects, reptiles, birds, and mammals, to meet the desiccation challenge. Because they transfer sperm from the body of the male directly into the body of the female by copulation, a watery medium continuously surrounds the sperm. Another important adaptation to reproduction on land is the tough, protective shell that surrounds the eggs of many species. Secreted by the female, this shell protects the developing embryo from drying out. An alternative adaptation for terrestrial reproduction is development of the embryo within the moist body of the mother.

The temperature extremes of terrestrial habitats also present challenges. In later chapters we discuss behavioral and physiological adaptations for maintaining body temperature.

RECONSTRUCTING PHYLOGENY

Learning Objectives

3 Critique the use of type of symmetry and type of body cavity to infer relationships among animal phyla.

4 Describe the distinguishing characteristics of the three major clades of coelomate animals: Lophotrochozoa, Ecdysozoa, and Deuterostomia.

Historically, biologists depended on fossils, on similarities in body plan, and on patterns of development to determine evolutionary relationships among various groups of animals. Now, molecular methods are providing additional data that help answer questions about phylogeny. For example, recent molecular analysis indicates the structure of RNA, genes that control development, and many other molecules are very similar among all animal groups that have been studied. Such complex molecules are unlikely to have evolved multiple times. Thus, these data, along with the *principle of parsimony* (see Chapter 22), support the hypothesis that animals evolved only once. They are a monophyletic group.

Biologists generally agree animals evolved from *choanoflagellates* (see Chapter 24). In some colonial flagellates, cells became specialized to perform specific functions such as movement, feeding, or reproduction. As this division of labor evolved, a colony of flagellates reached the level of cooperation and coordination that qualified it to be considered a single organism—the first animal. The choanoflagellates, fungi, and animals are the major groups classified as **opisthokonts.**

Biologists classify animals in two clades: Parazoa and Eumetazoa. The only animals classified as **Parazoa** (*para,* "alongside" and *zoa,* "animals") are sponges (phylum Porifera). The cells of sponges are loosely associated and do not form true tissues. Other animals have true tissues and are classified as **Eumetazoa** (*eu,* "true"; *meta,* "later"; *zoa,* "animals").

Biologists classify animals according to body symmetry

Symmetry refers to the arrangement of body structures in relation to the body axis. Most sponges are not symmetrical, so when cut in half, the two halves are not similar to one another. Most other animals exhibit either radial or bilateral body symmetry. Members of phylum Cnidaria (jellyfish, sea anemones, and their relatives), phylum Ctenophora (comb jellies), and adult echinoderms (sea stars and their relatives) have **radial symmetry.** In radial symmetry, the body has the general form of a wheel or cylinder, and similar structures are regularly arranged as spokes from a central axis (Fig. 28-1a, b). Multiple planes can be drawn through the central axis, each dividing the organism into two mirror images. An animal with radial symmetry receives stimuli equally from all directions in the environment.

Many radially symmetrical animals have modified radial symmetry. For example, sea anemones and ctenophores (comb jellies) actually have **biradial symmetry,** in which parts of the body have become specialized so that only two planes can divide the body into similar halves.

Most animals exhibit **bilateral symmetry,** at least in their larval stages. A bilaterally symmetrical animal can be divided through only one plane (which passes through the midline of the body) to produce roughly equivalent right and left halves that are mirror images (Fig. 28-1c, d). As bilateral symmetry evolved, a corresponding evolutionary trend led toward **cephalization,** the development of a head where sensory structures are concentrated. In many animal groups, concentrations of

ACTIVE FIGURE **28-1**

Radial and bilateral symmetry.

(a, b) In radial symmetry, multiple planes can be drawn through the central axis; each divides the animal into two mirror images. **(c, d)** In bilateral symmetry, the head end of the animal is its anterior end, and the opposite end is its posterior end. The back of the animal is its dorsal surface, and the belly is its ventral surface. The diagrams also illustrate various ways the body can be sectioned (cut) to study its internal structure. A sagittal section (lengthwise vertical cut) divides the animal into right and left parts. A frontal, or longitudinal, cut (lengthwise horizontal) divides the body into dorsal and ventral parts. Sections are used in illustrations throughout this book to show the structure and arrangement of tissues and organs.

BiologyNow™ Explore **the characteristics of animals** by clicking on this figure on your BiologyNow CD-ROM.

nerve cells in the head form a brain, and a nerve cord extends from the brain toward the rear end of the animal. Bilateral symmetry and cephalization are considered adaptations to locomotion. The head end of the animal meets its environment first and is best equipped to capture food or respond to danger.

To locate body structures in bilaterally symmetrical animals, it is helpful to define some basic terms and directions. The back surface of an animal is its **dorsal** surface; the underside (belly) is its **ventral** surface. **Anterior** (or **cephalic**) means toward the head end of the animal; **posterior,** or **caudal,** means toward the tail end. A structure is said to be **medial** if it is located toward the midline of the body and **lateral** if it is toward one side of the body; for example, the human ear is lateral to the nose. In human anatomy, the term **superior** refers to a structure located above some point of reference, or toward the head end of the body. The term **inferior** is used in human anatomy to mean located below some point of reference, or toward the feet.

A bilaterally symmetrical animal has three axes, each at right angles to the other two: an anterior-posterior axis extending from head to tail, a dorsal–ventral axis extending from back to belly, and a left–right axis extending from side to side. We can distinguish three planes or sections that divide the body into specific parts. A **sagittal plane** divides the body into right and left parts. A sagittal plane passes from anterior to posterior and from dorsal to ventral. A **frontal** plane divides a bilateral body into dorsal and ventral parts. A **transverse section,** or **cross section,** cuts at right angles to the body axis and separates anterior and posterior parts.

Biologists group animals according to type of body cavity

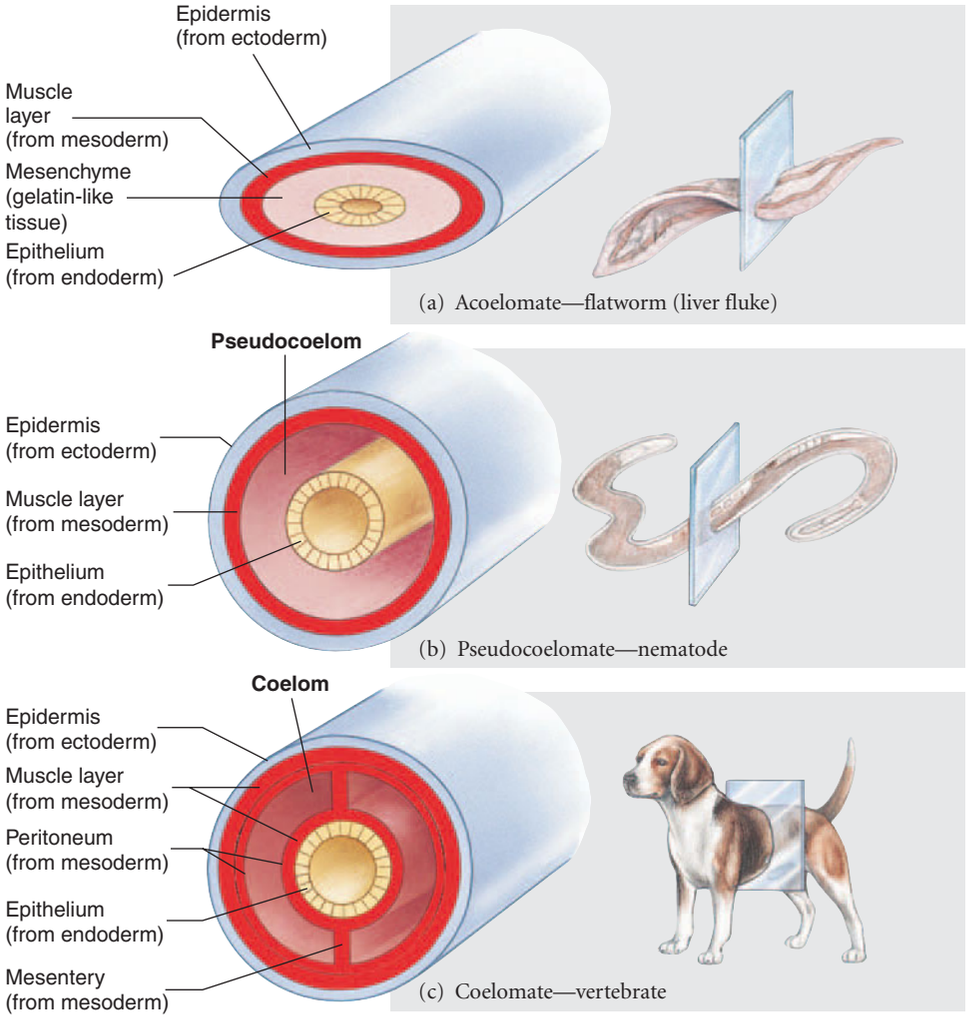
Biologists describe cnidarians and ctenophores as **diploblastic** because they have two tissue layers. These tissues develop from two types of embryonic tissue, or **germ layers.** In all animals, the outer germ layer, or **ectoderm,** gives rise to the outer covering of the body and to nervous tissue. The inner layer, or **endoderm,** forms the lining of the digestive tube and other digestive structures. All other eumetazoa are **triploblastic.** They have a third germ layer, the **mesoderm,** that gives rise to most other body structures, including muscles, skeletal structures, and circulatory system (when present).

Traditionally, biologists have classified triploblastic animals based on the presence and type of **body cavity,** or **coelom** (see′-lum), a fluid-filled space between the body wall and the digestive tube (Fig. 28-2). The flatworms (phylum Platyhelminthes) and ribbon worms (phylum Nemertea) are triploblastic but have a solid body; that is, they have no body cavity. They are called **acoelomates** (*a,* "without"; *coelom,* "cavity").

FIGURE **28-2**

Three basic body plans in triploblastic animals.

The germ layer from which each tissue was derived is indicated in parentheses. **(a)** An acoelomate animal has no body cavity. **(b)** A pseudocoelomate animal has a body cavity that is not completely lined with mesoderm. **(c)** In a coelomate animal the body cavity, or coelom, is completely lined with tissue that develops from mesoderm. Ectoderm is shown in blue, mesoderm in red, and endoderm in yellow.



In most animals, the body cavity is completely lined with mesoderm. Such a body cavity is a *true coelom.* Animals with true coeloms are **coelomates.** The coelom is a space that separates the body wall from the digestive tube, or gut, producing a **tube-within-a-tube body plan.** The body wall, which forms the outer tube, is covered with tissue that develops from ectoderm. Tissue derived from endoderm lines the inner digestive tube, which has an opening at each end: the mouth and the anus.

In some (typically, small) animals, the body cavity is not completely lined with mesoderm; it is called a **pseudocoelom** ("false coelom"). Animals with a pseudocoelom, like nematodes (roundworms) and rotifers, are **pseudocoelomates,** and biologists formerly classified them as a separate group. Recent evidence indicates pseudocoelomates are not a monophyletic group and probably evolved through a process of simplification from more than one group of animals with a true coelom.

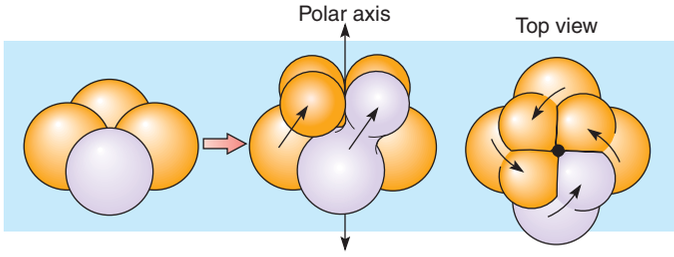
Coelomate animals form two main groups based on differences in development

Animals with a coelom form two main evolutionary lines: **Protostomia,** which include mollusks, annelids, and arthropods, and **Deuterostomia,** which include the echinoderms (such as sea stars and sea urchins) and chordates (the phylum that includes the vertebrates). Basic differences in their pattern of early development distinguish protostomes from deuterostomes.

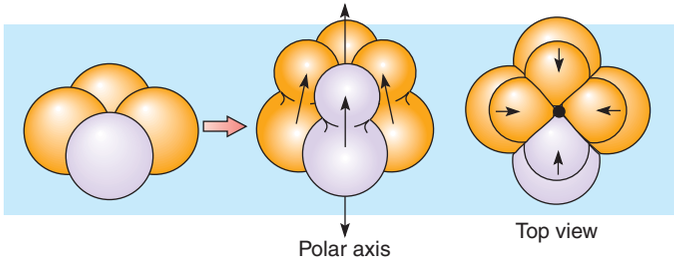
One important difference in the development of protostomes and deuterostomes is the pattern of cleavage, the first several cell divisions of the embryo. In many protostomes, the early cell divisions are diagonal to the polar axis (the long axis of the egg), resulting in a somewhat spiral arrangement of cells; any one cell lies between the two cells above or below it (Fig. 28-3). This pattern of division is known as **spiral cleavage.** In **radial cleavage,** characteristic of the deuterostomes, the early divisions are either parallel or at right angles to the polar axis. The resulting cells lie directly above or below one another.

In the protostomes, the developmental fate of each embryonic cell is typically fixed very early. For example, if the first four cells of an annelid embryo are separated, each cell develops into only a fixed quarter of the larva; this is called **determinate cleavage.** In deuterostomes, cleavage is usually **indeterminate.** If the first four cells of a sea star embryo, for instance, are separated, each cell can form a complete, though small, larva. If a few cells are removed from the blastula of an embryo undergoing determinate cleavage, some structure such as a limb, does not develop. In contrast, if a few cells are removed from a blastula undergoing indeterminate cleavage, other cells compensate, and the embryo develops normally.

During gastrulation a group of cells moves inward, forming a sac that becomes the embryonic gut. The opening to the outside is called the **blastopore.** In most protostomes, the blastopore develops into the mouth. The word *protostome* comes from Greek words meaning "first, the mouth." In deuterostomes the blastopore does not give rise to the mouth. Instead, it generally develops into the anus. A second opening that forms later in development gives rise to the mouth. The word *deuterostome* means "second, the mouth."



(a) Protostomes are characterized by spiral cleavage.



(b) Deuterostomes are characterized by radial cleavage.

FIGURE **28-3** **Spiral and radial cleavage.**

(a) Spiral cleavage is characteristic of protostomes. Note the spiral arrangement, with the upper cells centered between the lower cells. **(b)** In radial cleavage, characteristic of deuterostome embryos, the early divisions are either parallel to the polar axis or at right angles to it. The cells are stacked, with the upper cells centered directly above the lower cells. The pattern of cleavage can be appreciated by comparing the positions of the purple cells in *(a)* and *(b)*.

Another, though less reliable, difference between protostome and deuterostome development is the manner in which the coelom forms. In most protostomes, the mesoderm splits, and the split widens into a cavity that becomes the coelom (Fig. 28-4). This method of coelom formation is known as **schizocoely.** In deuterostomes, the mesoderm forms as "outpocketings" of the developing gut, a process called **enterocoely.** These outpocketings eventually pinch off and form pouches; the cavity within the pouches becomes the coelom.

Biologists are using molecular data to rethink animal relationships

PROCESS OF SCIENCE

Using molecular techniques, biologists are exploring similarities in DNA, ribosomal RNA, and *Hox* genes. Recall from Chapter 16 that *Hox* genes are a group of regulatory genes that help control early development. All major animal groups have them except sponges. Investigators suggest all the *Hox* gene groups had evolved by the beginning of the Cambrian period.

Although molecular data have thus far validated much of the phylogeny systematists have based on morphology and development, these data suggest changes in placement of several animal groups. For example, molecular data suggest evolution of animals was not an orderly progression from simple to complex. Until recently, biologists thought the very small (less than 3 mm) marine animals known as **Placozoans** were the earliest

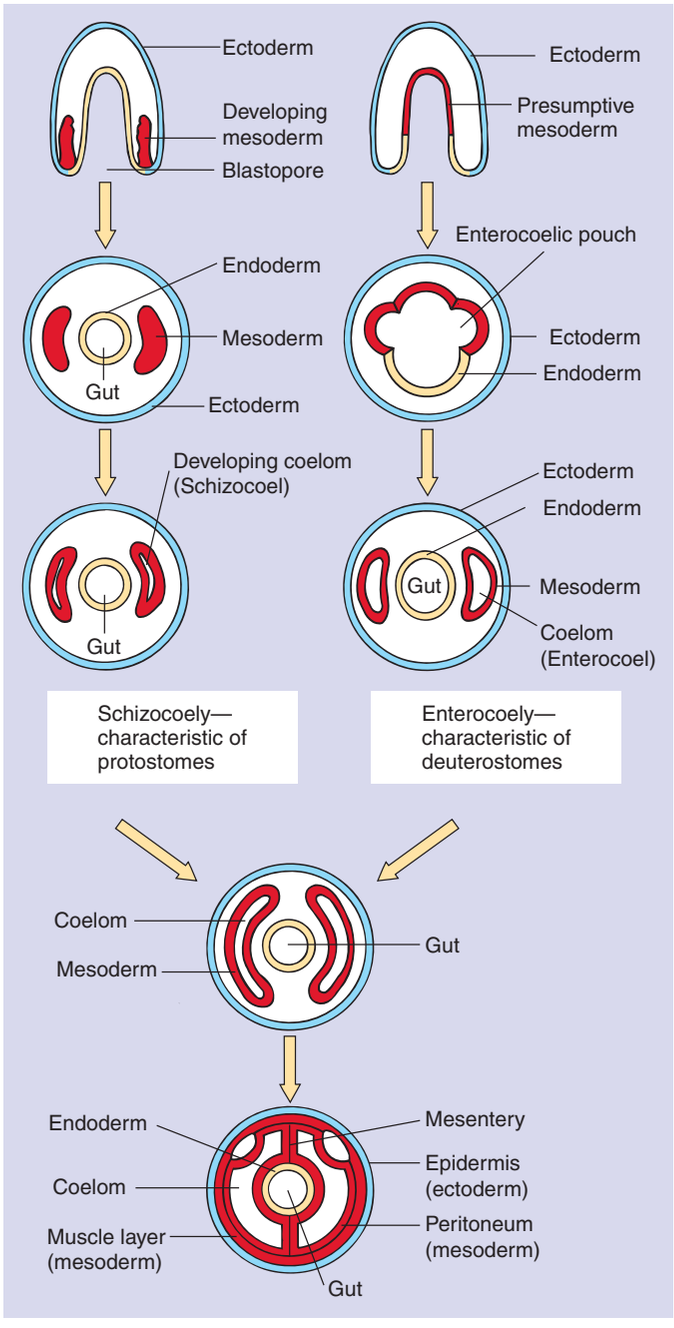


FIGURE **28-4** **Two types of coelom formation.**

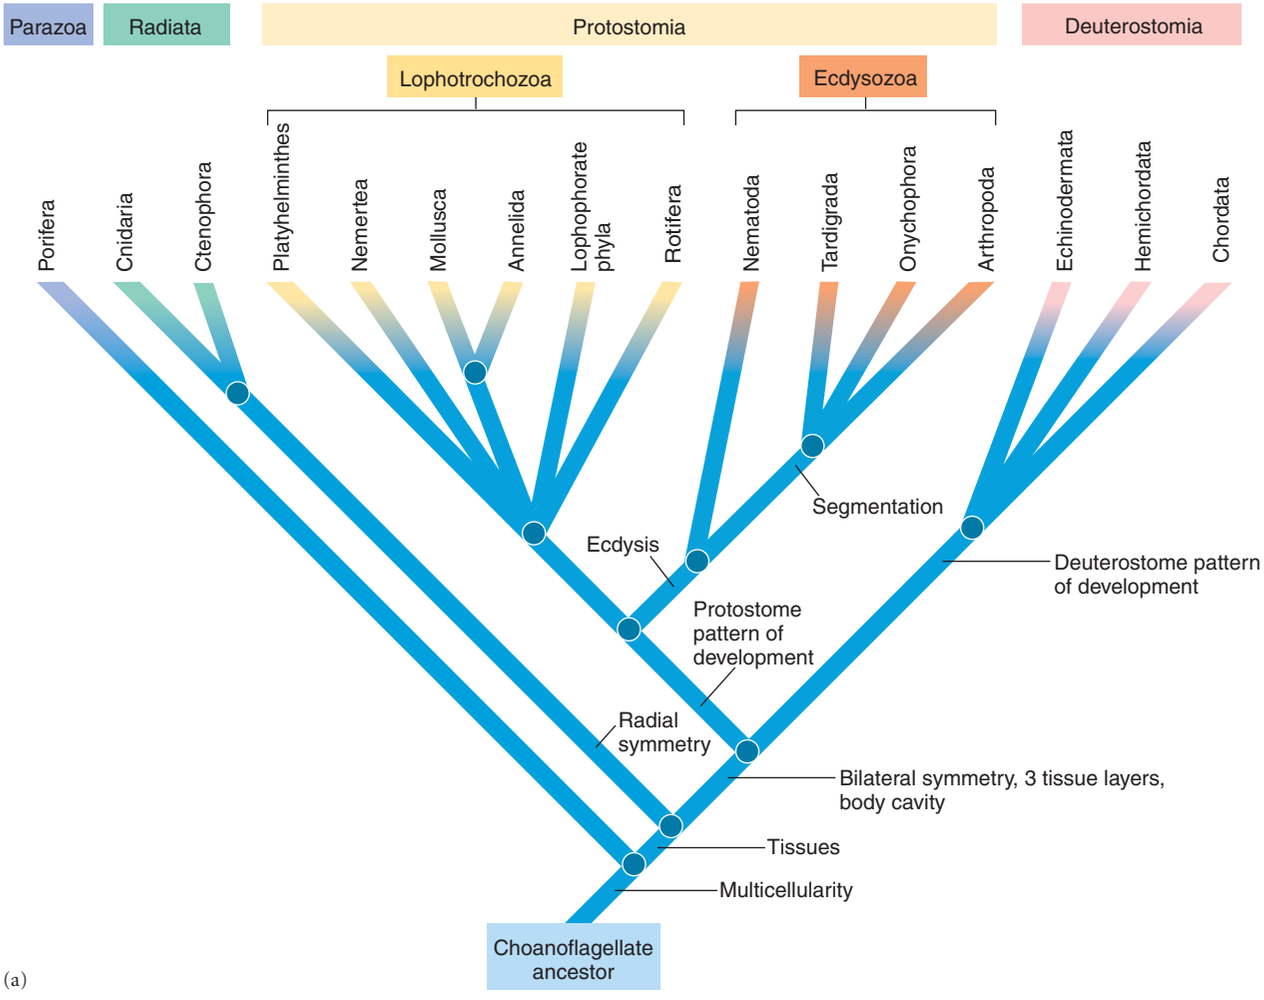
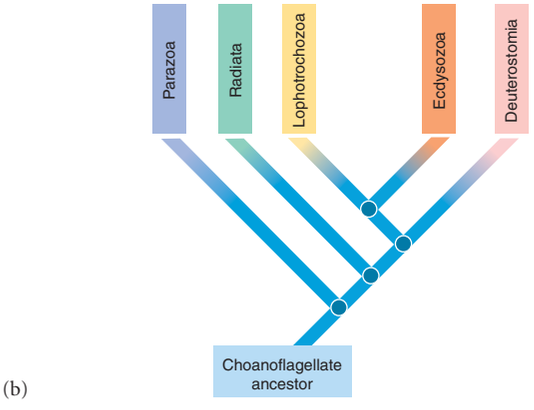
The coelom originates in the embryo from blocks of mesoderm that split off from each side of the embryonic gut. In protostomes the coelom typically forms by the process of schizocoely, in which the mesoderm *(red)* splits. The split widens, forming a cavity that becomes the coelom. In enterocoely, characteristic of deuterostomes, the mesoderm outpockets from the gut, forming pouches. The cavity within these pouches becomes the coelom. Ectoderm is shown in blue, endoderm in yellow. Top row, longitudinal sections of developing embryos; other diagrams are cross sections.

animals to evolve. Placozoans have flat, rounded bodies consisting of only a few thousand cells of four types. Biologists formerly classified them along with sponges as parazoa, but molecular data suggest the placozoans evolved later and are more

closely related to certain complex invertebrates. According to this view, placozoans became simplified later in the history of animal evolution.

As explained in the last section, biologists classify coelomate animals into protostome and deuterostome groups. Based on an evolving hypothesis of phylogeny, many systematists now subdivide the protostomes into two branches: the **Lophotrochozoa** and the **Ecdysozoa** (Fig. 28-5; Table 28-1). The Lophotrochozoa include the platyhelminthes (flatworms), nemerteans (ribbon worms), mollusks, annelids, the lophophorate phyla (groups that have a ciliated ring of tentacles surrounding the mouth), and rotifers. The Ecdysozoa, animals that molt (a





KEY CONCEPT: Any cladogram of animal relationships is a work in process. As new data are considered, our understanding of relationships among animal groups changes. Three major animal clades are Lophotrochozoa, Ecdysozoa, and Deuterostomia.

ACTIVE FIGURE **28-5** **Evolutionary relationships of major animal phyla.**

(a) Five main animal clades are Parazoa, Radiata, Lophotrochozoa, Ecdysozoa, and Deuterostomia. **(b)** A highly simplified cladogram showing the five main animal clades. Modifications of this cladogram are used as icons in Chapters 28 and 29.

TABLE **28-1** Overview of the Animal Kingdom

Major Groups and Phyla	Symmetry	Level of Organization	Digestion	Circulation
Parazoa				
Porifera (sponges)	None	Cells loosely arranged	Intracellular	Diffusion
Radiata				
Cnidarians (hydras, jellyfish, corals)	Radial	Diploblastic; tissues	Gastrovascular cavity with one opening	Diffusion
Ctenophores (comb jellies)	Biradial	Diploblastic; tissues	Gastrovascular cavity with mouth and anal pores	Diffusion
Protostome Coelomates of the Lophotrochozoan Branch				
Platyhelminthes* (flatworms)	Bilateral	Triploblastic; simple organ systems	Gastrovascular cavity with one opening	Diffusion
Nemertea (proboscis worms)	Bilateral	Triploblastic; organ systems	Complete digestive tube**	Blood vessels; no heart
Mollusca (clams, snails, squids)	Bilateral	Triploblastic; organ systems	Complete digestive tube	Open system† (closed in cephalopods)
Annelida (some marine worms, earthworms, leeches)	Bilateral	Triploblastic; organ systems	Complete digestive tube	Closed system
Lophophorates (brachiopods, phoronids, bryozoans)	Bilateral	Triploblastic; organ systems	Complete digestive tube	Closed system
Rotifera (wheel animals)	Bilateral	Triploblastic; organ systems	Complete digestive tube	Closed system
Protostome Coelomates of the Ecdysozoan Branch				
Nematoda (roundworms)	Bilateral	Triploblastic; organ systems	Complete digestive tube	Diffusion
Arthropoda (crustaceans, insects, arachnids)	Bilateral	Triploblastic; organ systems	Complete digestive tube	Open system
Deuterostome Coelomates				
Echinodermata (sea stars, sea urchins)	Embryo bilateral; adult pentaradial	Triploblastic; organ systems	Complete digestive tube	Open system; reduced
Hemichordata	Bilateral	Triploblastic; organ systems	Complete digestive tube	Open system
Chordata (tunicates, lancelets, vertebrates)	Bilateral	Triploblastic; organ systems	Complete digestive tube	Closed system

*Triploblastic, but have solid body (i.e., no body cavity).
**A complete digestive tube has a mouth for food intake and an anus for elimination of wastes.
†A type of circulatory system in which the heart pumps blood through vessels into tissues that have open ends, and the blood bathes the tissues directly.

process called *ecdysis*), include the nematodes and arthropods. Thus this phylogeny has three major clades of coelomate animals: Lophotrochozoa, Ecdysozoa, and Deuterostomia.

Now that we have briefly discussed animal body plans and some of the criteria for determining phylogenetic relationships, we survey representative animal phyla. In the remainder of this chapter, we discuss two groups that appeared early in animal evolution: the Parazoa and the Radiata. The cladogram (phylogenetic tree) shown in Figure 28-5 depicts one current view of the relationships among the major phyla of animals.

Review

- In what way do biologists use the type of body cavity to infer relationships among animal groups?
- How do the three main animal clades differ from one another?

BiologyNow™ Assess your understanding of **reconstructing phylogeny** by taking the pretest on your BiologyNow CD-ROM.

THE PARAZOA

Learning Objective

5 Identify distinguishing characteristics of phylum Porifera.

Sponges, the only members of the Parazoa, diverged early from the lineage leading to other animals. Because they have been evolving independently for so long, they are very different from other animals. Although they are multicellular and can be large, sponges function much like colonial, unicellular protozoa. Most cells of sponges are extremely versatile and can change form and function; the cells do not form true tissues.

Collar cells characterize sponges

Biologists have identified about 10,000 species of sponges and assigned them to phylum **Porifera.** The name *Porifera,* mean-

ing "to have pores," aptly describes the sponges, whose bodies are perforated by tiny holes. Sponges are aquatic, mainly marine, animals that range in size from 1 to 200 cm (0.4–79 in) in height. Many are asymmetrical, but they vary in shape from flat, encrusting growths to balls, cups, fans, or vases. Living sponges may be brightly colored—green, orange, red, yellow, blue, or purple—or they may be white or drab (Fig. 28-6). Some species are inhabited by symbiotic bacteria or algae that give them color.

Sponges most likely evolved from choanoflagellates, protozoa that have a single flagellum surrounded by a collar of microvilli (see Fig. 24-25). Sponges have **collar cells,** or **choanocytes,** flagellate cells that are strikingly similar to the choanoflagellates. Molecular biologists have discovered that choanoflagellates have receptor proteins known as *tyrosine kinases,* characteristic of multicellular animal cells. This finding suggests that some of the mechanisms necessary for cells to interact with one another have evolved in choanoflagellates.

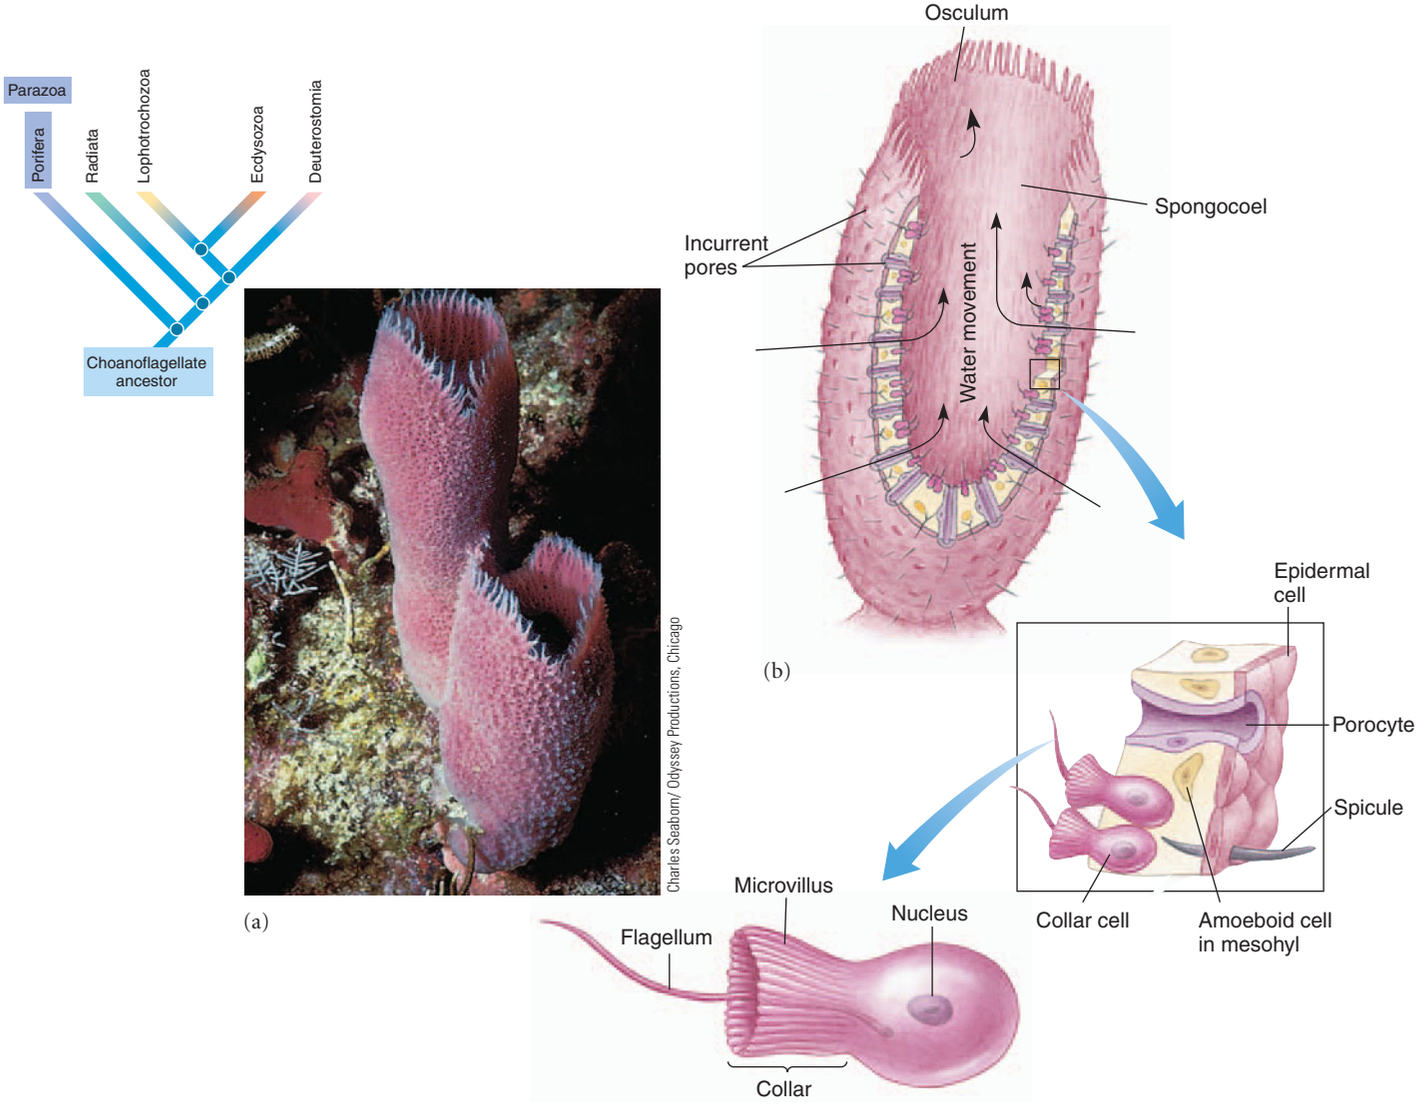
Sponge larvae have flagella and can swim about. Adult sponges attach to some solid object and have long been described as sessile. However, biologists have observed adults of several species moving slowly (about 4 mm per day) by extending footlike appendages.

In a simple sponge, water enters through hundreds of tiny pores *(ostia),* passes into the central cavity, or **spongocoel** (not a digestive cavity), and flows out through the sponge's open end, the **osculum.** In most types of sponges, the body wall is extensively folded, and complicated systems of canals provide increased surface area for food capture.

Although sponges are multicellular, their cells are loosely associated and do not form definite tissues. However, a division of labor exists among the several types of cells that make up the sponge, with certain cells specializing in nutrition, support, contraction, or reproduction. Epidermal cells form the outer layer of the sponge and line the canals. Specialized tubelike cells, called *porocytes,* form the pores of a simple sponge. These cells regulate the diameter of the pores by contracting.

FIGURE **28-6** **Sponge structure.**

(a) Tube sponges (*Spinosella plicifera*) from the Caribbean, attached to the coral reef substrate. **(b)** A simple sponge cut open to expose its organization. Water drawn through the pores passes through the spongocoel and exits through the osculum. Collar cells trap food particles in the stream of water.



Collar cells make up the inner layer of certain sponges. Each cell is equipped with a tiny collar surrounding the base of the flagellum. The collar is an extension of the plasma membrane and consists of microvilli. These cells create the water current that brings food and oxygen to the cells and carries away carbon dioxide and other wastes. Collar cells also trap and phagocytize food particles. Together, the collar cells of some complex sponges can pump a volume of water equal to the volume of the sponge each minute!

Between the outer and inner cell layers of the sponge body is a gelatin-like layer, the *mesohyl,* supported by slender skeletal spikes, or **spicules.** Amoeboid cells, which wander about in the mesohyl, secrete the spicules, which consist of calcium carbonate, silica, or a fibrous protein material known as *spongin.* Other amoeboid cells in the mesohyl are important in digestion and food transport.

Sponges are *suspension feeders,* adapted for trapping and eating whatever food the water brings to them. As water circulates through the body, food is trapped along the sticky collars of the choanocytes. Food particles are either digested within the collar cell or transferred to an amoeboid cell for digestion and transport of nutrients to epidermal cells. Undigested food passes out through the osculum and is simply eliminated into the water.

Gas exchange and excretion of wastes depend on diffusion into and out of individual cells. Although cells of the sponge are irritable and can react to stimuli, sponges do not have specialized nerve cells and so cannot react as a whole. Behavior appears limited to basic metabolic necessities such as capturing food and regulating the flow of water through the body.

Sponges reproduce both asexually and sexually. In asexual reproduction, a small fragment or bud may break free from the parent sponge and give rise to a new sponge. Such fragments may attach to the parent sponge, forming a colony. Most sponges are **hermaphrodites,** meaning the same individual can produce both eggs and sperm. Some of the amoeboid cells develop into sperm cells, others into egg cells. However, hermaphroditic sponges usually produce eggs and sperm at different times, and they cross-fertilize with other sponges. They release mature sperm into the water, which are taken in by other sponges of the same species.

Fertilization and early development take place within the jelly-like mesohyl. Zygotes develop into flagellate larvae that leave the parent along with the stream of outflowing water. After swimming about for awhile, a larva finds a solid object, attaches to it, and settles down to a sessile life.

Sponges have a remarkable ability to repair themselves when injured and to regenerate lost parts. If the cells of a sponge are separated experimentally, they recognize one another and their place in the whole, and aggregate, forming a complete sponge again.

Review

- Why are choanocytes significant? What is their function in sponges?
- In what ways do the cells of sponges specialize?

THE RADIATA

Learning Objectives

6 Identify distinguishing characteristics of phylum Cnidaria, describe three main classes of this phylum, and give examples of animals that belong to each class.

7 Identify distinguishing characteristics of phylum Ctenophora.

Recall that all animals except the sponges are classified as Eumetazoa. The Radiata, animals with radial symmetry, may have been the first eumetazoans to evolve. Biologists currently classify cnidarians and ctenophores as Radiata. However, the relationships of these groups to other animals and to each other is still a matter of debate.

Cnidarians have unique stinging cells

Most of the 10,000 or so species of phylum **Cnidaria** (pronounced "ni-dah′-ree-ah") are marine. The radially symmetrical cnidarian body is organized as a hollow sac with the mouth and surrounding tentacles located at one end. Biologists assign cnidarians to three main classes (Table 28-2). Class **Hydrozoa** includes hydras, and *hydroids,* such as *Obelia* and the Portuguese man-of-war; class **Scyphozoa** includes jellyfish; and class **Anthozoa** includes sea anemones and corals. Some cnidarians live a solitary existence, whereas many others, such as corals, form colonies.

Cnidarians have two body shapes: the polyp and the medusa (Fig. 28-7). The **polyp** form, represented by *Hydra,* typically has a dorsal mouth surrounded by tentacles. In the **medusa** (pl., *medusae*), or jellyfish form, the mouth is located in the lower concave, or *oral,* surface; the convex upper surface is the *aboral* surface. Some cnidarians have the polyp shape during one stage of their life cycle and the medusa form during another stage. The Portuguese man-of-war and some other cnidarians consist of colonies of many individuals, some of which are polyps and others medusae.

Cnidarians get their name from specialized cells, called **cnidocytes** (from a Greek word meaning "sea nettles"), that

TABLE **28-2** Major Classes of Phylum Cnidaria

Class and Representative Animals	Characteristics
Hydrozoa *Hydra, Obelia,* Portuguese man-of-war	Mainly marine, but some freshwater species; alternation of polyp and medusa stages in most species (polyp form only in *Hydra*); some form colonies.
Scyphozoa Jellyfish	Mainly marine; typically inhabit coastal water, free-swimming medusa most prominent form; polyp stage often reduced.
Anthozoa Sea anemones, corals, sea fans	Marine; solitary or colonial polyps; in most no medusa stage; gastrovascular cavity divided by partitions into chambers, increasing area for digestion; sessile.

contain stinging organelles. Cnidocytes are located mainly in the epidermis, especially on the tentacles. The cnidocytes contain stinging "thread capsules," or **nematocysts** (Fig. 28-8). When stimulated, a nematocyst releases a coiled, hollow thread. Some types of nematocyst threads are sticky. Others are long and coil around prey. A third type bears barbs or spines and can inject a protein toxin that paralyzes prey animals such as small crustaceans. Each cnidocyte has a small, projecting trigger *(cnidocil)* on its outer surface. Stimuli such as touch or chemicals dissolved in the water stimulate the nematocyst to fire its thread.

Cnidarians use their tentacles to capture prey and push it into the mouth. The mouth leads into the **gastrovascular cavity,** where digestion takes place. The mouth is the only opening into the gastrovascular cavity and so must serve for both ingestion of food and expulsion of wastes. Gas exchange and excretion occur by diffusion. The body wall is thin enough that no cell is far from the surface.

More highly organized than the sponge, cnidarians are diploblastic; that is, they have two definite tissue layers. The ectoderm gives rise to the outer **epidermis,** a protective layer covering the body. The endoderm gives rise to the inner **gastrodermis,** which lines the gastrovascular cavity and functions in digestion. These thin layers are separated by a gelatinous, mainly acellular, **mesoglea.**

Cnidarians have nerve cells that form **nerve nets** connecting sensory cells in the body wall to contractile and gland cells. Sense organs—for example, photoreceptors which detect light—are positioned around the edge of the body. An impulse set up by one of them passes in all directions more or less equally. The nerve cells are not organized to form a brain or nerve cord.

Both the epidermis and gastrodermis have cells specialized to contract (however, they are not true muscle cells). Contractile fibers in the epidermal cells run lengthwise, and those in the gastrodermis run circularly. These two sets of contractile cells act on the water-filled gastrovascular cavity, which forms a **hydrostatic skeleton** that supports the body and allows move-

FIGURE **28-8** **Nematocysts.**

When cnidarian stinging cells (cnidocytes) are stimulated, the nematocyst discharges, ejecting a thread that may entangle or penetrate the prey. Some nematocysts secrete a toxic substance that immobilizes the prey. **(a)** LM of discharged nematocysts of a Portuguese man-of-war (*Physalia physalis*). Photographed in the Gulf of Mexico. **(b)** Undischarged and discharged nematocyst. The cnidocil, or trigger, is a mechanoreceptor that discharges the nematocyst when it senses contact with an object.

ment. By contracting one set of contractile cells or the other, the hydra can shorten, lengthen, or bend its body (see Fig. 38-3).

Class Hydrozoa includes solitary and colonial forms

Although not really typical, the cnidarian beginning biology students most often study is the tiny, solitary *Hydra* found in freshwater ponds (Fig. 28-9). To the naked eye *Hydra* looks like a bit of frayed string. Because it has a remarkable ability to regenerate, biologists named *Hydra*

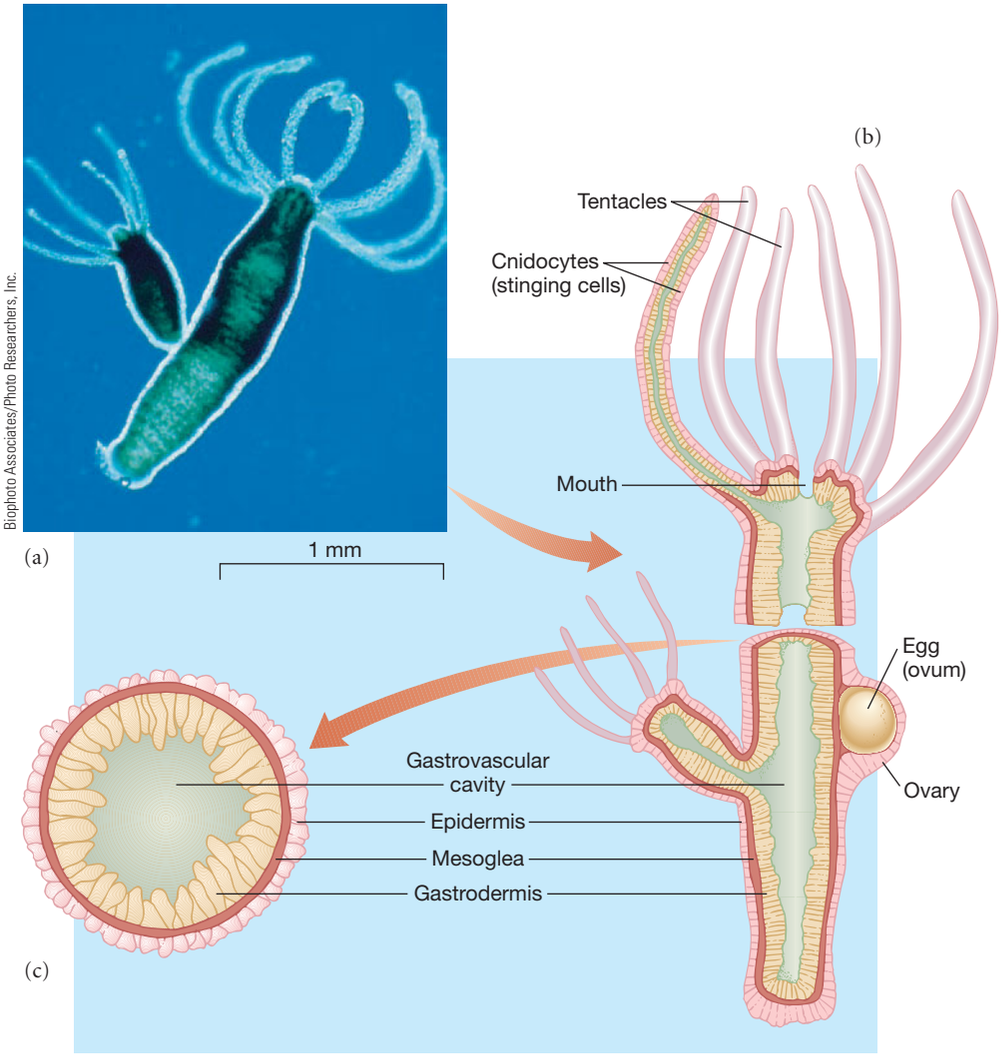

FIGURE **28-9**

Hydra, a freshwater hydrozoan.

(a) *Hydra viridis* with a large bud. When the bud separates from its parent, it becomes an independent individual. **(b)** Hydra cut longitudinally to show its internal structure. Asexual reproduction by budding is represented on the left; sexual reproduction is represented by the ovary on the right. Male hydras develop testes that produce sperm. **(c)** Cross section through the body of a hydra.

after the multiheaded monster of Greek mythology that could grow two new heads for each head cut off. When *Hydra* is cut into several pieces, each piece may regrow all the missing parts and become a whole animal.

Hydra lives in fresh water and typically attaches to a rock, aquatic plant, or detritus by a disc of cells at its base. Hydras reproduce asexually by budding during periods when environmental conditions are optimal. However, they differentiate as males and females and reproduce sexually in the fall or when pond water becomes stagnant. The zygote may become covered with a shell that protects it through the winter or until conditions become more favorable.

Many hydrozoans form colonies consisting of hundreds or thousands of individuals. A colony begins with a single polyp that reproduces asexually by budding. However, instead of separating from the parent, the bud remains attached and eventually forms additional buds. Several types of individuals may arise in the same colony, some specialized for feeding, some for reproduction, and others for defense.

Some marine cnidarians are remarkable for an alternation of sexual and asexual stages. This alternation of stages differs from the alternation of generations in plants in that both sexual and asexual forms are diploid; only sperm and eggs are haploid. The life cycle of the colonial marine hydrozoan *Obelia* illustrates alternation of sexual and asexual stages (Fig. 28-10).

The medusa stage is dominant among the jellyfish

Among the jellyfish, members of class Scyphozoa, the medusa is the dominant body form. Scyphozoan medusae are generally larger than hydrozoan medusae, and they have a thick, viscous mesoglea that gives firmness to the body. In scyphozoans, the polyp stage is small and inconspicuous or may even be absent. The largest jellyfish, *Cyanea,* may be more than 2 m (6.5 ft) in diameter and have tentacles 30 m (98 ft) long. These orange and blue "monsters," among the largest invertebrates, are dangerous to swimmers in the North Atlantic Ocean.

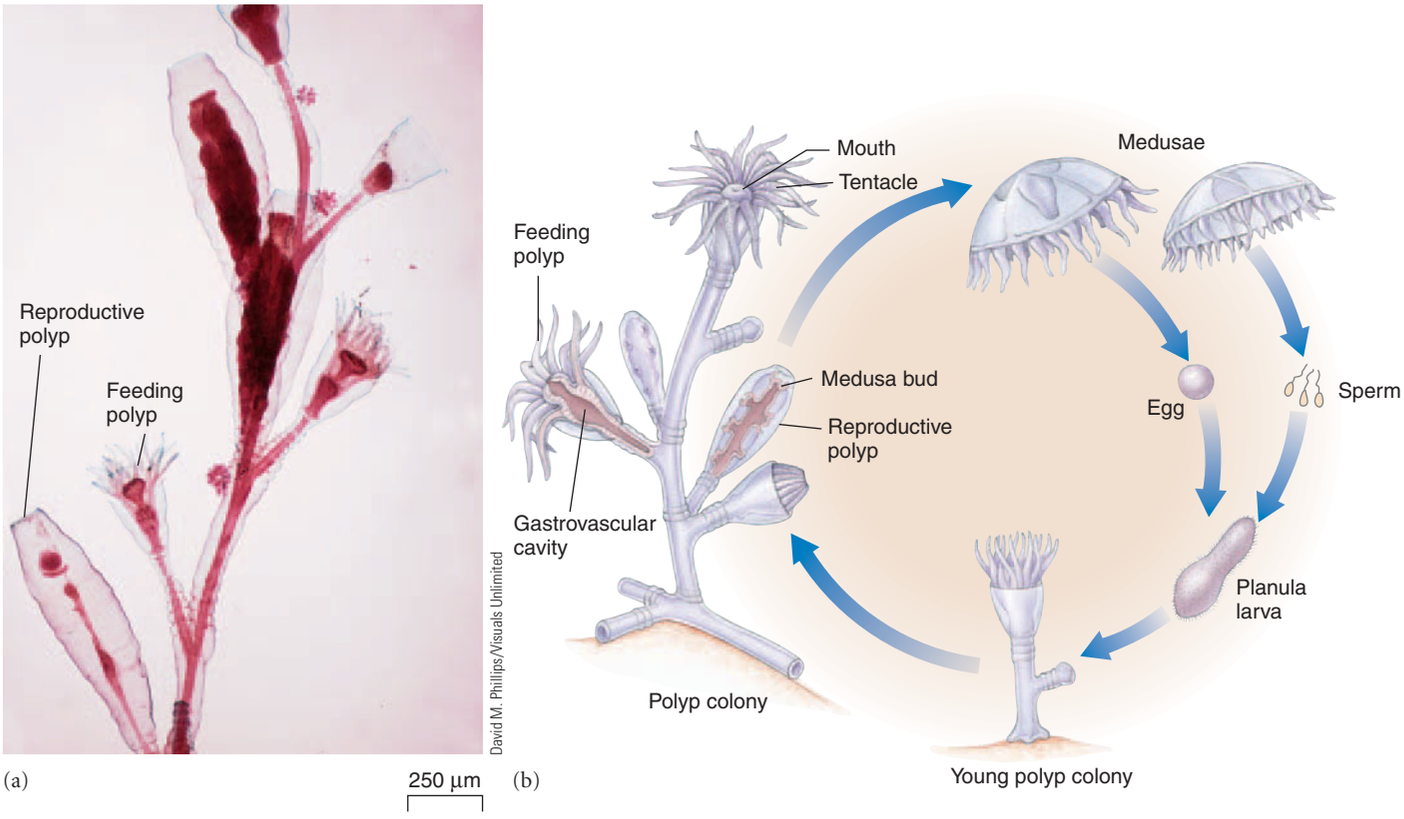
Anthozoans occur only as polyps

Sea anemones and corals, members of class Anthozoa, have either individual or colonial polyps but no free-swimming medusa stage. The polyp produces eggs and sperm, and the fertilized egg develops into a small, ciliated larva called a **planula.** This larval form may swim to a new location before attaching to develop into a polyp.

Anthozoans differ from hydrozoans in that a series of vertical partitions partially divides the gastrovascular cavity into a number of connected chambers. The partitions increase the surface area for digestion, enabling an anemone to digest an ani-

FIGURE **28-10** ***Obelia*, a marine colonial hydrozoan.**

The free-swimming medusae reproduce sexually, and the zygote develops into a planula larva. The larva develops into a polyp that forms a new colony. The colony grows as new polyps bud and remain attached.



mal as large as a crab. Although corals can capture prey, many tropical species depend for nutrition on photosynthetic algae *(zooxanthellae)* that live within cells lining the coral's digestive cavity (see Chapter 24 and Fig. 52-11). The relationship between coral and zooxanthellae is symbiotic and mutually beneficial. The algae provide the coral with oxygen and with carbon and nitrogen compounds. In exchange, the coral supplies the algae with waste products such as ammonia, from which the algae make nitrogenous compounds for both partners.

In warm, shallow seas, much of the bottom is covered with coral or anemones, most of them brightly colored. Coral reefs consist of colonies of millions of corals, and of certain algae (mainly coralline red algae). Living colonies occur only in the uppermost regions of such reefs, adding their own skeletons to the forming rock. Coral reefs are among the most productive of all ecosystems, rivaling tropical rain forests in species diversity (see Chapter 54). A single reef can serve as home for more than 3000 species of fishes and other marine organisms, and an estimated one fourth of all marine species depend on coral reefs.

During the past several years many coral reefs, especially those in coastal waters, have suffered serious damage from human activities. These include overfishing, mining reefs for building materials, polluting coastal waters with industrial chemicals, and smothering coral with the silt washed downstream from clearcut forests. **Coral bleaching** is the stress-induced loss of the colorful symbiotic algae (zooxanthellae) that inhabit coral cells (Fig. 28-11). Without their algae, coral become malnourished and die. Environmental factors suspected to contribute to coral bleaching include unusually high (associated with global warming) or low temperatures, pollution, changes in salinity, disease, and high doses of ultraviolet radiation (associated with the destruction of the ozone layer).

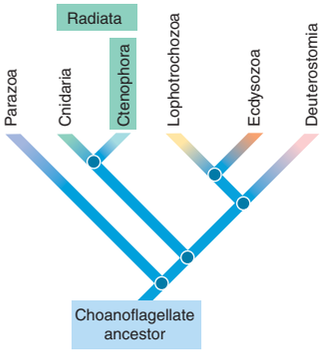
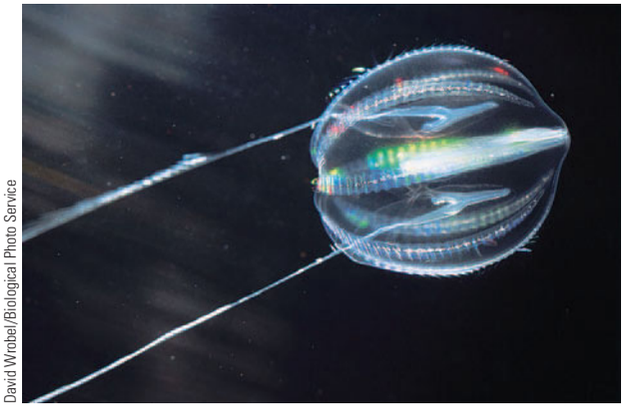
Comb jellies have adhesive glue cells that trap prey

The 100 or so species of comb jellies, members of phylum **Ctenophora,** all are marine. They are fragile, luminescent animals that may be as small as a pea or larger than a tomato. The outer surface of a ctenophore bears eight rows of cilia, resembling combs (Fig. 28-12). The coordinated beating of the cilia in these combs moves the animal through the water. A sense organ functions in balance and helps the animal orient itself. Some ctenophores have two tentacles. They do not have the stinging nematocysts characteristic of the cnidarians. However, their tentacles are equipped with adhesive glue cells, that trap prey.

Ctenophores are biradially symmetrical, meaning you could obtain equal halves by cutting through the body axis in two different ways. Because of their radial symmetry and feeding tentacles, the ctenophore body plan is somewhat similar to that of a cnidarian medusa. Ctenophores are also like cnidarians in that they consist of two cell layers separated by a thick, jelly-like mesoglea. Because of these similarities, biologists classify ctenophores near the cnidarians. However, their development is





David Wrobel/Biological Photo Service

FIGURE **28-12** **Ctenophore (comb jelly).**
Ctenophores are free-swimming, bioluminescent hermaphrodites capable of self-fertilization. The sea gooseberry (*Pleurobrachia*) has two long tentacles with adhesive cells used to capture prey.

different, and unlike cnidarians, their digestive system has a mouth for food intake at one end and two anal pores for the egestion of water and wastes at the other end. The similarities between ctenophores and cnidarians may be a result of convergent evolution from living in a similar environment, the ocean. Where, then, do the ctenophores belong on our cladogram (see Fig. 28-5)? Systematists will decide as they gather new data.

Review

- In what ways do cnidarians differ from sponges?
- Draw the life cycle of *Obelia.*
- How is a ctenophore like a cnidarian? In what ways is it different?

BiologyNow™ Assess your understanding of **the Radiata** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 List several characteristics common to most animals.

- Members of **kingdom Animalia** are eukaryotic, multicellular, **heterotrophic** organisms with cells specialized to perform specific functions. Typically, they are capable of locomotion at some time during their life cycle, can respond adaptively to external stimuli, and can reproduce sexually.
- In sexual reproduction, sperm and egg unite to form a **zygote** that undergoes **cleavage.** Multiple cell divisions result in the development of a hollow ball of cells, a **blastula.** The blastula undergoes **gastrulation,** forming embryonic tissues.

2 Compare the advantages and disadvantages of life in the ocean, in fresh water, and on land.

- Marine environments have relatively stable temperatures, provide buoyancy, and provide readily available food. Fluid and salt balance are more easily maintained than in fresh water. Currents and other water movements are a disadvantage.
- Fresh water offers a less constant environment and less food. Because fresh water is hypotonic to tissue fluid, animals must osmoregulate.
- Terrestrial animals must avoid dessication, deal with temperature changes, and protect gametes and embryos.

3 Critique the use of type of symmetry and type of body cavity to infer relationships among animal phyla.

- Many biologists have used the type of **body plan,** the basic structure of the body, to infer evolutionary relationships. For example, they hypothesized that cnidarians and ctenophores were closely related because they share **radial symmetry;** most other animals are **bilaterally symmetrical,** at least in their larval stages. However, analysis of more recent data suggests that cnidarians and ctenophores are not closely related. Adult echinoderms also have radial symmetry and are not related to these groups.
- Biologists have also inferred relationships based on level of tissue development and type of body cavity. Embryonic tissues, called **germ layers,** include the outer **ectoderm** which gives rise to the body covering and the nervous system; the inner, **endoderm,** which lines the gut and other digestive organs; and a middle, **mesoderm,** which gives rise to most other body structures.
- **Triploblastic** animals have traditionally been classified as **acoelomate** (no body cavity), **pseudocoelomate** (body cavity not completely lined with mesoderm), or **coelomate,** those with a true **coelom,** a body cavity completely lined with mesoderm. Recent data indicate pseudocoelomate animals do not form a natural group and probably evolved from coelomate ancestors.

4 Describe the distinguishing characteristics of the three major clades of coelomate animals: Lophotrochozoa, and Ecdysozoa, and Deuterostomia.

- Two major evolutionary branches of coelomates are **Protostomia** (mollusks, annelids, arthropods) and **Deuterostomia** (echinoderms and chordates). In protostomes the blastopore develops into the mouth; in deuterostomes the blastopore typically becomes the anus.
- Based on molecular data, many biologists now subdivide the protostomes into two clades, the **Lophotrochozoa** and the **Ecdysozoa.** The Lophotrochozoa include the platyhelminthes (flat worms), nemerteans (ribbon worms), mollusks, annelids, the lophophorate phyla (groups that have a ciliated ring of tentacles surrounding the mouth), and rotifers. The Ecdysozoa, animals that molt, include the nematodes and arthropods.

5 Identify distinguishing characteristics of phylum Porifera.

- Phylum **Porifera** consists of the sponges, animals characterized by flagellate **collar cells (choanocytes).** Sponges are the only members of the **Parazoa.**
- The sponge body is a sac with tiny openings through which water enters; a central cavity, or **spongocoel;** and an open end, or **osculum,** through which water exits. The cells of sponges are loosely associated; they do not form true tissues.

6 Identify distinguishing characteristics of phylum Cnidaria, describe three main classes of this phylum, and give examples of animals that belong to each class.

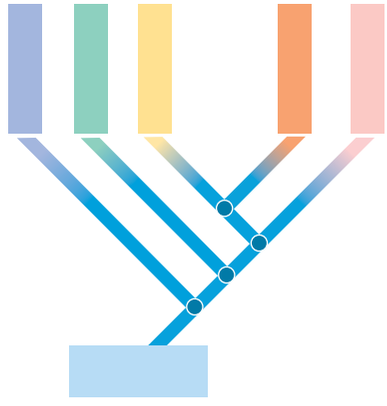
- Phylum **Cnidaria** is characterized by radial symmetry, two tissue layers, and **cnidocytes,** cells that contain stinging organelles called **nematocysts.** The **gastrovascular cavity** has a single opening that serves as both mouth and anus. Nerve cells form irregular, nondirectional **nerve nets** that connect sensory cells with contractile and gland cells.
- The life cycle of many cnidarians includes a sessile **polyp** stage and a free-swimming **medusa** stage.
- Phylum Cnidaria includes three main classes. Class **Hydrozoa** (hydras, hydroids, and the Portuguese man-of-war) are typically polyps and may be solitary or colonial. Class **Scyphozoa** (the jellyfish) are generally medusae. Class **Anthozoa** (sea anemones and corals) are polyps and may be solitary or colonial; anthozoans differ from hydrozoans in the organization of the gastrovascular cavity.

7 Identify distinguishing characteristics of phylum Ctenophora.

- Phylum **Ctenophora** consists of the comb jellies, which are fragile, luminescent marine predators with biradial symmetry, and eight rows of cilia that resemble combs. They are diploblastic and have tentacles with adhesive glue cells.

POST-TEST

1. Which of the following is *not* a defining characteristic of animals? (a) heterotrophs (b) multicellular (c) eukaryotic (d) presence of a coelom (e) form a zygote that undergoes cleavage
2. Which of the following is *not* an adaptation to terrestrial living? (a) internal fertilization (b) shell surrounding egg (c) adaptations for maintaining body temperature (d) surface for gas exchange deep in body (e) ability to maintain location
3. The Parazoa (a) are coelomates (b) include cnidarians (c) include all animals with radial symmetry (d) do not form true tissues (e) have a pseudocoelom
4. Cephalization (a) evolved along with bilateral symmetry (b) is the development of a digestive system (c) is characteristic of cnidarians (d) involves a concentration of excretory organs (e) first evolved in deuterostomes
5. The germ layer that gives rise to the outer covering of the body and the nervous system is the (a) gastrodermis (b) ectoderm (c) contractile layer (d) endoderm (e) mesoderm
6. Radial symmetry is characteristic of (a) protostomes (b) acoelomates (c) deuterostomes (d) cnidarians (e) Porifera
7. A true coelom is completely lined with (a) flagella (b) ectoderm (c) a contractile layer (d) endoderm (e) mesoderm
8. Protostomes are characterized by (a) spiral cleavage (b) indeterminate cleavage (c) enterocoely (d) radial symmetry (e) a distinctive body plan that includes a pseudocoelom
9. The evolution of animals (a) followed an orderly progression from simple to complex (b) will be better understood as biologists continue to collect molecular and other types of data (c) has been determined by studying classification (d) began with the placozoans (e) began with their common ancestor, a cnidarian
10. During cleavage, an animal (a) undergoes metamorphosis (b) becomes a larva (c) undergoes a series of mitotic divisions and becomes a blastula (d) becomes diploid (e) reproduces sexually
11. Collar cells (choanocytes) are characteristic of phylum (a) Porifera (b) Cnidaria (c) Coelomata (d) Lophotrochozoa (e) Ecdysozoa
12. Which of the following is an example of a deuterostome? (a) a lophotrochozoan (b) coral (c) chordate (d) planarian (e) a pseudocoelomate
13. Cnidocytes are (a) characteristic of sponges (b) found among cells lining the gastrovascular cavity (c) contain stinging organelles (d) are lined with mesoderm (e) have two main shapes
14. The marine hydrozoan *Obelia* (a) is seen mainly in the medusa form (b) lacks cnidocytes (c) has reproductive polyps that produce eggs and sperm (d) is one of the largest jellyfish known (e) alternates sexual and asexual stages during its life cycle
15. Corals (a) are coelomates (b) form symbiotic relationships with certain algae (c) lack a polyp stage (d) are remarkably resistant to environmental stressors (e) have bilateral symmetry
16. Ctenophores (a) tend to be sessile (b) have a digestive system with only one opening (c) exhibit bilateral symmetry (d) are characterized by adhesive glue cells on their tentacles (e) are free-swimming polyps
17. Label the branches of the diagram. Use Figure 28-5 to check your answers.



CRITICAL THINKING

1. Imagine you discover a new animal in a rain forest. How would you decide to which phylum it belongs? What are some characteristics that might contribute to your decision?
2. Several international monitoring projects are gathering data to help us understand coral reef destruction. Why is it important to take action to protect coral reefs?

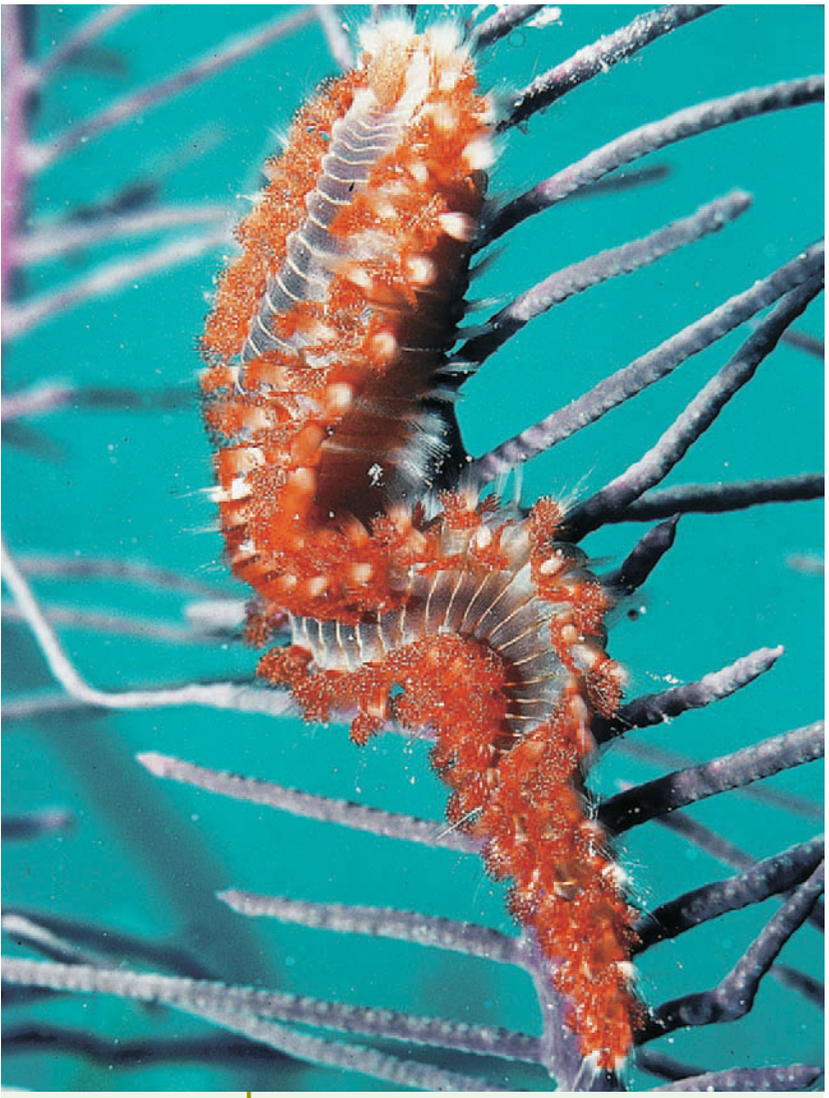
The Animal Kingdom: The Protostomes



Marty Snyderman/Visuals Unlimited

A bearded fireworm (*Hermodice carunculata*). The fireworm is a segmented worm (an annelid) up to 30 cm (11.8 in) in length. It lives in shallow marine waters—in coral reefs, beds of turtle grass, or under rocks. Fireworm bristles, which are filled with venom, can break off in the skin, causing irritation.

CHAPTER OUTLINE

- The Lophotrochozoa
- The Ecdysozoa

The **coelom,** one of the most important early animal adaptations, is a fluid-filled body cavity completely lined by mesoderm that lies between the digestive tube and the outer body wall (see Chapter 28). Evolution of the coelom produced a new body design, a **tube-within-a-tube plan.** The digestive tube (the inner tube) is attached to the body wall (the outer tube) at its ends. Typically, the digestive tube has a mouth at one end and an anus for eliminating wastes at the other end. Because the coelom separates the muscles of the body wall from those in the wall of the digestive tract, the digestive tube can move food along independently of body movements.

Animals with a coelom, and to a lesser extent those with a pseudocoelom, have another major advantage over acoelomate animals. Because it is an enclosed compartment (or series of compartments) of fluid under pressure, the coelom can serve as a **hydrostatic skeleton** in which contracting muscles push against a tube of fluid. In many coelomates, such as the fireworm shown here, a hydrostatic skeleton permits a greater range of movement than in acoelomate animals. The evolution of various shapes and divisions of the coelom provided the opportunity for animals to become specialized in swimming, crawling, or walking. Animals that can move quickly to capture food or avoid predators are more likely to survive. The hydrostatic skeleton also shapes the body of soft animals.

Evolution of the coelom provided a space where internal organs could develop. Most coelomate animals have well-developed circulatory, excretory, and nervous systems. Many internal organs are suspended within folds of the tissue lining the coelom and can move independently of the outer body wall. For example, the pumping action of the heart is possible because of the surrounding space the coelom provides. The fluid-filled coelom protects internal organs by cushioning them. The coelom also provides space for the gonads to develop. During the breeding season of many animals, such as birds, the gonads enlarge within the coelom as they fill with ripe gametes.

In some animals, fluid within the coelom helps transport materials such as food, oxygen, and wastes. Cells bathed by the coelomic fluid can exchange materials with it. The cells receive nutrients and oxygen from the coelomic fluid and excrete wastes into it. Some coelomates have excretory structures that remove wastes directly from the coelomic fluid.

Recall from Chapter 28 that animals with a coelom form two major branches: protostomes and deuterostomes, and that the **protostome coelomates** evolved along two branches: the Lophotrochozoa and the Ecdysozoa. These groups are sometimes referred to as *superphyla.* In this chapter we discuss the evolution, relationships, body plans, and life histories of several groups of the Lophotrochozoa and Ecdysozoa. ■

THE LOPHOTROCHOZOA

Learning Objectives

1. Characterize the protostome coelomates, describe their two main evolutionary branches, and give examples of animals assigned to each branch.
2. Identify distinguishing characteristics of phylum Nemertea and phylum Platyhelminthes; describe the main classes of phylum Platyhelminthes, giving examples of animals that belong to each class.
3. Describe the adaptive advantages of cephalization.
4. Describe the distinguishing characteristics of phylum Mollusca, and describe the classes discussed, giving examples.
5. Describe the distinguishing characteristics of phylum Annelida, and describe the three classes of annelids discussed, giving examples.
6. Describe the distinguishing characteristics of the lophophorate phyla.

The **Lophotrochozoa** include the platyhelminthes, nemerteans (ribbon worms), mollusks, annelids, the lophophorate phyla, and the rotifers (see Fig. 28-5). The name Lophotrochozoa comes from the names of the two major animal groups included: the Lophophorata and the Trochozoa. The *Lophophorata* include the lophophorate phyla, which are characterized by a lophophore, a ciliated ring of tentacles surrounding the mouth. The name *Trochozoa* refers to the trochophore larva that characterizes its two major groups—the mollusks and annelids.

Flatworms are bilateral acoelomates

Members of phylum **Platyhelminthes,** the **flatworms,** are flat, elongated, acoelomate animals that are bilaterally symmetrical. These soft-bodied animals left few fossils to provide clues to their evolutionary history. Biologists have historically assigned the 20,000 species to four classes. Class **Turbellaria** consists of the free-living flatworms, including planarians and their relatives. Classes **Trematoda** and **Monogenea** include the flukes, which are either internal or external parasites. Class **Cestoda** includes the tapeworms, which as adults are intestinal parasites of vertebrates (Table 29-1).

PROCESS OF SCIENCE

You may wonder why, if flatworms are acoelomate animals, we classify them as lophotrochozoans, which are coelomate animals. Molecular data, specifically 18S ribosomal RNA sequences, indicate phylum Platyhelminthes is not a monophyletic group. The flatworms known as *acoels,* traditionally classified in one order of class Turbellaria, differ significantly from other flatworms. The acoels may be closely related to the common ancestor that linked radially symmetrical animals with bilateral animals. Other flatworms appear more closely related to coelomates. If so, their body plan became simplified later in their evolutionary history. As biologists consider new data, their assessment of the phylogenetic relationships of flatworms may change.

Flatworms exhibit *bilateral symmetry* and have definite anterior and posterior ends. The beginnings of **cephalization** are evident. A simple brain and paired sense organs are concentrated at the anterior end. An animal with a front end ("head") generally moves forward. With a concentration of sense organs in the part of the body that first meets its environment, the animal can find food or detect an enemy quickly.

Flatworms are triploblastic (have all three germ layers) and have *three definite tissue layers.* In addition to an outer epidermis derived from ectoderm, and an inner endodermis derived from endoderm, the flatworm has a middle tissue layer that develops from mesoderm. Flatworms have no organs for circulation or gas exchange. These functions depend largely on diffusion through the body wall. The activities of some organs are coordinated, and form simple organ systems, for example, the digestive and nervous systems. As in the cnidarians, the digestive system has only one opening, a mouth. The *gastrovascular cavity* is often extensively branched.

Flatworms typically have a simple **nervous system.** The brain consists of two masses of nervous tissue, called **ganglia,** in the head region. In many species, the ganglia connect to two nerve cords that extend the length of the body. This nervous system is

TABLE 29-1 Classes of Phylum Platyhelminthes

Class and Representative Animals	Characteristics
Turbellaria Planarians	Mainly free-living; mainly marine; body covered by ciliated epidermis; typically carnivorous; prey on tiny invertebrates.
Trematoda and Monogenea Flukes	All parasites with a wide range of vertebrate and invertebrate hosts; may require intermediate hosts; adults have suckers for attachment to host.
Cestoda Tapeworms	Parasites of vertebrates; complex life cycle usually with one or two intermediate hosts; larval host may be invertebrate; typically have suckers and sometimes hooks for attachment to host; eggs produced within proglottids, which are shed; no digestive or nervous systems.

sometimes referred to as a "ladder-type nervous system," because a series of nerves connects the cords like the rungs of a ladder.

Parasitic flatworms—flukes and tapeworms—are highly adapted to and modified for their parasitic lifestyle. They have suckers or hooks for holding onto their hosts. The bodies of those that live in digestive tracts resist the digestive enzymes secreted by their hosts. Many have complicated life cycles and produce large numbers of eggs. Other adaptations include the loss of certain structures such as sense organs. Tapeworms have also lost the digestive system.

Planarians are free-living flatworms

Most members of class Turbellaria are free-living flatworms. Most are marine, but many inhabit freshwater habitats, and some are terrestrial. Turbellarian flatworms typically have a muscular pharynx that takes in food; a simple brain, eyespots and other sensory organs in the head; **protonephridia,** structures that function in osmoregulation and metabolic waste disposal (excretion); and complex reproductive organs. **Planarians** are turbellarian flatworms found in ponds and quiet streams throughout the world. The common American planarian *Dugesia* is about 15 mm (0.6 in) long, with what appear to be crossed eyes and flapping "ears" called **auricles** (Fig. 29-1). The auricles actually serve as organs of chemoreception, important in locating food.

Planarians are carnivorous, trapping small animals in a mucous secretion. The digestive system consists of a single opening (the mouth), a tubelike, muscular **pharynx** (the first portion of the digestive tube), and a branched gastrovascular cavity. A planarian projects its pharynx outward through its mouth, using it to suck in prey. The long, highly branched gastrovascular cavity distributes food to all parts of the body, so each cell can receive nutrients by diffusion.

Although excretion also takes place mainly by diffusion, some metabolic wastes are excreted by the *protonephridia.* These structures function primarily in fluid balance, or *osmoregulation.* Protonephridia are blind tubules that end in **flame bulbs,** collecting cells equipped with cilia. The beating of the cilia channels waste through the system of tubules and eventually out of the body through excretory pores. Osmoregulation and protonephridia are discussed further in Chapter 46 (see Fig. 46-3).

Planarians are capable of learning. Memory is not localized within the ganglia but appears to be retained throughout the nervous system. Planarians reproduce either asexually or sexually. In asexual reproduction, an individual constricts in the middle and divides into two planarians. Each regenerates its missing parts. Sexually, these animals are **hermaphrodites.** During the warm months of the year, each is equipped with a complete set of male and female organs. Two planarians come together in copulation and exchange sperm cells so that their eggs are cross-fertilized.

Flukes parasitize other animals

Although their body plan resembles that of the free-living flatworms, the **flukes,** members of classes Trematoda and Monogenea, have structures, such as hooks and suckers, for attachment to the host. Flukes also have extremely complex and prolific reproductive organs.

Flukes that are parasitic in humans include blood flukes, widespread in tropical areas of the world, and liver flukes, common in Asia, particularly in areas where humans use their own feces for fertilizing crops. Blood flukes of the genus *Schistosoma* infect about 200 million people who live in tropical areas. Both blood flukes and liver flukes go through complicated life cycles involving a number of different forms, alternation of sexual and asexual stages, and parasitism on one or more intermediate hosts (such as snails and fishes) (Fig. 29-2). The aquatic snails that serve as intermediate hosts thrive in ponds, rice paddies, and marshy areas that form when dams are built.

Tapeworms inhabit the intestine of vertebrates

Adult members of the more than 5000 different species of class Cestoda live as parasites in the intestine of probably every kind

FIGURE **29-1** **The common planarian, *Dugesia*.**

BiologyNow™ Watch **the fluke life cycle** by clicking on this figure on your BiologyNow CD-ROM.

of vertebrate, including humans. Tapeworms are long, flat, ribbon-like animals strikingly specialized for their parasitic mode of life. Among their many adaptations are suckers and sometimes hooks on the "head," or **scolex,** that enable the parasite to attach to the host's intestine (Fig. 29-3).

The reproductive adaptations and abilities of tapeworms are extraordinary. The body of the tapeworm consists of a long

FIGURE **29-3** ▶ **Scolex of the tapeworm.**

The small tapeworm (***Acanthrocirrus retrisrostris***) reaches maturity in the intestine of wading birds that eat barnacles. The color-enhanced SEM shows the piston-like cluster of hooks that can be withdrawn into the head or thrust out and buried in the host's tissue. Beneath the hooks, two of the four powerful suckers are visible.

chain of segments called **proglottids.** Each proglottid is an entire reproductive machine equipped with both male and female reproductive organs and containing up to 100,000 eggs. Because an adult tapeworm may have as many as 2000 segments, its reproductive potential is staggering. A single tapeworm can produce 600 million eggs in a year. Proglottids farthest from the tapeworm's head contain the ripest eggs; these segments are shed from the host's body along with the feces.

The tapeworm has no mouth or digestive system. Digested food from the host is absorbed across the worm's body wall. The tapeworm also lacks well-developed sense organs. Some tapeworms have complex life cycles, spending their larval stage within the body of an intermediate host and their adult life within the body of a different, final host. Figure 29-4 illustrates the life cycle of the beef tapeworm, which can infect humans when they eat undercooked beef containing the larvae.

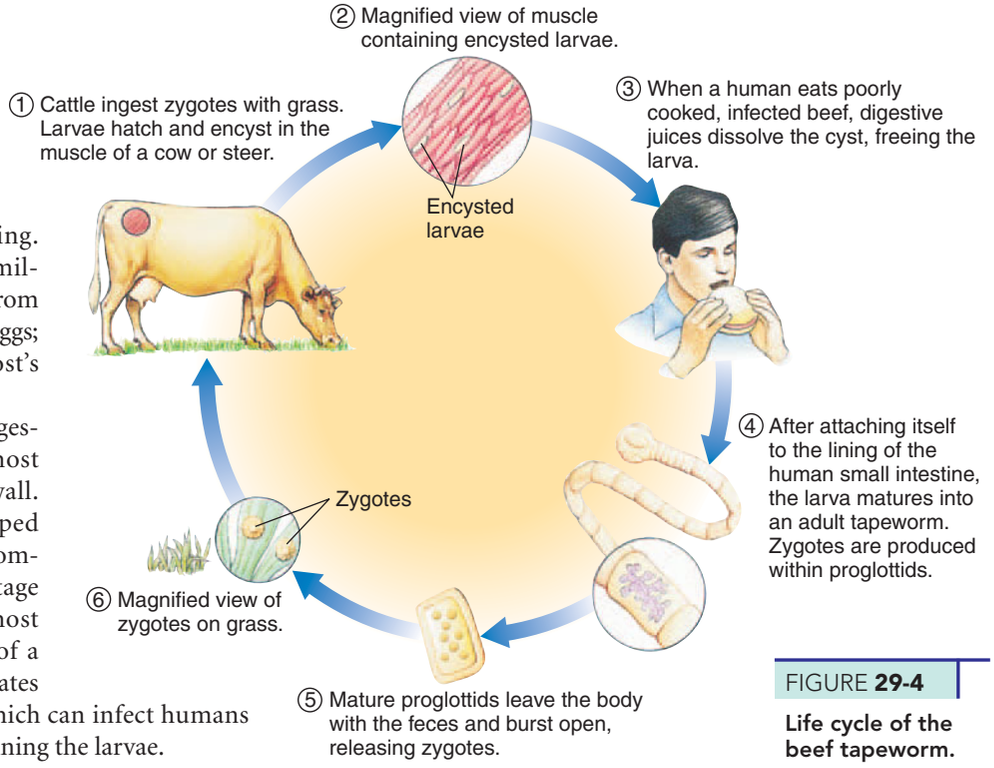

FIGURE **29-4**
Life cycle of the beef tapeworm.

Phylum Nemertea is characterized by the proboscis

Phylum **Nemertea,** the ribbon worms or proboscis worms, is a relatively small group (about 1150 species) of free-living animals (Fig. 29-5). Almost all are marine, although a few inhabit fresh water or damp soil. They are carnivorous, feeding on crustaceans and other worms. Nemerteans have long narrow bodies, either cylindrical or flattened, generally ranging in length from 5 cm (2 in) to about 2 m (6.5 ft), although some are much longer. Some are a vivid orange, red, or green, with black or colored stripes.

Their most remarkable organ, the **proboscis,** from which they get one of their common names, *proboscis worms,* is a long, hollow, muscular tube that can be rapidly everted (turned inside out) from the anterior end of the body. The proboscis wraps around prey. In some species it is sharp, and in various species it secretes toxic fluid that immobilizes prey. The proboscis is a *derived character* that distinguishes nemerteans from all other invertebrate groups.

Historically, the nemerteans were of special evolutionary interest because biologists thought they were the earliest animals to have a circulatory system and a tube-within-a-tube body plan. Nemerteans have no heart; blood is circulated by contractions of muscular blood vessels and by movements of the body. Although the nemerteans are functionally acoelomate, the chamber surrounding the proboscis is a true coelomic space, known as a **rhynchocoel,** derived like the coelom in coelomate protostomes (see Chapter 28). The system of blood vessels is probably homologous to the coelom of other coelomate animals. Biologists now view the rhyncocoel as a remnant of the coelom of a coelomate ancestor. Because of its presence and recent molecular evidence, biologists now classify nemerteans with the lophotrochozoans.

Mollusks have a muscular foot, visceral mass, and mantle

Phylum **Mollusca** includes clams, oysters, snails, slugs, octopods, and the largest of all the invertebrates, the giant squid, which averages 9 to 16 m (about 30–53 ft) in length, including its tentacles. More than 50,000 living species and 35,000 fossil species (second only to the arthropods in number) have been described. Representative mollusks are illustrated in Figure 29-6. In this chapter we discuss four of the eight recognized classes and list them in Table 29-2.

Although most mollusks are marine, many snails and clams live in fresh water, and some species of snails and slugs inhabit the land. Mollusks probably evolved early in the history of the protostome clade, soon after the evolution of the coelom but before the origin of the segmented body that is characteristic of annelids. Although mollusks vary widely in outward appearance, most share certain basic characteristics:

1. A soft body, usually covered by a dorsal shell composed mainly of calcium carbonate.
2. A broad, flat, muscular **foot,** located ventrally, which is used for locomotion.
3. The body organs (viscera) concentrated as a **visceral mass** located above the foot.
4. A **mantle,** a thin sheet of tissue that covers the visceral mass and usually contains glands that secrete a shell. The mantle

FIGURE **29-5** **Nemerteans (proboscis worms).**

(b) Lateral view of a typical nemertean. Note the complete digestive tract that extends from mouth to anus, giving this animal a tube-within-a-tube body plan.

generally overhangs the visceral mass, forming a mantle cavity that contains gills and other structures.

5. A rasplike structure called a **radula,** which is a belt of teeth in the mouth region. (The radula is not present in clams or their relatives, which are suspension feeders.)
6. The coelom is generally reduced to small compartments around certain organs, including the heart and excretory organs *(metanephridia)*. The main body cavity is typically a **hemocoel,** a space containing blood (see following discussion of open circulatory system).

Mollusks have all organ systems typical of complex animals. The digestive system is a tube, often coiled, consisting of a mouth, buccal cavity (mouth cavity), esophagus, stomach, intestine, and anus. The mollusk radula, located within the buccal cavity, projects out of the mouth and is used to scrape particles of food from the surface of rocks or the ocean floor. Sometimes the radula is used to drill a hole in the shell of a prey animal or to tear off pieces of a plant.

Most mollusks have an **open circulatory system** in which the blood, called **hemolymph,** bathes the tissues directly. The heart pumps blood into a single blood vessel, the aorta, which may branch into other vessels. Eventually blood flows into a network of large spaces called *sinuses,* where the tissues are bathed directly; this network makes up the hemocoel, or blood cavity. From the sinuses, blood drains into vessels that conduct it to the gills, where it is recharged with oxygen. After passing through the gills, the blood returns to the heart. Thus, blood flow in a mollusk follows the pattern:

Heart ⟶ aorta ⟶ smaller blood vessels ⟶ blood sinuses (hemocoel) ⟶ blood vessels to gills ⟶ heart

In open circulatory systems, blood pressure tends to be low, and tissues are not very efficiently oxygenated. Because most mollusks are slow-moving animals with low metabolic rates, this type of circulatory system is adequate. The active cephalopods (the class that includes the squids and octopods), have a **closed circulatory system,** in which blood flows through a complete circuit of blood vessels.

Most marine mollusks pass through one or more larval stages. The first larval stage is typically a **trochophore larva,** a free-swimming, top-shaped larva with two bands of cilia around its middle (Fig. 29-7). In many mollusks (gastropods

TABLE **29-2** **Major Classes of Phylum Mollusca**

Class and Representative Animals	Characteristics
Polyplacophora Chitons	Primitive marine animals with shell consisting of eight separate transverse plates; head reduced; broad foot used for locomotion.
Gastropoda Snails, slugs, nudibranchs	Marine, freshwater, or terrestrial; coiled shell in many species; torsion of visceral mass; well-developed head with tentacles and eyes.
Bivalvia Clams, oysters, mussels	Marine or freshwater; body laterally compressed; two-part shell hinged dorsally; hatchet-shaped foot; suspension feeders.
Cephalopoda Squids, octopods	Marine; predatory; foot modified into tentacles, usually bearing suckers; well-developed eyes; closed circulatory system.

FIGURE **29-7** **A trochophore larva.**

The first larval stage of a marine mollusk, the trochophore larva, is also characteristic of annelids. Just above the mouth a characteristic band of ciliated cells functions as a swimming organ and, in some species, collects suspended food particles.

such as snails and bivalves such as clams), the trochophore larva develops into a **veliger larva,** which has a shell, foot, and mantle. The veliger larva is unique to the mollusks.

Chitons may be similar to ancestral mollusks

Class **Polyplacophora** (meaning "many plates") consists of the **chitons,** sluggish marine animals with flattened bodies (see Fig. 29-6a). Their most distinctive feature is a shell composed of eight separate but overlapping dorsal plates. The head is reduced, and there are no eyes or tentacles.

The chiton inhabits rocky intertidal zones, using its broad, flat foot to move and to hold firmly onto rocks. By pressing its mantle against the substratum and lifting the inner edge of the mantle, the chiton can produce a partial vacuum. The resulting suction lets the animal adhere powerfully to its perch. Using its radula for grazing, the chiton scrapes algae and other small organisms off rocks and shells.

Gastropods are the largest group of mollusks

Class **Gastropoda,** which includes snails, slugs, and their relatives, is the largest and most diverse group of mollusks (see Fig. 29-6b). In fact, with more than 40,000 extant species, gastropods comprise the second largest class in the animal kingdom, second only to insects. Most gastropods inhabit marine waters, but others make their homes in brackish or fresh water, or on land. We think of snails as having a single, spirally coiled shell into which they can withdraw the body, and many do. However, other gastropods, such as limpets, have shells like flattened dunce caps. Still others, such as garden slugs and the beautiful marine slugs known as **nudibranchs,** have no shell at all (Fig. 29-8).

Bruce Watkins/Animals Animals

FIGURE **29-8** **Nudibranch.**

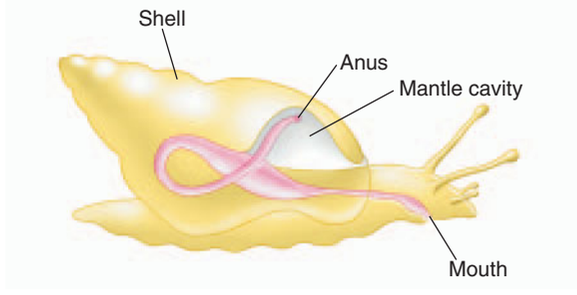
(a) A nudibranch (*Chromodoris porterae*) feeds on a lightbulb tunicate (*Clavelina huntsmani*).

Many gastropods have a well-developed head with tentacles. Two simple eyes may be located on stalks that extend from the head. The gastropod uses its broad, flat foot for creeping. Most land snails do not have gills. Instead, the mantle is highly vascularized and functions as a lung. Biologists describe these garden snails and slugs as **pulmonate** ("having a lung").

Torsion, a twisting of the visceral mass, is a unique feature of gastropods. This twisting is unrelated to the coiling of the shell. As the bilateral larva develops, one side of the visceral mass grows more rapidly than the other side. This uneven growth rotates the visceral mass. The visceral mass and mantle twist permanently up to 180 degrees relative to the head. As a result, the digestive tract becomes somewhat U-shaped, and the anus comes to lie above the head and gill (Fig. 29-9). Subsequent growth is dorsal and usually in a spiral coil. Torsion limits space in the body, and typically the gill, metanephridium (excretory organ), and gonad are absent on one side. Some biologists hypothesize that torsion is an adaptation that protects the head by allowing it to enter the shell first during withdrawal from potential predators. Without torsion, the foot would be withdrawn first.

FIGURE **29-9** **Embryonic torsion in a gastropod.**

As the bilateral larva develops, the visceral mass twists 180 degrees relative to the head. The digestive tube coils, and the anus becomes relocated near the mouth.



Bivalves typically burrow in the mud

Class **Bivalvia** includes the clams, oysters, mussels, scallops and their relatives (see Fig. 29-6c). Typically, the soft body of members of class Bivalvia is laterally compressed and completely enclosed by a two-part shell that hinges dorsally and opens ventrally (Fig. 29-10). This arrangement allows the hatchet-shaped foot to protrude ventrally for locomotion and for burrowing in mud. The two parts, or **valves,** of the shell are connected by an elastic ligament. Stretching of the ligament opens the shell. Large, strong adductor muscles attached to the shell permit the animal to close its shell.

The inner, pearly layer of the bivalve shell is made of calcium carbonate secreted in thin sheets by the epithelial cells of the mantle. Known as *mother-of-pearl,* this material is valued for making jewelry and buttons. Should a bit of foreign matter lodge between the shell and the mantle, the epithelial cells covering the mantle secrete concentric layers of calcium carbonate around the intruding particle. Many species of oysters and clams form pearls in this way.

Some bivalves, such as oysters, attach permanently to the substrate. Others burrow slowly through rock or wood, seeking protected dwellings. The shipworm, *Teredo,* a clam that damages dock pilings and other marine installations, is just looking for a home. A few bivalves, such as scallops, swim rapidly by clapping their two shells together with the contraction of a large adductor muscle (the part of the scallop that humans eat).

Clams and oysters are suspension feeders that trap food particles in sea water. They take water in through an extension of the mantle called the **incurrent siphon.** Water leaves by way of an **excurrent siphon.** As the water passes over the gills, mucus secreted by the gills traps food particles in the water. Cilia move the food to the mouth. An oyster can filter more than 30 L (about 32 quarts) of water per hour. As suspension feeders, bivalves have no radula, and indeed they are the only group of mollusks that lack this structure.

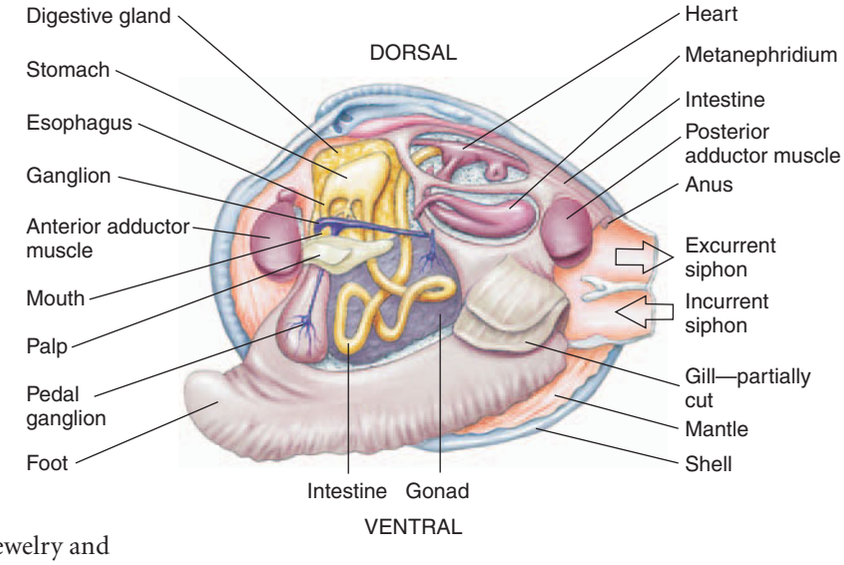


FIGURE **29-10** **Internal anatomy of a clam.**
The two shells of a bivalve hinge dorsally and open ventrally.

Cephalopods are active, predatory animals

In contrast with most other mollusks, members of the class **Cephalopoda** (meaning "head-foot") are fast-swimming predatory animals (see Fig. 29-6d). The cephalopod mouth is surrounded by tentacles, or arms: 8 in octopods, 10 in squids, and as many as 90 in the chambered nautilus. The large head has well-developed eyes that form images. Although they develop differently, the eyes are structurally similar to vertebrate eyes and function in much the same way. The octopus has no shell, and the shell of the squid is greatly reduced and is located inside the body.

Nautilus has a coiled shell consisting of many chambers built up over time. Each year the animal lives in the newest and largest chamber of the series. *Nautilus* secretes a mixture of gases similar to air into the other chambers. By regulating the amount of gas in the chambers, the animal controls its depth in the ocean.

The tentacles of squids, octopods, and cuttlefish are covered with suckers for seizing and holding prey. In addition to a radula, the mouth has two strong, horny beaks used to kill prey and tear it to bits. The mantle is thick and muscular and fitted with a funnel-like **siphon.** By filling the cavity with water and ejecting it through the siphon, the cephalopod achieves forceful jet propulsion. Squids and cuttlefish have streamlined bodies adapted for efficient swimming.

In addition to speed, the cephalopod has two other adaptations that facilitate escape from its predators, which include certain whales and moray eels. One is its ability to confuse the enemy by rapidly changing colors. By expanding and contracting *chromatophores,* cells in the skin that contain pigment granules, the cephalopod can display an impressive variety of mottled colors. Another defense mechanism is its **ink sac,** which produces a thick, black liquid the animal releases in a dark cloud when alarmed. While its enemy pauses, temporarily blinded and confused, the cephalopod escapes. The ink inactivates the chemical receptors of some predators, making them incapable of detecting their prey.

The octopus feeds on crabs and other arthropods, catching and killing them with a poisonous secretion of its salivary glands. During the day the octopus usually hides among the rocks; in the evening it emerges to hunt for food. Its motion is incredibly fluid, giving little hint of the considerable strength in its eight arms.

Small octopods survive well in aquariums and have been studied extensively. Because they are relatively intelligent and can make associations among stimuli, researchers have used them as models for studying learning and memory. Their highly adaptable behavior more closely resembles that of the vertebrates than the more stereotypic patterns of behavior seen in other invertebrates (see Chapter 50).

Annelids are segmented worms

Members of phylum **Annelida,** the segmented worms, have bilateral symmetry and a tubular body that may be partitioned into more than 100 ringlike segments. This phylum, composed of about 15,000 species, includes three main classes: the polychaetes, a group of marine and freshwater worms; the earthworms; and the leeches (Table 29-3 and Fig. 29-11).

The term *Annelida* (meaning "ringed") refers to the series of rings, or segments, that make up the annelid body. Both the body wall and many of the internal organs are segmented. Some structures, such as the digestive tract and certain nerves, extend the length of the body, passing through successive segments. Other structures, such as excretory organs, are repeated in each segment. In polychaetes and earthworms, segments are separated from one another internally by transverse partitions called **septa.**

One advantage of **segmentation** is that it facilitates locomotion. The coelom is divided into segments, and each segment has its own muscles. This arrangement allows the animal to elongate one part of its body while shortening another part. The annelid's hydrostatic skeleton is important in movement. In polychaetes and earthworms, bristle-like structures called **setae** (sing., *seta*), located on each segment, provide traction as the worm moves by alternating contraction of its longitudinal and circular muscles.

The annelid nervous system generally is a simple brain consisting of a pair of ganglia, and a ventral nerve cord. A pair of ganglia and lateral nerves are repeated in each segment. Annelids have a large, well-developed coelom, a closed circulatory system, and a complete digestive tract extending from mouth to anus. Respiration is *cutaneous,* that is, through the skin, or by gills. Typically, a pair of metanephridia (excretory tubules) is located in each segment (described in Chapter 46).

TABLE 29-3 Major Classes of Phylum Annelida

Class and Representative Animals	Characteristics
Polychaeta Sandworms, tubeworms	Mainly marine; each segment bears a pair of parapodia with many setae; well-developed head; separate sexes; trochophore larva.
Oligochaeta Earthworms	Terrestrial and freshwater worms; few setae per segment; lack well-developed head; hermaphroditic.
Hirudinea Leeches	Most are blood-sucking parasites that inhabit fresh water; appendages and setae absent; prominent muscular suckers.

Most polychaetes are marine worms with parapodia

Class **Polychaeta** includes marine worms that swim freely in the sea, burrow in the mud near the shore, or live in tubes they secrete or make by cementing bits of shell and sand together with mucus. Each body segment typically bears a pair of paddle-shaped appendages called **parapodia** (sing., *parapodium*) that function in locomotion and in gas exchange. These fleshy structures bear many stiff setae (the name *Polychaeta* means "many bristles"; see the fireworm in the chapter introduction). Most polychaetes have a well-developed head bearing eyes and antennae. The head may also be equipped with tentacles and palps (feelers). Polychaetes develop from free-swimming trochophore larvae similar to those of mollusks.

Many polychaete species have evolved behavioral patterns that ensure fertilization. By responding to certain rhythmic variations, or cycles, in the environment, nearly all the females

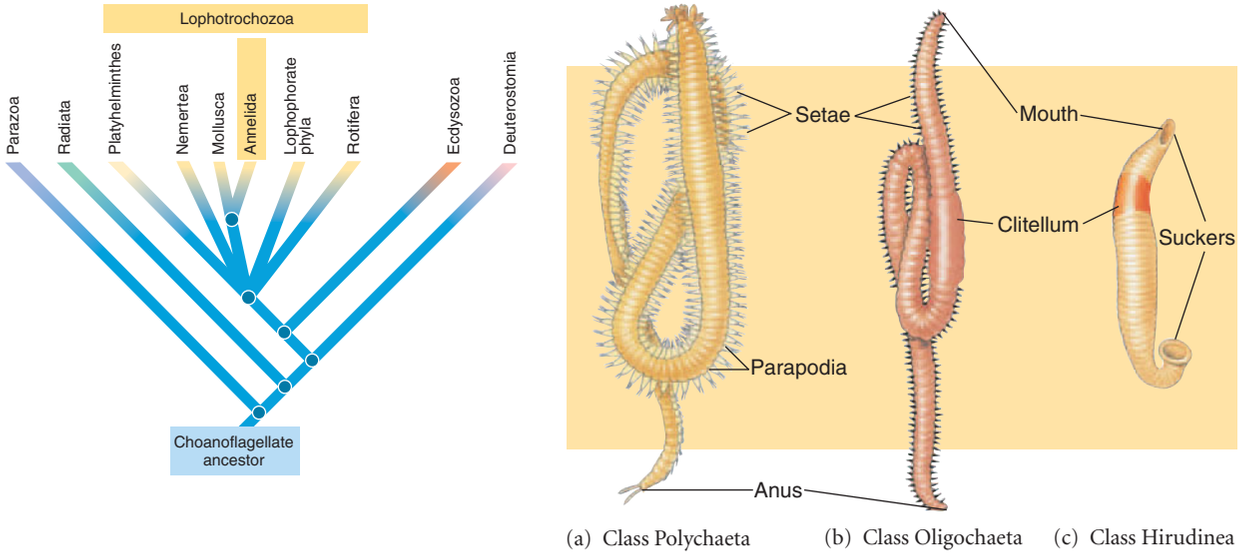

FIGURE 29-11 Three major classes of annelids.

and males of a given species release their gametes into the water at the same time. For example, more than 90% of reef-dwelling *Palolo* worms of the South Pacific shed their eggs and sperm within a 2-hour period on one night of the year. In this animal the seasonal rhythm limits the reproductive period, which is related to the lunar cycle and tides, to October or November. The posterior portion of the *Palolo* worm, loaded with eggs or sperm, breaks off from the rest of the body. It comes to the surface and bursts, releasing its gametes. Local islanders eagerly await this annual event when they can gather great numbers of the swarming polychaetes, which they bake or eat raw.

Earthworms help maintain fertile soil

The 3000 or so species of the class **Oligochaeta** live almost exclusively in fresh water and in moist terrestrial habitats. These worms lack parapodia, have few bristles per segment (the name *Oligochaeta* means "few bristles"), and lack a well-developed head. All oligochaetes are hermaphroditic.

Lumbricus terrestris, the common earthworm, is about 20 cm (8 in) long. Its body has more than 100 segments, separated externally by grooves that indicate the internal position of the septa (Fig. 29-12). The earthworm's body is somewhat protected from drying by a thin, transparent cuticle, secreted by the cells of the epidermis. Mucus secreted by gland cells of the epidermis forms an additional protective layer over the body surface. The body wall has an outer layer of circular muscles and an inner layer of longitudinal muscles.

An earthworm literally eats its way through the soil, ingesting its own weight in soil and nutritious decaying vegetation every 24 hours. Earthworms enhance the formation and maintenance of fertile soil. As they move about, earthworms turn and aerate the soil, and enrich it with nitrogenous wastes.

The earthworm processes its meal of soil in a complex digestive system. Food is swallowed through the muscular **pharynx** and passes through the **esophagus,** which is modified to form a thin-walled **crop** where food is stored and a thick-walled, muscular **gizzard.** In the gizzard, food is ground to bits as it moves among sand grains consumed along with the meal. The rest of the digestive system is a long, straight **intestine** that chemically digests food and absorbs nutrients. Wastes pass out of the intestine to the exterior through the **anus.**

The efficient, closed circulatory system consists of two main blood vessels that extend longitudinally. The dorsal blood vessel, just above the digestive tract, collects blood from vessels in the segments, then contracts to pump the blood anteriorly. In the region of the esophagus, five pairs of blood vessels propel blood from the dorsal to the ventral blood vessel. Located just below the digestive tract, the ventral blood vessel carries blood posteriorly. Small vessels branch from it and deliver blood to the various structures in each segment, as well as to the body wall. Within these structures blood flows through tiny capillaries before returning to the dorsal blood vessel.

Gas exchange takes place through the moist skin. Oxygen is transported by the respiratory pigment hemoglobin in the blood plasma (the liquid part of the blood). The excretory system consists of paired metanephridia, repeated in almost every segment of the body.

The nervous system consists of a pair of **cerebral ganglia** (a simple brain) just above the pharynx, and a subpharyngeal ganglion, just below the pharynx. A ring of nerve fibers connects these ganglia. From the lower ganglion a ventral nerve cord ex-

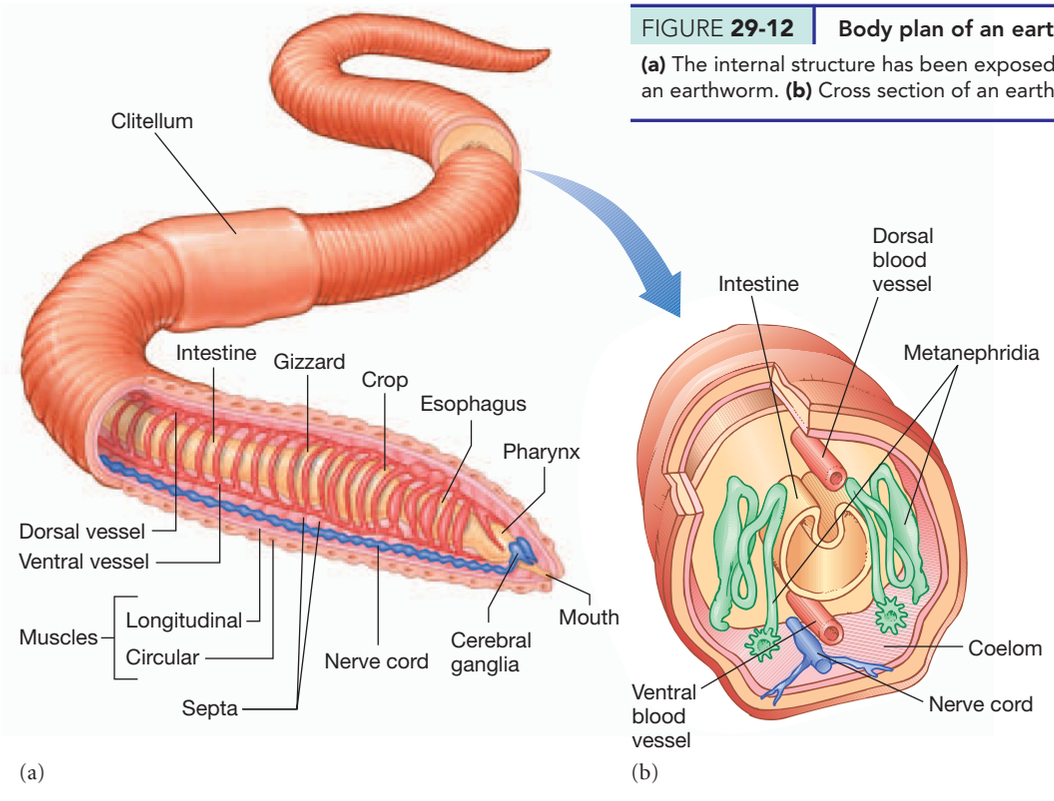

FIGURE **29-12** **Body plan of an earthworm.**

(a) The internal structure has been exposed at the anterior end of an earthworm. **(b)** Cross section of an earthworm.

tends beneath the digestive tract to the posterior end of the body. In each segment along the nerve cord is a pair of fused segmental ganglia. Nerves extend laterally from the segmental ganglia to the muscles and other structures of that segment. The segmental ganglia coordinate muscle contraction of the body wall, allowing the worm to creep along.

Like other oligochaetes, earthworms are hermaphroditic. During copulation, two worms, headed in opposite directions, press their ventral surfaces together. These surfaces become glued together by the thick mucous secretions of each worm's *clitellum,* a thickened ring of epidermis. Sperm are then exchanged and stored in the *seminal receptacles* (small sacs) of the other worm. A few days later each clitellum secretes a membranous cocoon containing a sticky fluid. As the cocoon is slipped forward, eggs are laid in it. Sperm are added as the cocoon passes over the openings of the seminal receptacles. As the cocoon slips free over the worm's head, its openings constrict so that a spindle-shaped capsule is formed. The fertilized eggs develop into tiny worms within this capsule. This complex reproductive pattern is an adaptation to terrestrial life; the cocoon protects the delicate gametes and young worms from drying out.

Many leeches are blood-sucking parasites

Most leeches, members of class **Hirudinea,** inhabit fresh water, but some live in the sea or in moist areas on land. About 75% of the known species of leeches are blood-sucking parasites. Some leeches are nonparasitic predators that capture small invertebrates such as earthworms and snails. Leeches differ from other annelids in having neither setae nor parapodia.

Leeches have muscular suckers at both anterior and posterior ends. Most parasitic leeches attach themselves to a vertebrate host, bite through the skin, and suck out a quantity of blood, which is stored in pouches in the digestive tract. *Hirudin,* an anticoagulant secreted by glands in the crop, ensures leeches a full meal of blood. In 30 minutes, a leech can suck out as much as ten times its own weight in blood. Some leeches feed only about twice each year because they digest their food slowly over several months.

Leeches have been used since ancient times for drawing blood from areas swollen by poisonous stings and bites. During the 19th century they were widely used to remove "bad blood," thought to be the cause of many diseases. Leeches are used in modern medicine to remove excess fluid and blood that accumulates within body tissues as a result of injury, disease, or surgery (Fig. 29-13). The leech attaches its sucker near the site of injury, makes an incision, and secretes hirudin. The hirudin prevents the blood from clotting and dissolves already existing clots.

The lophophorate phyla are distinguished by a ciliated ring of tentacles

Biologists are still debating the evolutionary position of the **lophophorate phyla**—Brachiopoda, Phoronida, and Bryozoa. With a few exceptions, lophophorates are marine animals adapted for life on the ocean floor. The **lophophore,** a ciliated ring of tentacles that surrounds the mouth, is specialized for capturing suspended particles in the water.

Brachiopods, or lampshells, are solitary marine animals that inhabit cold water. They superficially resemble clams and other bivalve mollusks because the body is enclosed between two shells (Fig. 29-14a). However, they differ from bivalve mol-

FIGURE **29-13** **Leeches.**

lusks in that the shells are dorsal and ventral, rather than lateral; each shell is symmetrical about the midline, and the two shell valves are typically of unequal size. Brachiopods attach to the substrate by a long stalk. Cilia on the lophophore beat, bringing water laden with food into the slightly opened shell. Although there are now only about 350 living species, brachiopods were abundant and diversified during the Paleozoic era. Paleobiologists have described about 30,000 fossil species.

Only about 12 extant species of **phoronids** are known. Some phoronids secrete tubes of sediment and live in them, extending their lophophores from their tubes for feeding. **Bryozoa,** or "moss animals," form sessile colonies by asexual budding (Fig. 29-14b). Their colonies, which can consist of millions of individuals, may appear plantlike. Other bryozoan colonies have the appearance of coral. About 5000 extant species are known.

Rotifers have a crown of cilia

Among the less familiar invertebrates are the "wheel animals" of phylum **Rotifera.** Although no larger than many protozoa, these aquatic, microscopic animals are multicellular. More than 1800 species have been described. Most inhabit fresh water, but some live in marine environments or damp soil. Rotifers were formerly classified as pseudocoelomates, but many biologists now hypothesize that rotifers evolved from animals with a coelom. Because they have a cuticle, some systematists classify them as ecdysozoans related to nematodes and arthropods. However, other systematists classify rotifers with the lophotrochozoans.

Rotifers have a characteristic crown of cilia on their anterior end. The cilia beat rapidly during swimming and feeding, giving the appearance of a spinning wheel (Fig. 29-15). Rotifers

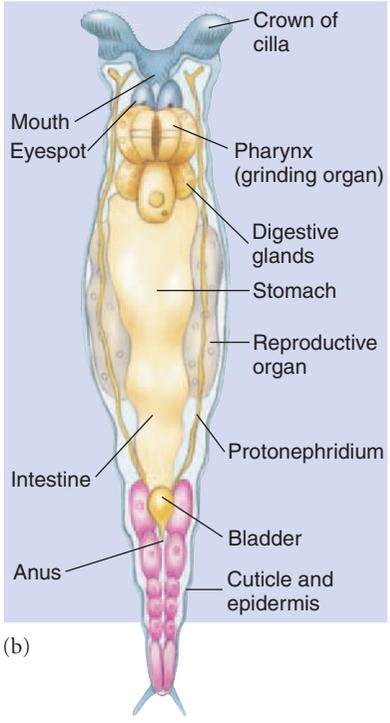
100 mm



(b)

feed on tiny organisms suspended in the stream of water drawn into the mouth by the cilia. A muscular organ posterior to the mouth grinds the food. The complete digestive tract ends in an anus through which wastes are eliminated.

Rotifers have a nervous system with a "brain" and sense organs, including eyespots. Protonephridia with flame cells remove excess water from the body and may also excrete metabolic wastes.

Biologists have discovered that, like some other animals with a pseudocoelom, rotifers are "cell constant." Each member of a given species has exactly the same number of cells. Indeed, each part of the body has a precisely fixed number of cells arranged in a characteristic pattern. Cell division does not take place after embryonic development, and mitosis cannot be induced; growth and repair are not possible. One of the challenging problems of biological research is discovering the difference between such nondividing cells and the dividing cells of other animals. Do you think rotifers could develop cancer?

Review

- What are some advantages of bilateral symmetry and cephalization?
- On what basis have biologists now classified nemerteans as lophotrochozoans?
- How does the lifestyle of a gastropod differ from that of a cephalopod? Identify adaptations that have evolved in each for its particular lifestyle.
- What are two distinguishing characteristics for each of the following: (a) mollusks (b) annelids (c) nematodes?

Biology Now™ Assess your understanding of **the lophotrochozoa** by taking the pretest on your BiologyNow CD-ROM.

THE ECDYSOZOA

Learning Objectives

7 Describe the distinguishing characteristics of phylum Nematoda.

8 Describe the distinguishing characteristics of phylum Arthropoda; distinguish among the subphyla and classes of arthropods, giving examples of animals that belong to each group.

9 Discuss factors that have contributed to the great biological success of insects.

The **Ecdysozoa** include the nematodes (roundworms) and arthropods, animals characterized by a **cuticle,** a noncellular body covering secreted by the epidermis. The name Ecdysozoa refers to the process of **ecdysis,** or **molting,** characteristic of animals in this group. During ecdysis, an animal sheds its cuticle. The taxonomic validity of the Ecdysozoa has been supported by many types of data, most notably by a 2001 study that analyzed more than 300 ribosomal RNA genes and 138 morphologic characters.

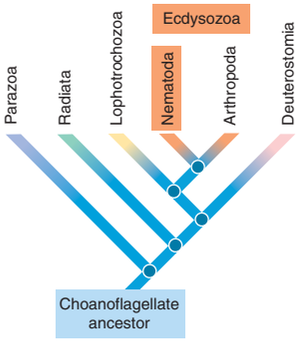
Roundworms are of great ecological importance

Members of phylum **Nematoda,** the **roundworms,** play key ecological roles as decomposers and predators of smaller organisms. Many soil nematodes eat bacteria. Nematodes are numerous and widely distributed in soil and in marine and freshwater sediments. Nearly 20,000 species have been identified, and many remain to be discovered. The nematodes rival the insects in number of individuals. A spadeful of soil may contain more than a million of these mainly microscopic worms, which thrash around, coiling and uncoiling.

The elongated, cylindrical, threadlike nematode body is pointed at both ends and covered with a tough, flexible *cuticle* (Fig. 29-16). Secreted by the underlying epidermis, the thick cuticle gives the nematode body shape and offers some protection. The epidermis is unusual in that it does not consist of distinct cells.

Nematodes have a fluid-filled pseudocoelom that serves as a hydrostatic skeleton. It transmits the force of muscle contraction to the enclosed fluid. Movement of fluid in the pseudocoelom is also important in nutrient transport and distribution. Like ribbon worms, nematodes exhibit bilateral symmetry, a complete digestive tract, three definite tissue layers, and definite organ systems; however, they lack specific circulatory structures. The sexes are usually separate, and the male is generally smaller than the female.

Traditionally, biologists classified nematodes as a single phylum based on the pseudocoelom, wormlike body structure, and other characters such as absence of a well-defined head. However, molecular evidence suggests that nematodes are not a monophyletic group and that they evolved from more complex



T.E. Adams/Visuals Unlimited

FIGURE **29-16**

LM of a free-living nematode.

This unidentified aquatic nematode is shown among the cyanobacterium *Oscillatoria,* which it eats.

animals by a simplification in body plan. Systematists now classify nematodes with the Ecdysozoa. Like arthropods and other ecdysozoans, the nematode sheds its cuticle periodically.

Caenorhabditis elegans, a free-living soil nematode, is an important model research organism for biologists studying the genetic control of development (see Chapter 16). Although most nematodes are free-living, others are important parasites in plants and animals. More than 50 species of roundworms are human parasites, including *Ascaris,* hookworms, pinworms, and the trichina worm.

The common intestinal parasite ***Ascaris*** is a white worm about 25 cm (10 in) long. *Ascaris* spends its adult life in the human intestine, where it ingests partly digested food (Fig. 29-17). Like most parasites, it devotes a great deal of effort to reproduction to ensure survival of its species. A mature female may produce as many as 200,000 eggs a day.

Hookworms hook onto the lining of the intestine and suck blood, potentially causing serious tissue damage and blood loss. **Pinworms** are the most common worms found in children. The tiny pinworm eggs are often ingested by eating with hands contaminated with them. The **trichina worm** lives inside a variety of animals, including pigs, rats, and bears. Humans typically become infected by eating undercooked, infected meat. Larvae encyst in skeletal muscle.

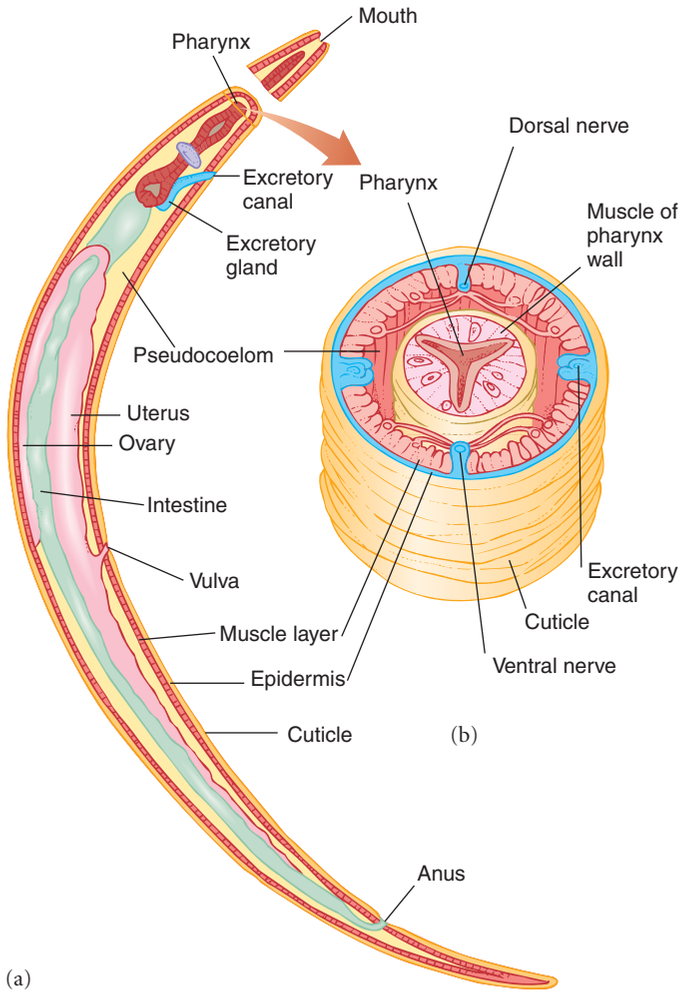


FIGURE **29-17** **The roundworm *Ascaris*.**

(a) Longitudinal section. Note the complete digestive tract that extends from mouth to anus. **(b)** Cross section through *Ascaris* shows the tube-within-a-tube body plan. The protective cuticle that covers the body helps the animal resist drying.

Arthropods are characterized by jointed appendages and an exoskeleton of chitin

Phylum **Arthropoda,** the most biologically successful group of animals, includes more than 1 million species, and biologists predict millions more will be identified. More than 80% of all known animals are arthropods! They are more diverse and live in a greater range of habitats than do the members of any other animal phylum. The following adaptations have greatly contributed to their success:

1. The arthropod body, like that of the annelid, is segmented. *Segmentation* is important from an evolutionary perspective because it provides the opportunity for specialization of body regions. In arthropods groups of segments are specialized, by virtue of their shape, muscles, or the appendages they bear, to perform particular functions.
2. A hard **exoskeleton,** composed of chitin and protein, covers the entire body and appendages. The exoskeleton serves as a coat of armor protecting against predators and helps prevent excessive loss of moisture. It also supports the underlying soft tissues. Arthropods move effectively because distinct muscles attach to the inner surface of the exoskeleton and operate the joints of the body and appendages. A disadvantage of the exoskeleton is that it is nonliving, and the arthropod periodically outgrows it. *Molting* is the process of shedding an old exoskeleton and growing a larger one. The shed exoskeleton represents a net metabolic loss, and molting also leaves the arthropod temporarily vulnerable to predators.
3. **Paired, jointed appendages,** from which this phylum gets its name (*arthropod* means "jointed foot"), are modified for many different functions. They serve as swimming paddles, walking legs, mouth parts for capturing and manipulating food, sensory structures, or organs for transferring sperm.
4. The nervous system, which resembles that of the annelids, consists of a "brain" (cerebral ganglia) and ventral nerve cord with ganglia. In some arthropods, successive ganglia may fuse together. Arthropods have a variety of very effective sense organs. Many have organs of hearing, and **antennae** that sense taste and touch. Most insects and many crustaceans have **compound eyes** composed of many light-sensitive units called **ommatidia** (see Figure 41-13). The compound eye can form an image and is especially adapted for detecting movement.

Arthropods have an *open circulatory system.* A dorsal, tubular heart pumps hemolymph into a dorsal artery, which may branch into smaller arteries. From the arteries, hemolymph flows into large spaces that collectively make up the hemocoel. Eventually hemolymph re-enters the heart through openings, called *ostia,* in its walls.

The exoskeleton presents a barrier to diffusion of oxygen and carbon dioxide through the body wall, necessitating the evolution of specialized respiratory systems for gas exchange. Most aquatic arthropods have gills that function in gas exchange, whereas many terrestrial forms have a system of internal branching air tubes called **tracheae,** or **tracheal tubes.** Other terrestrial arthropods have platelike **book lungs.**

The coelom is small and filled chiefly by the organs of the reproductive system. The arthropod digestive system is a tube similar to that of the earthworm. Excretory structures vary somewhat from class to class.

Arthropod evolution and classification are controversial

PROCESS OF SCIENCE

Two groups of animals thought to be closely related to arthropods are the onychophorans and the tardigrades. The wormlike members of phylum **Onychophora,** or velvet worms, most likely branched early from the arthropod line. They have paired appendages, although they are not jointed. As in arthropods, their jaws are derived from appendages. Some biologists place the tardigrades, or water bears, close to the arthropods (see Fig. 2-12). Assigned to phylum **Tardigrada,** these tiny animals have unbranched, clawed legs. Like arthropods, onychophorans and tardigrades have a thick cuticle and must molt in order to grow. The body is segmented in all three groups, and all share similarities in the circulatory system.

Arthropod fossils have been identified that date back to the Precambrian era. Early in their evolutionary history (more than 540 mya), arthropods diverged into several groups. Arthropods evolved rapidly during the Cambrian explosion, as evidenced by many diverse fossils in the Burgess Shale and other ancient sites.

We discuss five main groups: based on emerging molecular and other data: the extinct trilobites, and the extant Myriapoda, Chelicerata, Crustacea, and Hexapoda (Table 29-4). Some systematists consider each of these groups a phylum; others view them as subphyla or classes. In this edition, we classify these groups as subphyla. However, as you study the following sections, bear in mind that arthropod systematics is a work in progress. Both the relationship of arthropods to other protostomes and the relationships among arthropods continue to be topics of lively debate.

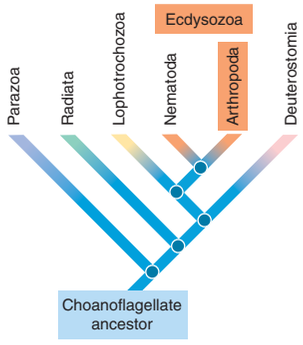
TABLE **29-4** Extant Arthropod Subphyla

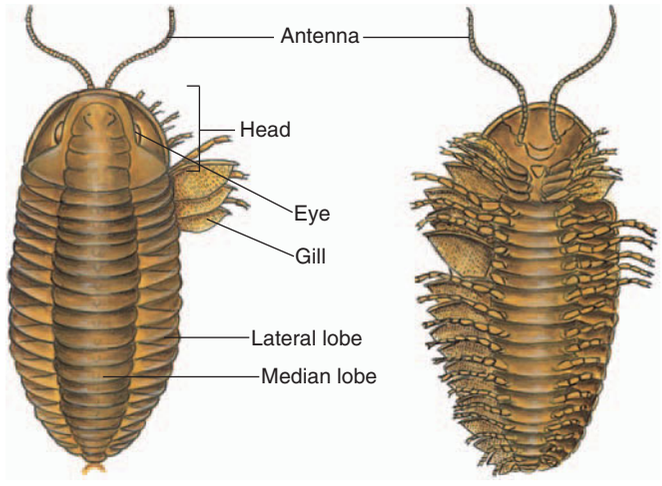
Subphylum and Selected Classes	Body Divisions	Appendages: Antennae, Mouthparts	Appendages: Legs	Gas Exchange	Development	Main Habitat
Myriapoda Class Chilopoda (centipedes) Class Diplopoda (millipedes)	Head with segmented body	Uniramous. Antennae: 1 pair Mouth parts: mandibles; Maxillae	Chilopods: 1 pair/segment Diplopods: usually 2 pairs/segment	Tracheae	Direct	Terrestrial
Chelicerata Class Merostoma (horseshoe crabs) Class Arachnida (spiders, scorpions, ticks, mites)	Cephalothorax and abdomen	Uniramous. Antennae: none Mouthparts: chelicerae; pedipalps	Merostomes: 5 pairs of walking legs Arachnids: 4 pairs on cephalothorax	Merostomes: gills Arachnids: book lungs or tracheae	Direct, except mites and ticks	Merostomes: marine Arachnids: mainly terrestrial
Crustacea Class Malacostraca (lobsters, crabs, shrimp, isopods) Class Cirripedia (barnacles) Class Copepoda (copepods)	Head, thorax, abdomen	Biramous. Antennae: 2 pairs Mouthparts: mandibles, 2 pairs of maxillae (for handling food)	Typically 1 pair/segment	Gills	Usually larval stages (nauplius larva)	Marine or freshwater; a few are terrestrial
Hexapoda Class Insecta (bees, ants, grasshoppers, roaches, flies, beetles)	Head, thorax, and abdomen	Uniramous. Antennae: 1 pair Mouthparts: mandibles, maxillae	3 pairs on thorax	Tracheae	Typically, larval stages; most with complete metamorphosis	Mainly terrestrial

FIGURE **29-18**

Trilobites.

Biologists consider these extinct marine arthropods the most primitive members of the phylum. **(a)** Dorsal view of a trilobite. **(b)** Ventral view.





(a) (b)

Trilobites were early arthropods

Among the earliest arthropods to evolve, **trilobites** inhabited shallow Paleozoic seas more than 500 million years ago. These arthropods, which have been extinct for about 250 million years, lived on the sea bottom and dug into the mud. Most ranged from 3 to 10 cm, but a few reached almost 1 m in length.

Covered by a hard, segmented exoskeleton, the trilobite body was a flattened oval divided into three parts: an anterior head bearing a pair of antennae and a pair of compound eyes; a thorax; and a posterior abdomen (Fig. 29-18; also see introduction to Chapter 20). At right angles to these divisions, two dorsal grooves extended the length of the animal, dividing the body into a median lobe and two lateral lobes. (The name *trilobite* derives from this division of the body into these three longitudinal parts.) Each segment had a pair of segmented **biramous appendages,** appendages with two jointed branches extending from their base. In trilobites, each appendage consisted of an inner walking leg and an outer branch with gills.

Subphylum Myriapoda includes centipedes and millipedes

Members of subphylum **Myriapoda** are characterized by **uniramous** (unbranched) **appendages,** jawlike **mandibles,** and a single pair of antennae. Centipedes (class **Chilopoda**) and millipedes (class **Diplopoda**) are terrestrial and are typically found beneath stones or wood in the soil in both temperate and tropical regions. These animals are similar in having a head and an elongated trunk with many segments, each bearing uniramous legs (Fig. 29-19).

Centipedes ("hundred-legged") have one pair of legs on each segment behind the head. Most centipedes do not have enough legs to merit their name; typically they have 30 or so, although a few species have 100 or more. The legs of centipedes are long, enabling them to run rapidly. Centipedes are carnivorous and feed on other animals, mostly insects. Larger centipedes will eat snakes, mice, and frogs. With their poison claws located just behind the head on the first trunk segment, centipedes capture and kill their prey.

Millipedes ("thousand-legged") have two pairs of legs on most body segments. Diplopods are not as agile as chilopods, and most species can crawl only slowly over the ground. However, they can powerfully force their way through earth and rotting wood. Millipedes are generally herbivorous and feed on both living and dead vegetation.

FIGURE **29-20** **Chelicerates.**

(a) The only living merostomes are a few closely related species of horseshoe crabs. Seasonally, horseshoe crabs (*Limulus polyphemus*) return to beaches for mating. In this photograph, males are competing for a female. **(b)** A female black widow spider (*Latrodectus mactans*) rests on her web. The venom of the black widow spider is a neurotoxin. **(c)** Color-enhanced SEM of a house dust mite (*Dermatophagoides*), a common inhabitant of homes. This mite is associated with house dust allergies.

Chelicerates have no antennae

Subphylum **Chelicerata** includes the merostomes (horseshoe crabs) and the arachnids. The chelicerate body consists of a *cephalothorax* (fused head and thorax) and an abdomen. Chelicerates are the only arthropods without antennae. They have no chewing mandibles. Instead, the first pair of appendages, located immediately anterior to the mouth, are the **chelicerae** (sing. *chelicera*), fanglike feeding appendages. The second pair of appendages are the **pedipalps.** The chelicerae and pedipalps are modified to perform different functions in various groups, including manipulation of food, locomotion, defense, and copulation. The four pairs of legs on the cephalothorax are specialized for walking.

Almost all the **merostomes** are extinct. Only the horseshoe crabs have survived, essentially unchanged for more than 350 million years. *Limulus polyphemus,* the species common along the shore of North America, is horseshoe-shaped (Fig. 29-20a). Its long, spikelike tail is used in locomotion, not for defense or offense. Horseshoe crabs feed on mollusks, worms, and other invertebrates that they find on the sandy ocean floor.

Arachnids include spiders, scorpions, ticks, harvestmen (daddy long-legs), and mites (Fig. 29-20b, c). Most of the 65,000 or so named species are carnivorous and prey on insects and other small arthropods. The arachnid body consists of a cephalothorax and abdomen, with six pairs of jointed appendages. In spiders, the first pair, the chelicerae, are fanglike structures used to penetrate prey. Some spider species use the chelicerae to inject poison into their prey. Spiders use the second pair of appendages, the pedipalps, to hold and chew food. Many arachnid species have pedipalps modified as sense organs for tasting food or for reproduction (for sperm transfer and courtship displays). Scorpions use their very large pedipalps as pincers for capturing prey. Chelicerates use the remaining four pairs of appendages for walking.

Typically, spiders have 8 eyes arranged in two rows of 4 each along the anterior dorsal edge of the cephalothorax. The eyes detect movement and locate objects, and in some species form a relatively sharp image.

Gas exchange in arachnids takes place by either tracheal tubes, book lungs, or both. A **book lung** consists of 15 to 20 plates, like pages of a book, that contain tiny blood vessels. Air enters the body through abdominal slits and circulates between the plates. As air passes over the blood vessels in the plates, oxygen diffuses into the blood and carbon dioxide diffuses out of the blood into the air. As many as four pairs of book lungs provide an extensive surface area for gas exchange.

The spider has unique glands in its abdomen that secrete silk, an elastic protein that is spun into fibers by organs called *spinnerets.* The silk is liquid as it emerges from the spinnerets but hardens after it leaves the body. Spiders use silk to build nests, to encase their eggs in a cocoon, and, in some species, to trap prey in a web. Many spiders lay down a silken dragline that serves as

a safety line and also as a means of communication between members of a species. From a dragline another spider can determine the sex and maturity level of the spinner.

Although all spiders, as well as scorpions, have poison glands useful in capturing prey, only a few produce poison toxic to humans. The most widely distributed poisonous spider in the United States is the black widow (*Latrodectus mactans;* Fig. 29-20b). Its poison is a neurotoxin that interferes with transmission of messages from nerves to muscles. The brown recluse spider (*Loxosceles reclusa*) is more slender than the black widow and has a violin-shaped dorsal stripe on its cephalothorax. Its venom destroys the tissues surrounding the bite and, like the venom of the black widow, can occasionally be fatal. Although painful, spider bites cause fewer than five fatalities per year in the United States.

Although some mites contribute to soil fertility by breaking down organic matter, many are serious nuisances. They eat crops, infest livestock and pets, and inhabit our own bodies. Certain mites cause mange in dogs and other domestic animals. Chiggers (red bugs), the larval form of red mites, attach themselves to the skin and secrete an irritating digestive fluid that may cause itchy red welts.

Larger than mites, ticks are parasites on dogs, deer, and many other animals. They transmit diseases such as Rocky Mountain spotted fever, Texas cattle fever, relapsing fever, and Lyme disease (see Fig. 52-1).

Crustaceans are vital members of marine food webs

Subphylum **Crustacea** includes lobsters, crabs, shrimp, barnacles, and their relatives (Fig. 29-21). Paleobiologists have dated crustacean fossils back to the Cambrian period (more than 505 million years ago). Recent studies suggest crustaceans form a clade with members of subphylum Hexapoda.

Many crustaceans are primary consumers of algae and detritus. Countless billions of microscopic crustaceans are part of marine zooplankton, the free-floating, mainly microscopic organisms in the upper layers of the ocean. These crustaceans are food for many fishes and other marine animals, such as certain baleen whales.

A distinctive feature of crustaceans is the *nauplius larva,* which is often the first stage after hatching. This larva has only the most anterior three pairs of appendages. Crustaceans are also characterized by mandibles, biramous appendages, and two pairs of antennae. Their antennae serve as sensory organs for touch and taste. Most adult crustaceans have compound eyes, and many crustaceans have **statocysts,** sense organs that detect gravity (see Fig. 41-4).

The hard **mandibles,** used for biting and grinding food, are the third pair of appendages; they lie on each side of the ventral mouth. Posterior to the mandibles are two pairs of appendages, the first and second **maxillae,** used for manipulating and holding food. Several other pairs of appendages are present. Some are modified for walking. Others may be specialized for swimming, sperm transmission, carrying eggs and young, or sensation.

Crustaceans are the only group of arthropods that are primarily aquatic, and so, not surprisingly, they typically have gills for gas exchange. Two large glands located in the head excrete metabolic wastes and regulate salt balance. Most crustaceans have separate sexes. During copulation, the male uses specialized appendages to transfer sperm into the female. Newly hatched animals may resemble adults, or they may pass by successive molts through a series of larval stages before they develop the adult body.

Barnacles, the only sessile crustaceans, differ markedly in external anatomy from other members of the subphylum. They are marine suspension feeders that secrete complex limestone cups within which they live (see Fig. 29-21a). The larvae of barnacles are free-swimming forms that go through several molts. They eventually become sessile and develop into the adult form. The 19th-century naturalist Louis Agassiz described the barnacle as "nothing more than a little shrimplike animal standing on its head in a limestone house and kicking food into its mouth." The bane of marine boaters, barnacles can proliferate on ship

FIGURE **29-21**

Crustaceans.

bottoms in great numbers. Their presence can reduce the speed of a ship by more than 30%.

Isopods are mainly tiny (5–15 mm in length) marine crustaceans that inhabit the ocean floor. However, this group includes some familiar terrestrial animals: pillbugs and sowbugs. The mainly microscopic *copepods* are the largest group of crustaceans. Marine copepods are the most numerous component of zooplankton.

The largest order of crustaceans, *Decapoda,* contains more than 10,000 species of lobsters, crayfish, crabs, and shrimp. Most decapods are marine, but a few, such as the crayfish, certain shrimp, and a few crabs, live in fresh water. The crustaceans in general and the decapods in particular show striking specialization and differentiation of parts in the various regions of the animal. In the lobster, the appendages in the different parts of the body differ markedly in form and function (Fig. 29-22).

The five segments of the lobster's head and the eight segments of its thorax are fused into a cephalothorax, which is covered on the top and sides by a shield, the **carapace,** composed of chitin impregnated with calcium salts. The two pairs of antennae serve as chemoreceptors and tactile sense organs. The mandibles are short and heavy, with opposing surfaces used in grinding and biting food. Behind the mandibles are two pairs of accessory feeding appendages: the first and second maxillae. The appendages of the first three segments of the thorax are the maxillipeds, which aid in chopping up food and passing it to the mouth. The fourth segment of the thorax has a pair of large **chelipeds,** or pinching claws. The last four thoracic segments bear walking legs.

The appendages of the first abdominal segment are part of the reproductive system and function in the male as sperm-transferring structures. The following four abdominal segments bear paired **swimmerets,** small paddle-like structures used by some decapods for swimming and by the females of all species for holding eggs. Each branch of the sixth abdominal appendages consists of a large flattened structure. Together with the flattened posterior end of the abdomen, they form a tail fan used for swimming backward.

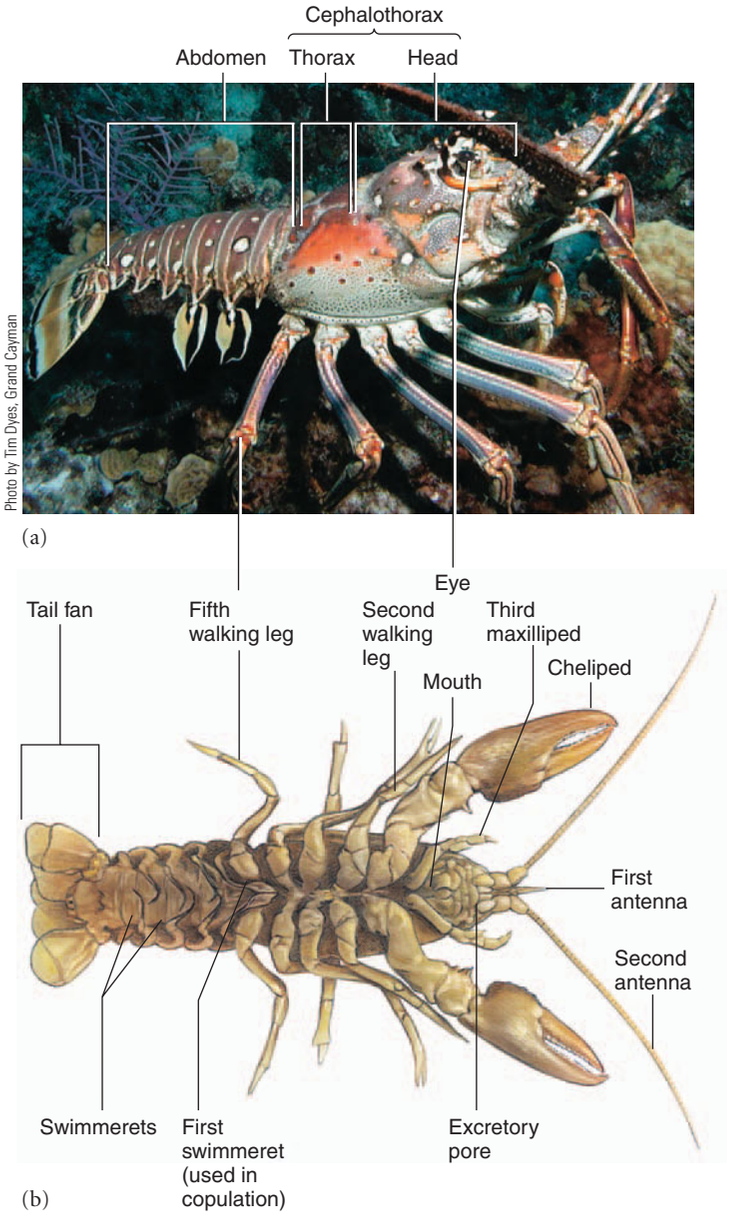

FIGURE **29-22** **Anatomy of the lobster.**

(a) Like other decapods, the spiny lobster (*Panulirus argus*) has five pairs of walking legs. The first pair of walking legs is modified as chelipeds *(large claws).* Photographed in Grand Cayman. **(b)** Ventral view of a lobster. Note the variety of specialized appendages.

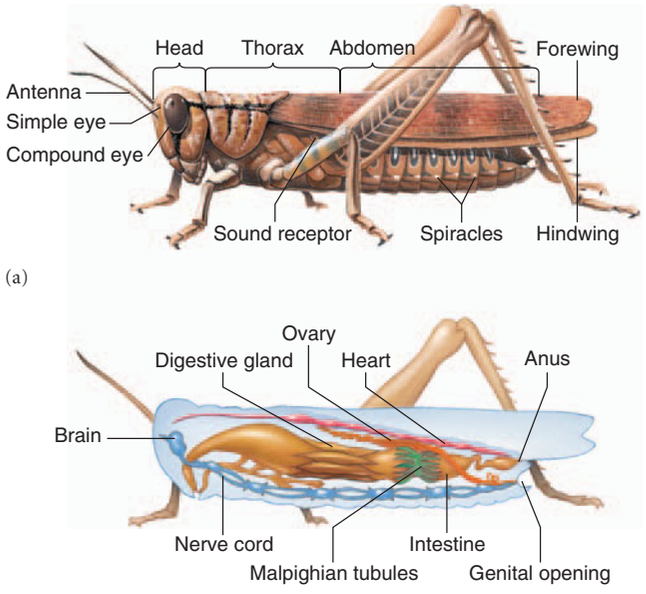
Insects belong to subphylum Hexapoda

With more than 1 million described species (and perhaps millions more not yet identified), class **Insecta** of subphylum **Hexapoda,** is the most successful group of animals on our planet in terms of diversity, geographic distribution, number of species, and number of individuals (Table 29-5). What they lack in size, insects make up in sheer numbers. If we could weigh all the insects in the world, their weight would exceed that of all the remaining terrestrial animals. Although primarily terrestrial, some insect species live in fresh water, a few are truly marine, and others inhabit the shore between the tides.

The earliest fossil hexapods—primitive, wingless species—date back to the Devonian period more than 360 million years ago (mya). Hexapod fossils from the Carboniferous period more than 286 mya include both wingless and primitive winged species. Cockroaches, mayflies, and cicadas are among the insects that have survived relatively unchanged from the Carboniferous period to the present day. Until recently biologists thought insects made up a monophyletic taxon and were closely related to myriapods (centipedes and millipedes). Recent molecular and developmental studies suggest insects are not a monophyletic group and are more closely related to crustaceans. Molecular data also suggest a group of wingless, soil hexapods known as *springtails* may have evolved independently of the insects.

We describe an insect as an **articulated** (jointed), **tracheated** (having tracheal tubes for gas exchange) **hexapod** (having six feet). The insect body consists of three distinct parts: head, tho-

KEY CONCEPT: Insects, the most successful of all animals, are articulated, tracheated hexapods.



ACTIVE FIGURE **29-23** **Anatomy of the grasshopper.**

(b) Internal anatomy.

BiologyNow™ See **the butterfly life-cycle** in action by clicking on this figure on your BiologyNow CD-ROM.

rax, and abdomen (Fig. 29-23). Their uniramous (unbranched) appendages include three pairs of legs that extend from the adult thorax, and, in many orders, one or two pairs of wings. One pair of antennae protrudes from the head, and the sense organs include both simple and compound eyes. Their complex mouthparts, which include mandibles and maxillae, are adapted for piercing, chewing, sucking, or lapping.

The tracheal system of insects has made an important contribution to their diversity. Air enters the tracheal tubes, or tracheae, through **spiracles,** tiny openings in the body wall. Oxygen passes directly to the internal organs. This effective oxygen delivery system permits insects to have the high metabolic rate necessary for activities such as flight, even though they have an open circulatory system.

Excretion is accomplished by two or more **Malpighian tubules,** which receive metabolic wastes from the blood, concentrate the wastes, and discharge them into the intestine. Unique to terrestrial arthropods, Malpighian tubules also perform the extremely important function of conserving water (see Fig. 46-4).

The sexes are separate, and fertilization takes place internally. Several molts occur during development. The immature stages between molts are called **instars.** Primitive insects with no wings, such as silverfish, have direct, or simple, development: The young hatch as juveniles that resemble the adult form. Other insects, such as grasshoppers and cockroaches, undergo **incomplete metamorphosis** in which the egg gives rise to a larva that resembles the adult in many ways but lacks functional wings and reproductive structures. The larva goes through a series of molts during which it becomes more like the adult.

Most insects, including bees, butterflies, and fleas, undergo **complete metamorphosis** with four distinct stages in the life cycle: **egg, larva, pupa,** and **adult.** The wormlike larva does not look at all like the adult. For example, caterpillars have an entirely different body form from butterflies. Typically, an insect spends most of its life as a larva. Eventually the larva stops feeding, molts, and enters a pupal stage, usually within a protective cocoon or underground burrow. The pupa does not feed and typically cannot defend itself. Energy reserves stored during the larval stage are spent remodeling its body. When it emerges as an adult, it is equipped with functional wings and reproductive organs.

Certain species of bees, ants, and termites exist as colonies or societies made up of several different types of individuals, each adapted for some particular function. The members of some insect societies communicate with each other by "dances" and by means of **pheromones,** substances secreted to the external environment. Social insects and their communication are discussed in Chapter 50.

Adaptations that contribute to the biological success of insects. What are the secrets of insect success? The tough exoskeleton protects insects from predators and helps prevent water loss. Segmentation allows mobility and flexibility, and permits regional specialization of the body. For example, cephalization and highly developed sense organs are important in both offense and defense. The insect body plan has been modified and specialized in so many ways that insects are adapted to a remarkable number of lifestyles. The jointed appendages are specialized for various types of feeding, sensory functions, and different types of locomotion (walking, jumping, swimming). For example, grasshopper mouthparts are adapted for biting and chewing leaves. Moth and butterfly mouthparts are adapted for sucking nectar from flowers, and mosquito mouthparts are adapted for sucking blood. Aphids and leafhoppers have mouthparts specialized to pierce plants and feed on plant juices.

Another adaptation that contributes to insect success is the ability to fly. Unlike other terrestrial invertebrates, which creep slowly along on or under the ground, many insects fly rapidly through the air. Their wings and small size facilitate their wide distribution and, in many instances, their immediate survival. For example, when a pond dries up, adult aquatic insects can fly to another habitat.

The reproductive capacity of insects is amazing. Under ideal conditions, the fruit fly *Drosophila* can produce 25 generations in one year! Insect eggs are protected by a thick membrane, and several eggs may, in addition, be enclosed in a protective egg case. By dividing the insect life cycle into different stages, metamorphosis reduces intraspecific competition; larval forms have different lifestyles so they do not compete with adults for food or habitats.

Insects have many interesting adaptations for offense and defense (see Fig. 6-8). We all are familiar with the stingers of bees and wasps, which are specialized egg-laying structures (ovi-

TABLE 29-5 Some Orders of Insects

Order, Number of Species, Some Characteristics, and Representative Adult

Insects with Incomplete Metamorphosis (egg ⟶ larva ⟶ adult)

Homoptera (33,000)

Aphids, Leafhoppers, Cicadas, Scale insects
2 pairs membranous wings; piercing-sucking mouthparts form beak; parasites of plants; vectors of plant diseases

Buffalo treehopper
Stictocephala bubalus

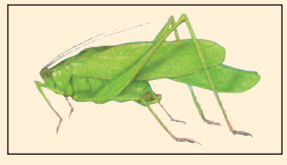
Odonata (6000)

Dragonflies, Damselflies
Two pairs of long membranous wings; chewing mouthparts; large, compound eyes; active predators; larvae very different from adult

Damselfly
Ischnura

Orthoptera (20,000)

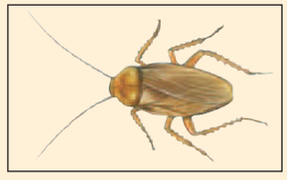
Grasshoppers, Crickets
Forewings leathery, hindwings membranous; chewing mouthparts; most herbivorous, some cause crop damage; some predatory



Fork-tailed bush katydid
Scudderia furcata

Blattaria (3700)

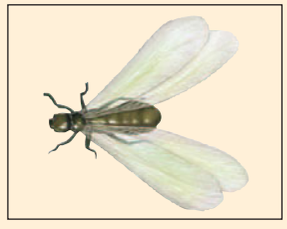
Cockroaches
When wings present, forewings leathery, hindwings membranous; chewing mouthparts; legs adapted for running



American cockroach
Periplaneta americana

Isoptera (2000)

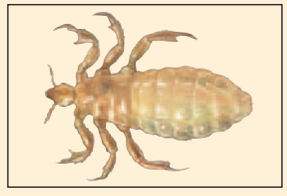
Termites
2 pairs of wings, or none; wings shed by sexual forms after mating; chewing mouthparts; social insects, form large colonies; eat wood



Eastern subterranean termite
Reticulitermes flavipes

Anoplura (500)

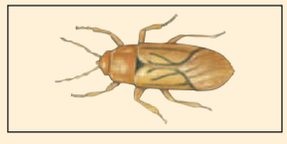
Sucking lice
No wings; piercing-sucking mouthparts; ectoparasites of mammals; head and body louse and crab louse are human parasites; vectors of typhus fever



Human head and body louse
Pediculus humanus

Hemiptera (true bugs) (62,000)

Chinch bugs, Bed bugs, Water striders
Hindwings membranous; forewings smaller; piercing-sucking mouthparts form beak; most herbivorous; some parasitic.

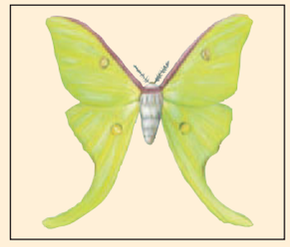


Chinch bug
Blissus leucopterus

Insects with Complete Metamorphosis (egg ⟶ larva ⟶ pupa ⟶ adult)

Lepidoptera (140,000)

Moths, Butterflies
Usually 2 pairs of membranous, colorful, scaled wings; sucking mouthparts; larvae are wormlike caterpillars that eat plants; adults suck flower nectar; important pollinators



Luna moth
Aetias luna

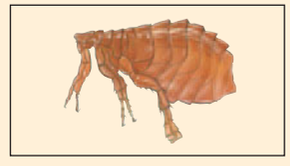
Diptera (150,000)

Houseflies, Mosquitos
Only forewings functional in flying; hindwings small, knoblike balancing organs (halteres); mouthparts usually adapted for sucking (and piercing in some); larvae are maggots that damage domestic animals or food; adults transmit diseases such as sleeping sickness, yellow fever, or malaria

Deerfly
Chrysops vittatus

Siphonaptera (1750)

Fleas
No wings; piercing sucking mouthparts; legs adapted for clinging and jumping; parasites on birds and mammals; vectors of bubonic plague and typhus



Dog Flea
Ctenocephalides canis

Coleoptera (350,000)

Beetles, Weevils
Forewings modified as protective coverings for membranous hindwings (which are sometimes absent); chewing mouthparts; largest order of insects; most herbivorous; some aquatic

Colorado potato beetle
Leptinotarsa decemlineata

Hymenoptera (190,000)

Ants, Bees, Wasps
Usually 2 pairs of membranous wings; mouthparts may be modified for sucking or lapping nectar; many are social insects; some sting; important pollinators

Bald-faced hornet
Vespula maculata

Insects with No Metamorphosis (egg ⟶ immature form ⟶ adult)

Thysanura (320)

Silverfish
No wings; biting-chewing mouthparts; 2–3 "tails" extend from posterior tip of abdomen; inhabit dead leaves; eat starch in books

Silverfish
Lepisma saccharina

positors). Many insects have **cryptic coloration,** blending into the background of their habitat; some look like dead twigs or leaves. Others mimic poisonous insects, deriving protection from this resemblance. Still others "play dead" by remaining motionless.

Insects communicate by tactile, auditory, visual, or chemical signals. For example, certain ant species use pheromones to mark trails and to warn of danger. Other insects use pheromones to attract a mate.

Impact of insects on humans. Not all insects compete with humans for food or cause us to scratch, swell up, or recoil from their presence. Bees, wasps, beetles, and many other insects pollinate flowers of crops and fruit trees. Some insects destroy other insects that are harmful to humans. For example, dragonflies eat mosquitos. And some organic farmers and home gardeners buy ladybird beetles, which are adept at ridding plants of aphids and other insect pests. Insects are important members of many food webs. Many birds, mammals, amphibians, reptiles, and some fishes depend on insects for food. Many beetles and the larvae (maggots) of flies are detritus feeders—they break down dead plants and animals and their wastes, permitting nutrients to be recycled.

Many insect products are useful to humans. Bees produce honey as well as beeswax, which we use to make candles, lubricants, and other products. Shellac is made from lac, a substance given off by certain scale insects that feed on the sap of trees. And the labor of silkworms provides us with beautiful fabric.

On the negative side, insects destroy billions of dollars worth of crops each year. Termites destroy buildings, and moths damage clothing. Fire ants not only inflict painful stings but cause farmers serious economic loss because of their large mounds, which damage mowers and other farm equipment.

Blood-sucking flies, screw worms, lice, fleas, and other insects annoy and transmit disease in humans and domestic animals. Mosquitos are vectors of malaria (see Fig. 24-10) and yellow fever. Body lice transmit the typhus rickettsia, and houseflies sometimes transmit typhoid fever and dysentery. Tsetse flies transmit African sleeping sickness, and fleas may be vectors of bubonic plague.

Review

- What function does the pseudocoelom have in nematodes?
- Why is segmentation an important characteristic of the arthropod body?
- How do myriapods differ from chelicerates?
- What are the functions of each of these appendages in a lobster? maxillae; chelipeds; swimmerets?
- Define an insect. What are four adaptations that have contributed to insect success?

SUMMARY WITH KEY TERMS

1 Characterize the protostome coelomates, describe their two main evolutionary branches, and give examples of animals assigned to each branch.

- The **protostome coelomates** are characterized by spiral cleavage, determinate cleavage, and the development of the mouth from the blastopore. The **coelom** is a fluid-filled cavity completely lined with mesoderm. The evolution of the coelom permitted many innovations, including the **tube-within-a-tube body plan** and the **hydrostatic skeleton.** The coelom provides space for internal organs and for gonads to develop. It helps transport materials and protects internal organs.
- The protostome coelomates include two main branches: the Lophotrochozoa and the Ecdysozoa. The **Lophotrochozoa** include the platyhelminthes, nemerteans, mollusks, annelids, the lophophorate phyla, and the rotifers. The **Ecdysozoa** include the nematodes (roundworms), and arthropods.

2 Identify distinguishing characteristics of phylum Nemertea and phylum Platyhelminthes; describe the main classes of phylum Platyhelminthes, giving examples of animals that belong to each class.

- Phylum **Nemertea** (ribbon worms) is a lophotrochozoan group characterized by the **proboscis,** a muscular tube used in capturing food and in defense. The coelom is reduced; it consists of the **rhynchocoel,** a space surrounding the proboscis. Nemerteans have a tube-within-a-tube body plan, a complete digestive tract with mouth and anus, and a circulatory system.
- Phylum **Platyhelminthes,** the flatworms, are acoelomate animals with bilateral symmetry, **cephalization,** three definite tissue layers, and well-developed organs. Many flatworms are **hermaphrodites;** a single animal produces both sperm and eggs.
- Flatworms have a ladder-type nervous system, typically consisting of sense organs and a simple brain consisting of two **ganglia** connected to two nerve cords that extend the length of the body. They have **protonephridia,** organs that function in osmoregulation and disposal of metabolic wastes.
- Phylum Platyhelminthes includes four classes: Class **Turbellaria** is comprised of free-living flatworms, including **planarians.** Classes **Trematoda** and **Monogenea** include the parasitic **flukes,** and the parasitic tapeworms comprise class **Cestoda.** The parasitic flukes and tapeworms typically have suckers or hooks for holding onto their hosts; they have complicated life cycles with intermediate hosts and produce large numbers of eggs.

3 Describe the adaptive advantages of cephalization.

- Flatworms show the beginnings of cephalization, the evolution of a head with the concentration of sense organs and nerve cells (a simple brain) at the anterior end. Cephalization increases the effectiveness of a bilateral animal to find food and detect enemies.

4 Describe the distinguishing characteristics of phylum Mollusca, and describe the classes discussed, giving examples.

- Members of phylum **Mollusca** are soft-bodied animals usually covered by a shell. They have a ventral **foot** for locomotion and a **mantle** that covers the **visceral mass,** a concentration of body organs.

SUMMARY WITH KEY TERMS *(continued)*

- Mollusks have an **open circulatory system** with the exception of cephalopods, which have a **closed circulatory system.** Mollusks have paired excretory tubules called metanephridia. A rasplike **radula** functions as a scraper in feeding in all groups except the bivalves, which are suspension feeders. Typically, marine mollusks have a free-swimming, ciliated **trochophore larva.**
- Class **Polyplacophora** includes the sluggish marine **chitons,** which have shells that consist of eight overlapping plates.
- Class **Gastropoda,** the largest group of mollusks, includes the snails, slugs, and their relatives. In gastropods, the body undergoes **torsion,** a twisting of the visceral mass. The shell (when present) is coiled. Torsion is not related to shell coiling.
- Class **Bivalvia** includes the aquatic clams, scallops, and oysters; a two-part shell, hinged dorsally, encloses the bodies of these suspension feeders.
- Class **Cephalopoda** includes the squids, octopods, and *Nautilus.* Cephalopods are active, predatory swimmers. Tentacles surround the mouth, located in the large head.

5 Describe the distinguishing characteristics of phylum Annelida, and describe the three classes of annelids discussed, giving examples.

- Phylum **Annelida,** the segmented worms, includes many aquatic worms, earthworms, and leeches. Annelids have conspicuously long bodies with **segmentation** both internally and externally; their large compartmentalized coelom serves as a hydrostatic skeleton.
- Class **Polychaeta** consists of marine worms characterized by appendages called **parapodia,** which are used for locomotion and gas exchange. The parapodia bear many bristle-like structures called **setae.**
- Class **Oligochaeta,** comprised of the earthworms, is characterized by a few short setae per segment. The body is divided into more than 100 segments separated internally by **septa.**
- Class **Hirudinea,** the leeches, is characterized by the absence of setae and appendages. Parasitic leeches are equipped with suckers for holding onto their host.

6 Describe the distinguishing characteristics of the lophophorate phyla.

- The **lophophorate phyla,** marine animals that have a lophophore, include the **brachiopods, phoronids,** and **bryozoa.** The **lophophore,** a ciliated ring of tentacles surrounding the mouth, is specialized for capturing suspended particles in the water.

7 Describe the distinguishing characteristics of phylum Nematoda.

- Phylum **Nematoda,** the **roundworms,** are pseudocoelomates with bilateral symmetry, three tissue layers, and a complete digestive tract. The nematode body is covered by a tough **cuticle** that helps prevent desiccation. Parasitic nematodes in humans include ***Ascaris,*** **hookworms, trichina worms,** and **pinworms.**

8 Describe the distinguishing characteristics of phylum Arthropoda; distinguish among the subphyla and classes of arthropods, giving examples of animals that belong to each group.

- Phylum **Arthropoda** is composed of segmented animals with **paired, jointed appendages** and an armor-like **exoskeleton** of chitin. **Molting** is necessary for the arthropod to grow.
- Arthropods have an open circulatory system with a dorsal heart that pumps **hemolymph.**
- Aquatic forms have gills; terrestrial forms have either **tracheae** or **book lungs.**
- The **trilobites** are extinct marine arthropods covered by a hard, segmented shell.
- Subphylum **Myriapoda** includes class **Chilopoda,** the centipedes, and class **Diplopoda,** the millipedes; members of this subphylum have unbranched appendages and a single pair of antennae.
- Subphylum **Chelicerata** includes the **merostomes** (horseshoe crabs) and the **arachnids** (spiders, mites, and their relatives). The chelicerate body consists of a cephalothorax and abdomen; there are six pairs of jointed appendages, of which four pairs serve as legs.
- The first pair of appendages are **chelicerae,** the second pair are **pedipalps.** These appendages are adapted for manipulation of food, locomotion, defense, or copulation. Chelicerates have no antennae and no mandibles.
- Subphylum **Crustacea** includes lobsters, crabs, shrimp, pillbugs, and barnacles. The body consists of a cephalothorax and abdomen; they typically have five pairs of walking legs.
- Crustaceans have two pairs of **antennae** that sense taste and touch. The third appendages are **mandibles** used for chewing. Two pairs of **maxillae,** posterior to the mandibles, manipulate and hold food.
- Subphylum **Hexapoda** includes class **Insecta.** Insects have unbranched appendages and a single pair of antennae. An insect is an **articulated, tracheated hexapod;** its body consists of head, thorax, and abdomen. Insects have tracheae for gas exchange and **Malpighian tubules** for excretion.

9 Discuss factors that have contributed to the great biological success of insects.

- The biological success of the insects results from many adaptations, including the versatile exoskeleton, segmentation, specialized jointed appendages, ability to fly, highly developed sense organs, **metamorphosis** (which reduces intraspecific competition), effective reproductive strategies, effective mechanisms for defense and offense, and the ability to communicate.

POST-TEST

1. Which of the following is associated with the evolution of the coelom? (a) radial symmetry (b) tube-within-a-tube body plan (c) incomplete metamorphosis (d) bilateral symmetry (e) development of ganglia
2. Cephalization (a) evolved along with bilateral symmetry (b) refers to the development of a digestive system (c) is associated with radial symmetry (d) involves a concentration of excretory organs (e) first evolved in arthropods
3. Rudimentary cephalization, protonephridia, and auricles characterize some numbers of phylum (a) Arthropoda (b) Cnidaria (c) Platyhelminthes (d) Mollusca (e) Crustacea

POST-TEST *(continued)*

4. Trochophore larvae are characteristic of (a) Arthropoda (b) Cnidaria (c) Platyhelminthes (d) Mollusca (e) Crustacea
5. Tapeworms are classified in phylum (a) Porifera (b) Cnidaria (c) Platyhelminthes (d) Ctenophora (e) Coelomata
6. Which of the following is *not* an adaptation of parasitic life? (a) production of a few well-protected eggs (b) hooks (c) suckers (d) reduced digestive system (e) intermediate host
7. The hydrostatic skeleton (a) results in torsion (b) permits contracting muscles to recover quickly (c) permits a greater range of movement than possible in acoelomate animals (d) is a unique characteristic of annelids (e) permits ecdysis
8. Which of the following is *not* characteristic of nemerteans (proboscis worms)? (a) large coelom (b) tube-within-a-tube body plan (c) complete digestive tube (d) muscular tube for capturing food (e) circulatory system
9. Which of the following characteristics is associated with phylum Mollusca? (a) mandibles (b) mantle (c) pedipalps (d) chelipeds (e) setae
10. Which of the following belong to phylum Mollusca? (a) gastropods and crustaceans (b) oligochaetes and polychaetes (c) chelicerates and bryozoans (d) crustaceans and nemerteans (e) gastropods and cephalopods
11. Which of the following belongs to Ecdysozoa? (a) mollusks (b) annelids (c) nematodes (d) nemerteans (e) lophophorates
12. Which of the following is *not* a nematode? (a) hookworm (b) trichina worm (c) *Ascaris* (d) leech (e) pinworm
13. Which of the following is *not* true of the lophophorates? (a) this group includes the bryozoa (b) some have shells and look somewhat like mollusks (c) characterized by a ciliated ring of tentacles at anterior end (d) mainly marine animals (e) some of its members are articulated, tracheated hexapods
14. Torsion in mollusks (a) is characteristic of bivalves (b) is a twisting of the visceral mass (c) involves coiling of the molluscan shell (d) begins in the adult stage (e) depends on action of parapodia
15. Trilobites (a) were early mollusks (b) are members of phylum Onychophora (c) are characterized by parapodia and setae (d) were early arthropods (e) are an evolutionary link between annelids and arthropods
16. Which of the following belong to subphylum Hexapoda? (a) insects (b) horseshoe crabs (c) crustaceans (d) centipedes (e) spiders
17. The correct sequence in insect complete metamorphosis is (a) egg ⟶ immature form ⟶ adult (b) egg ⟶ trochophore larva ⟶ veliger larva ⟶ adult (c) egg ⟶ pupa ⟶ larva ⟶ adult (d) egg ⟶ larva ⟶ pupa ⟶ adult (e) adult ⟶ larva ⟶ egg ⟶ pupa
18. Which of the following is characteristic of insects? (a) biramous appendages (b) mandibles (c) chelicerae (d) eight legs (e) two pairs of antennae
19. Which of the following is *not* characteristic of arthropods? (a) exoskeleton (b) trochophore larva (c) paired, jointed appendages (d) chitin (e) segmentation
20. Spiders are characterized by (a) mandibles and maxillae (b) six pairs of legs on the abdomen (c) one pair of antennae (d) biramous appendages (e) chelicerae and pedipalps

CRITICAL THINKING

1. Discuss the idea that every evolutionary adaptation has both advantages and disadvantages, using each of the following characteristics as an example: (a) cephalization (b) the arthropod exoskeleton (c) segmentation with specialization
2. Hypothesize why oysters secrete calcium carbonate layers around foreign particles.
3. Insects that undergo complete metamorphosis outnumber those that do not by more than ten to one. Hypothesize an explanation.

The Animal Kingdom: The Deuterostomes

© Ed Robinson/Tom Stack & Associates

Representative deuterostomes This marine habitat photographed in Hawaii includes an echinoderm known as a pencil urchin (*Heterocentrotrus mammilatus*), and chordates, represented by fishes, the clown wrasse (*Coris gaimard*) with its yellow tail and the Moorish idol (*Zanchus cornutus*).

CHAPTER OUTLINE

- Echinoderms
- Chordate Characters
- Invertebrate Chordates
- Introducing the Vertebrates
- Jawless Fishes
- Fishes and Amphibians
- Amniotes

What does a sea star have in common with a fish, frog, hawk, or human? You may think it strange to group the **echinoderms**—the sea stars, sea urchins, and sand dollars—with the **chordates,** the phylum to which we humans and other **vertebrates** (animals with a backbone) belong. However, even though these animals look and behave very differently, evidence suggests that echinoderms and chordates share a common ancestor and are closely related. They are both **deuterostomes,** animals that make up a major evolutionary branch of the animal kingdom.

Biologists also include the **hemichordates,** a small group of wormlike marine animals, with the deuterostomes. The most familiar of the hemichordates are the acorn worms, animals that live buried in mud or sand. The hemichordates have a characteristic ring of cilia surrounding the mouth. A distinguishing derived character is the three-part body: a proboscis, collar, and trunk.

In this chapter we focus on echinoderms, such as the pencil urchin, and chordates, represented in the photograph by the fishes. The largest chordate subphylum is Vertebrata, which includes the animals with which we are most familiar—fishes, amphibians, reptiles, birds, and mammals.

Deuterostomes evolved from a common ancestor more than 550 mya (during the Precambrian). These animals share several derived characters (evolutionary novelties absent in the common ancestor of deuterostomes; see Chapter 22). Their defining characters are similarities in their patterns of development (see Chapter 28). Deuterostomes are characterized by radial, rather than spiral, cleavage. Their cleavage is indeterminate, which means the fate of their cells is fixed later in development than is the case in protostomes. In deuterostomes, the blastopore becomes the anus (or is located near the future site of the anus), and the mouth develops from a second opening at the anterior end of the embryo. Pharyngeal slits are also characteristic of deuterostomes, but the extant echinoderms have lost this character.

Fossil evidence of the first chordates, and perhaps also the first vertebrates, has been found in rocks more than 550 million years old from the Cambrian period. However, the inter-

pretation of these fossils is controversial. Investigators disagree about which fossil or group represents the deuterostome ancestor of the chordate lineage. They also disagree about which group represents the ancestral chordate that gave rise to the vertebrates. Another issue is how the invertebrate chordates are related to the vertebrate groups. Investigators are studying recently discovered fossils and applying molecular techniques to these problems. ■

ECHINODERMS

Learning Objectives

1. Identify the three main branches of deuterostomes.
2. List three shared, derived characters of echinoderms, and describe the main classes of echinoderms.

All members of phylum **Echinodermata** inhabit marine environments. They are found in the ocean at all depths. About 7000 living and more than 13,000 extinct species have been identified. The echinoderms probably evolved during the early Cambrian period and achieved maximum diversity by the middle of the Paleozoic era, about 400 million years ago (mya). By the beginning of the Mesozoic era 248 mya, they had declined, leaving six main groups that have survived to the present day (Fig. 30-1): class Crinoidea, sea lilies and feather stars; class Asteroidea, sea stars; class Ophiuroidea, basket stars and brittle stars; class Echinoidea, sea urchins and sand dollars; class Holothuroidea, sea cucumbers; and class Concentricycloidea, sea daisies.

The echinoderms are in many ways unique in the animal kingdom. Echinoderm larvae are bilaterally symmetrical, ciliated, and free-swimming. However, during development the body form reorganizes, and the adult exhibits **pentaradial symmetry,** in which the body is arranged in five parts around a central axis. Echinoderms have an **endoskeleton,** an internal skeleton, that is covered by a thin, ciliated epidermis. The endoskeleton consists of $CaCO_3$ plates and spines. The name *Echinodermata,* meaning "spiny-skinned," was inspired by the spines that project outward from the endoskeleton. Some groups have pincer-like, modified spines called **pedicellariae** on the body surface (Fig. 30-2). These structures, unique to the echinoderms, keep the surface of the animal free of debris.

The most unique derived character of echinoderms is the hydraulic **water vascular system,** a network of fluid-filled canals that functions in locomotion, feeding, and gas exchange. Branches of the water vascular system lead to numerous tiny **tube feet** that extend when filled with fluid. Each tube foot receives fluid from the main system of canals. A rounded muscular sac, or **ampulla,** at the base of the foot, stores fluid and is used to operate the tube foot. A valve separates each tube foot from other parts of the system. When the valve shuts, the ampulla contracts, forcing fluid into the tube foot so that it extends. At the bottom of the foot is a suction-type structure that presses against and adheres to whatever surface the tube foot is on.

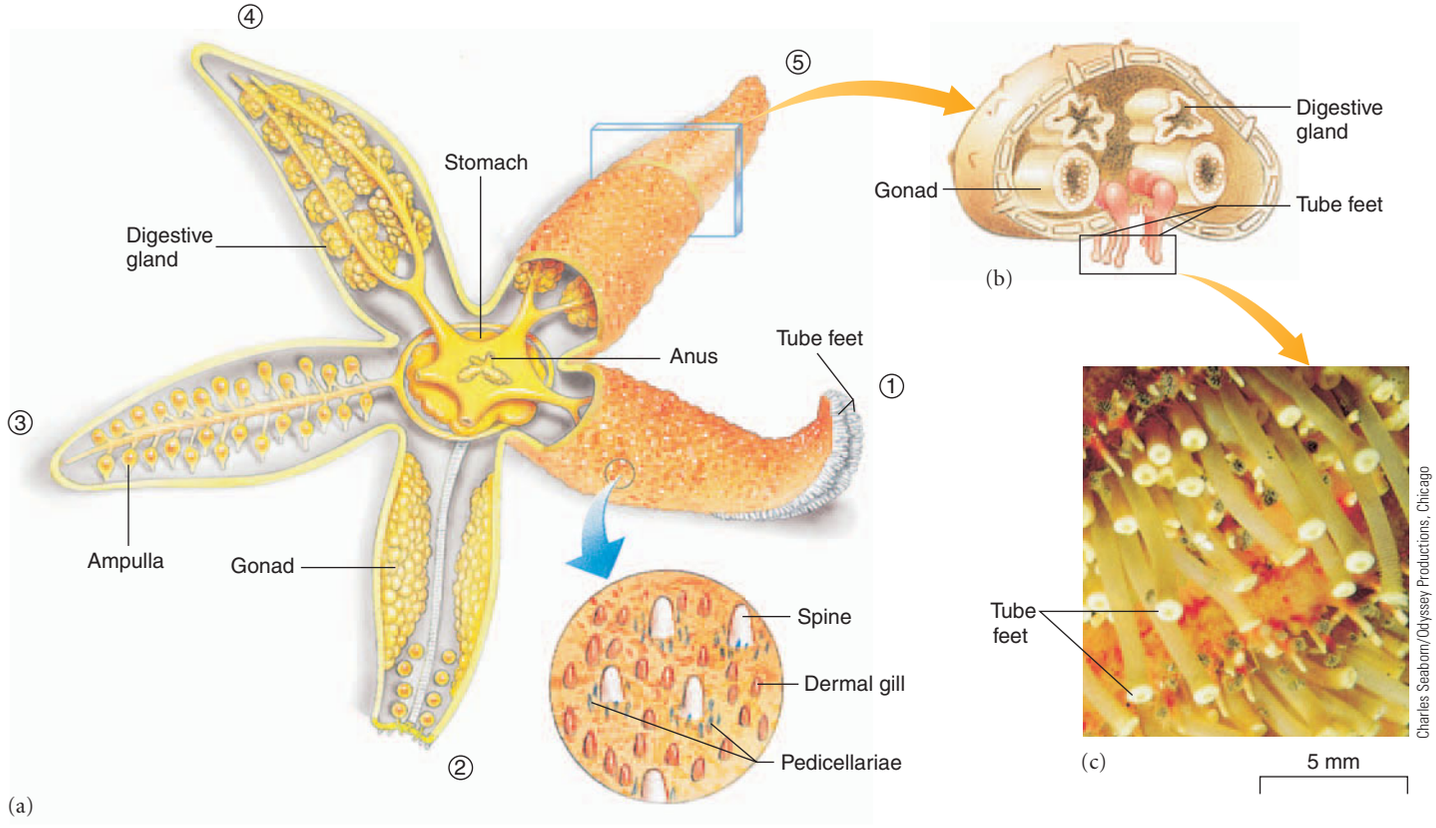

FIGURE **30-2** **Body plan of a sea star.**

(a) A sea star viewed from above, with its arms in various stages of dissection. Similar structures are present in each arm. The two-part stomach is in the central disc with the anus on the aboral *(upper)* surface and the mouth beneath on the oral surface. ① Upper surface with magnified detail. The end is turned up to show the tube feet on the lower surface. ② The arm is dissected to show well-developed gonads. ③ Upper body and digestive glands have been removed, exposing the ampullae of some of the hundreds of tube feet *(magnified view).* ④ Other organs have been removed to show the digestive glands. ⑤ Upper surface. **(b)** Cross section through arm and tube feet. **(c)** LM of tube feet of a sea star.

Echinoderms have a well-developed coelom, and the coelomic fluid transports materials. Although its structure varies in different groups, the complete digestive system is the most prominent body system. A variety of respiratory structures are found in the various classes. No excretory organs are present. The nervous system is simple, generally consisting of a nerve ring with nerves that extend out from it. Echinoderms have no brain. The sexes are usually separate, and eggs and sperm are generally released into the water, where fertilization takes place.

Members of class Crinoidea are suspension feeders

Class **Crinoidea,** the oldest class of living echinoderms, includes the feather stars and the sea lilies (see Fig. 30-1a). Although a great many extinct crinoids are known, there are relatively few living species. The feather stars are motile crinoids, although they often remain in the same location for long periods. Sea lilies are sessile and remain attached to the ocean floor by a stalk.

Crinoids remove suspended food from the water. In all other echinoderms, the mouth is located on the underside of the disk toward the substratum, but in crinoids the **oral surface** (mouth surface) is on the upper side of the disk. A number of branched, feathery arms also extend upward. Along the feathery arms are numerous tube feet shaped like small tentacles and coated with mucus that traps microscopic organisms.

Many members of class Asteroidea capture prey

Sea stars, or starfish, are members of class **Asteroidea** (see Fig. 30-1b). Their bodies consist of a central disk from which extend 5 to more than 20 arms, or rays (see Fig. 30-2). The undersurface of each arm has hundreds of pairs of tube feet. The mouth lies in the center of the underside of the disk. The endoskeleton consists of a series of calcareous plates that permit some movement in the arms. Delicate dermal gills, small extensions of the body wall, carry on gas exchange.

Most sea stars are carnivorous predators and scavengers that feed on crustaceans, mollusks, annelids, and even other echinoderms. Occasionally they catch small fish. The sea star's water vascular system does not permit rapid movement, so its prey are usually slow-moving or stationary animals such as clams.

To attack a clam or other bivalve mollusk, the sea star mounts it and assumes a humped position as it straddles the edge opposite the hinge. Then, holding itself in position with its tube feet, the sea star slides its thin, flexible stomach out through its mouth and between the closed, or slightly gaping, valves (shell parts) of the clam. The sea star secretes enzymes that digest the soft parts of the clam to the consistency of a thick soup while the clam is still in its own shell. The partly digested meal passes into the sea star body, where it is further digested by enzymes secreted from glands located in each arm.

The circulatory system in sea stars is poorly developed and probably of little help in circulating materials. Instead, this function is assumed by the coelomic fluid, which fills the large coelom and bathes the internal tissues. Metabolic wastes pass to the outside by diffusion across the tube feet and dermal gills. The nervous system consists of a ring of nervous tissue encircling the mouth and a nerve extending from this ring into each arm.

Class Ophiuroidea is the largest class of echinoderms

Basket stars and brittle stars (serpent stars), members of class **Ophiuroidea,** are the largest group of echinoderms, both in number of species and in number of individuals (see Fig. 30-1c). These animals resemble sea stars in that their bodies consist of a central disk with arms, but the arms are long and slender and more sharply set off from the central disk. Ophiuroids can move more rapidly than sea stars, using their arms to perform rowing or even swimming movements. Their tube feet lack suckers and are not used in locomotion; they are used to collect and handle food and may also serve a sensory function, perhaps that of taste.

Members of class Echinoidea have movable spines

Sea urchins and sand dollars, the animals of class **Echinoidea,** have no arms (see Fig. 30-1d and chapter opening photograph). Their skeletal plates are flattened and fused to form a solid shell called a **test.** The flattened body of the sand dollar is adapted for burrowing in the sand, where it feeds on tiny organic particles. Sand dollars have smaller spines than do sea urchins.

The sea urchin body is covered with spines that in some species can penetrate flesh and are difficult to remove. So threatening are these spines that swimmers on tropical beaches are often cautioned to wear shoes when venturing offshore, where these living pincushions may live in abundance. Sea urchins use their tube feet for locomotion. They also push themselves along with their movable spines. Many sea urchins graze on algae, scraping the sea floor with their calcareous teeth.

Members of class Holothuroidea are elongated, sluggish animals

Sea cucumbers, members of class **Holothuroidea,** are appropriately named, for some species are about the size and shape of a cucumber. The elongated body is a flexible, muscular sac (see Fig. 30-1e). The mouth is usually surrounded by a circle of tentacles that are modified tube feet. The endoskeleton consists of microscopic plates embedded in the body wall. More highly developed than that of other echinoderms, the circulatory system functions to transport oxygen and perhaps nutrients as well.

Sea cucumbers are sluggish animals that usually live on the bottom of the sea, sometimes burrowing in the mud. Some graze with their tentacles, whereas others stretch their branched tentacles out in the water and wait for dinner to float by. Algae and other morsels are trapped in mucus along the tentacles.

An interesting habit of some sea cucumbers is evisceration, in which the digestive tract, respiratory structures, and gonads are ejected from the body, usually when environmental conditions are unfavorable. When conditions improve, the lost parts are regenerated. Even more curious is the fact that when certain sea cucumbers are irritated or attacked, they direct their rear end toward the enemy and shoot red tubules out of their anus! These unusual weapons are sticky, and the attacking animal may become hopelessly entangled. Some of the tubules release a toxic substance.

Members of class Concentricycloidea have a unique water vascular system

Biologists established class **Concentricycloidea** to accommodate sea daisies, a group of interesting echinoderms first discovered in 1986. Sea daisies inhabit bacteria-rich wood sunk in deep water and apparently ingest bacteria through their body surface. Their small, disk-shaped, flat bodies (less than 1 cm in diameter) have no arms or mouth.

Review

- What are three derived characters of echinoderms? Describe each.
- How do sea stars differ from crinoids? From sea urchins?

FIGURE **30-3** **Evolutionary relationships of the chordates.**

This diagram shows possible phylogenetic relationships among deuterostomes, including chordates (tan region), based on morphological and DNA data.

CHORDATE CHARACTERS

Learning Objective

3 Describe four shared derived characters of chordates.

Biologists currently divide phylum **Chordata** into three subphyla: Urochordata, which consists of marine animals called *tunicates;* Cephalochordata, marine animals called *lancelets;* and Vertebrata, animals with backbones. Of these extant chordate groups, the urochordates were the earliest to evolve (Fig. 30-3).

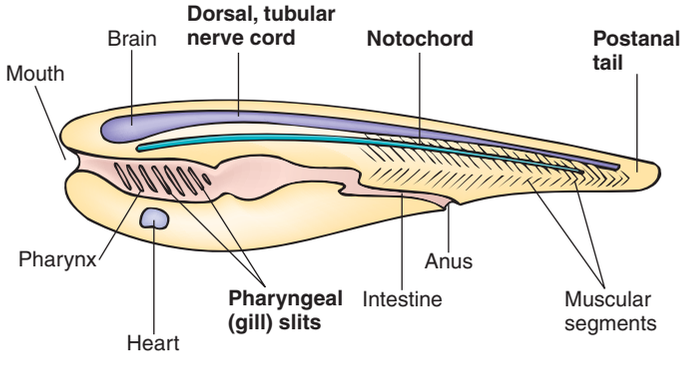
Chordates are deuterostome coelomates with bilateral symmetry, a tube-within-a-tube body plan, and three well-developed germ layers (Fig. 30-4). Typically, they have an endoskeleton and a closed circulatory system with a ventral heart. Chordates have segmented bodies, but specialization is so pronounced that the basic segmentation of the body plan may not be apparent. For example, in vertebrates, although segmentation of the body is not obvious, muscles and nerves are segmentally organized. Chordates are compared to echinoderms in Table 30-1.

Four shared derived characters that distinguish the chordates are the notochord; the dorsal, tubular nerve cord; gill slits; and a postanal tail.

1. All chordates have a **notochord** during some time in their life cycle. The notochord is a dorsal longitudinal rod that is firm, but flexible, and supports the body.
2. At some time in their life cycle, chordates have a **dorsal, tubular nerve cord.** The chordate nerve cord differs from the nerve cord of most other animals in that it is located dorsally rather than ventrally, is hollow rather than solid, and is single rather than double.
3. Chordates have **pharyngeal slits** (also called *pharyngeal gill slits*) during some time in their life cycle. In the embryo, a series of alternating branchial (gill) arches and grooves develop in the body wall in the pharyngeal (throat) region. Pharyngeal pouches extend laterally from the anterior portion of the digestive tract toward the grooves.

FIGURE **30-4** **Generalized chordate body plan.**

Note the notochord; dorsal, tubular nerve cord; pharyngeal (gill) slits; and postanal tail.



Early chordates, like many living chordates, were probably suspension feeders. The arrangement of pharyngeal pouches and slits permitted them to take water in through the mouth, concentrate small particles of food in the gut, and let the water escape from the body through the slits. The pharyngeal slits and the arches supporting them became modified for gas exchange in fishes and some other aquatic vertebrates. Early in vertebrate evolution, anterior pharyngeal arches evolved into jaws.

4. Chordates have a larva or embryo with a muscular **postanal tail,** an appendage that extends posterior to the anus.

Review

- What is a notochord?
- What is the significance of pharyngeal slits?

Biology Now™ Assess your understanding of **chordate characters** by taking the pretest on your BiologyNow CD-ROM.

INVERTEBRATE CHORDATES

Learning Objectives

4 Describe the invertebrate chordate subphyla.
5 Discuss the evolution of chordates.

The invertebrate chordates include tunicates and lancelets. Biologists assign the tunicates to subphylum Urochordata, and the lancelets to subphylum Cephalochordata.

Tunicates are common marine animals

The **tunicates,** which make up subphylum **Urochordata,** include the sea squirts, or **ascidians,** and their relatives. Larval tunicates have typical chordate characteristics and superficially resemble tadpoles. The expanded body has a pharynx with slits, and the long muscular tail contains a notochord and a dorsal, tubular nerve cord. Some tunicates *(appendicularians)* are common members of the zooplankton that retain their chordate features and ability to swim.

Most tunicates are ascidians, commonly known as *sea squirts* (class Ascidiacea). A sea squirt larva swims for a time, then attaches itself to the sea bottom and loses its tail, notochord, and much of its nervous system. Adult sea squirts are barrel-shaped, sessile marine animals unlike other chordates. Indeed, they are often mistaken for sponges or cnidarians (Fig. 30-5). Only the pharyngeal slits and the structure of its larva indicate that the sea squirt is a chordate.

Adult tunicates develop a protective covering, or **tunic,** that may be soft and transparent or quite leathery. Curiously, the tunic consists of a carbohydrate much like cellulose. The tunic has two openings: the incurrent siphon, through which water and food enter, and the excurrent siphon, through which water, waste products, and gametes pass to the outside. Sea squirts get their name from their practice of forcefully expelling a stream of water from the excurrent siphon when irritated.

Tunicates are suspension feeders that remove plankton from the stream of water passing through the pharynx. Food particles are trapped in mucus secreted by cells of the *endostyle,* a groove that extends the length of the pharynx. Ciliated cells of the pharynx move the stream of food-laden mucus into the esophagus. Much of the water entering the pharynx passes out through the pharyngeal slits into an **atrium** (chamber) and is discharged through the excurrent siphon.

Some species of tunicates form large colonies in which members share a common tunic and excurrent siphon. Colonial forms often reproduce asexually by budding. Sexual forms are usually hermaphroditic.

Lancelets may be closely related to vertebrates

Most species of subphylum Cephalochordata belong to the genus *Branchiostoma,* which consists of animals commonly known as **lancelets,** or **amphioxus.** Lancelets are translucent, fish-shaped animals, 5 to 10 cm long and pointed at both ends. They are widely distributed in shallow seas, either swimming freely or burrowing in the sand near the low-tide line. In some parts of the world, lancelets are an important source of food. One Chinese fishery reports an annual catch of 35 tons (about 1 billion lancelets).

Chordate characteristics are highly developed in lancelets. The notochord extends from the anterior tip ("head"; hence the name *Cephalochordata*) to the posterior tip. Many pairs of pharyngeal slits are evident in the large pharyngeal region, and a dorsal, tubular nerve cord extends the entire length of the animal (Fig. 30-6). Although superficially similar to fishes, lancelets have a far simpler body plan. They do not have paired fins, jaws, sense organs, a heart, or a well-defined head or brain.

Like the tunicates, lancelets use their cilia to draw a current of water into the mouth and then strain out microscopic organisms. Food particles are trapped in mucus in the pharynx and are then carried back to the intestine.

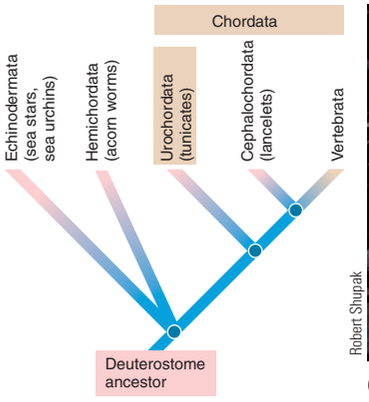
Water passes through the pharyngeal slits into the atrium, a chamber with a ventral opening (the *atriopore*) just anterior to the anus. Metabolic wastes are excreted by segmentally arranged, ciliated *protonephridia* that open into the atrium. In contrast with other invertebrates, the blood flows anteriorly in the ventral vessel and posteriorly in the dorsal vessel. This circulatory pattern is similar to that of fishes.

Recent molecular and morphological findings suggest that lancelets are the vertebrates' closest living relative. One similarity is the lancelet nerve cord, which has specialized regions that correspond to the vertebrate forebrain and midbrain.

Chordate phylogeny is controversial

PROCESS OF SCIENCE

No clear fossil record of chordate ancestors exists, but evidence suggests they were small, soft-bodied animals. **Yunnanozoans** are a distinctive group of well-preserved fossils that occur in **Chengjiang,** an early Cambrian fossil site in China. At this site,



(a)

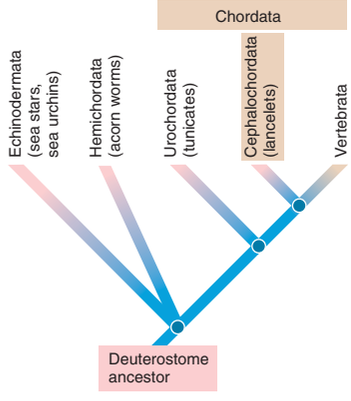
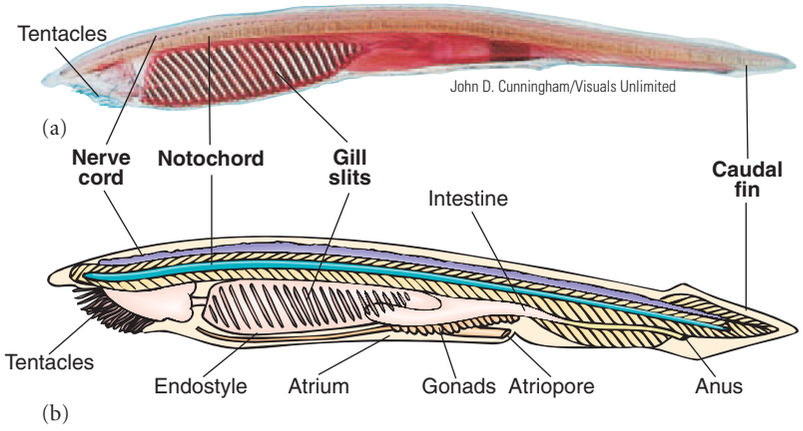
fine-grained rocks about 530 million years old have preserved soft-bodied animals in great detail. One yunnanozoan, named ***Haikouella,*** was about 3 cm long and had a nerve cord and notochord. Some biologists interpret a species of *Haikouella,* reported in 2003, as an early deuterostome, but not as a chordate. Other scientists disagree, and instead, hypothesize that the yunnanozoans were vertebrate-like chordates. Biologists need additional data to settle this controversy.





(a)

(b)

FIGURE 30-6

Cephalochordate body plan.

(a) Photograph of a lancelet, *Branchiostoma* (amphioxus). Note the prominent pharyngeal gill slits. **(b)** Longitudinal section showing internal structure.

The rocks of the Burgess Shale of British Columbia, Canada, which date back to the Cambrian period, have also been a rich source of fossils. Among these fossils, biologists discovered a lancelet-like animal they named ***Pikaia.*** This animal had a notochord with muscles attached to it allowing for locomotion. Biologists interpret the fossil as an early cephalochordate.

Based on morphological and molecular evidence, the hemichordates are probably closely related to the echinoderms. Many systematists consider subphyla cephalochordata and Vertebrata to be **sister taxa,** groups that diverged from a recent common ancestor. That ancestor may have resembled a tunicate larva.

Recently, scientists sequenced part of the genome of the sea squirt *Ciona intestinalis,* the most studied ascidian tunicate. Based on their findings, these scientists reported their insights into chordate and vertebrate evolution. They found that *Ciona* has most vertebrate gene families in simplified form. For example, *Ciona* has only a single copy of each gene family involved in cell signaling and regulation of development, whereas vertebrates have two or more copies of these gene families. Interestingly, *Ciona* has genes for some vertebrate structures and processes, even though it does not express these genes. These data suggest the sea squirt genetic makeup corresponds to that of the chordate ancestor.

Review

- How are the main derived chordate characters evident in a tunicate larva, an adult tunicate, and in a lancelet?

INTRODUCING THE VERTEBRATES

Learning Objective

6 Describe four shared derived characters of vertebrates.

With about 48,000 species, the **vertebrates,** members of subphylum **Vertebrata,** are less diverse and much less numerous than the insects but rival them in their adaptations to an enormous variety of lifestyles. In addition to the basic chordate characteristics, vertebrates have a number of shared derived characters not found in other groups.

The vertebral column is a key vertebrate character

The vertebrates are distinguished from other chordates in having a backbone, or **vertebral column,** that forms the skeletal axis of the body. This flexible support develops around the notochord, and in most species it largely replaces the notochord during embryonic development. The vertebral column consists of cartilaginous or bony segments called **vertebrae.** Dorsal projections of the vertebrae enclose the nerve cord along its length. Anterior to the vertebral column, a cartilaginous or bony **cranium,** or braincase, encloses and protects the brain, the enlarged anterior end of the nerve cord.

The cranium and vertebral column are part of the **endoskeleton.** In contrast with the nonliving exoskeleton of many invertebrates, the vertebrate endoskeleton is a living tissue that grows with the animal. In most vertebrates, the skeleton is mainly bone, a tissue that contains fibers made of the protein collagen. The hard matrix of bone consists of the compound hydroxyapatite, composed mainly of calcium phosphate.

Many characters common to vertebrates have been derived from a group of cells called **neural crest cells.** These cells, found only in vertebrates, appear early in development and migrate to various parts of the embryo. Neural crest cells give rise to or influence the development of many structures, including nerves, head muscles, cranium, and jaws.

Recall that invertebrates show an evolutionary trend toward **cephalization,** the concentration of nerve cells and sense organs in a definite head. Vertebrate evolution is characterized by *pronounced* cephalization. The brain has become larger and more elaborate, and its various regions have specialized to perform different functions. Ten or 12 pairs of **cranial nerves** emerge from the brain and extend to various organs of the body. Vertebrates have well-developed sense organs concentrated in the head: eyes; ears that serve as organs of balance and, in some vertebrates, for hearing as well; and organs of smell and taste.

Most vertebrates have two pairs of appendages. The fins of fishes are appendages that stabilize them in the water. Paired pectoral and pelvic fins are also used in steering. Biologists hypothesize that jointed appendages that facilitated locomotion on land evolved from the lobed (divided) fins of lungfishes.

Vertebrates have a closed circulatory system with a ventral heart and blood containing hemoglobin. The complete digestive tract has specialized regions and large digestive glands (the liver and pancreas). Several complex **endocrine glands,** which are ductless glands, secrete hormones. Paired kidneys regulate fluid balance. The sexes are typically separate.

Certain aspects of vertebrate phylogeny are still unclear

The study of evolutionary relationships of vertebrates is an important focus of research. Biologists consider the vertebrates and lancelets as sister groups that diverged from a common ancestor. The earliest "vertebrates" to evolve were **agnathans** (*a,* "without"; *gnathos,* "jaw"): the hagfishes, followed by the lampreys. Biologists assign hagfishes to class **Myxini** and lampreys to class **Cephalaspidomorphi.** However, a problem hinders this classification because the hagfishes do not quite qualify as vertebrates. Although they have many vertebrate characters, including a cranium, hagfishes have no trace of vertebrae. The notochord is their only axial support. Based on the cranium, many biologists now use the term **Craniata** to designate a clade that includes the vertebrates plus the hagfishes. They view the Myxini as the sister group of all other craniates.

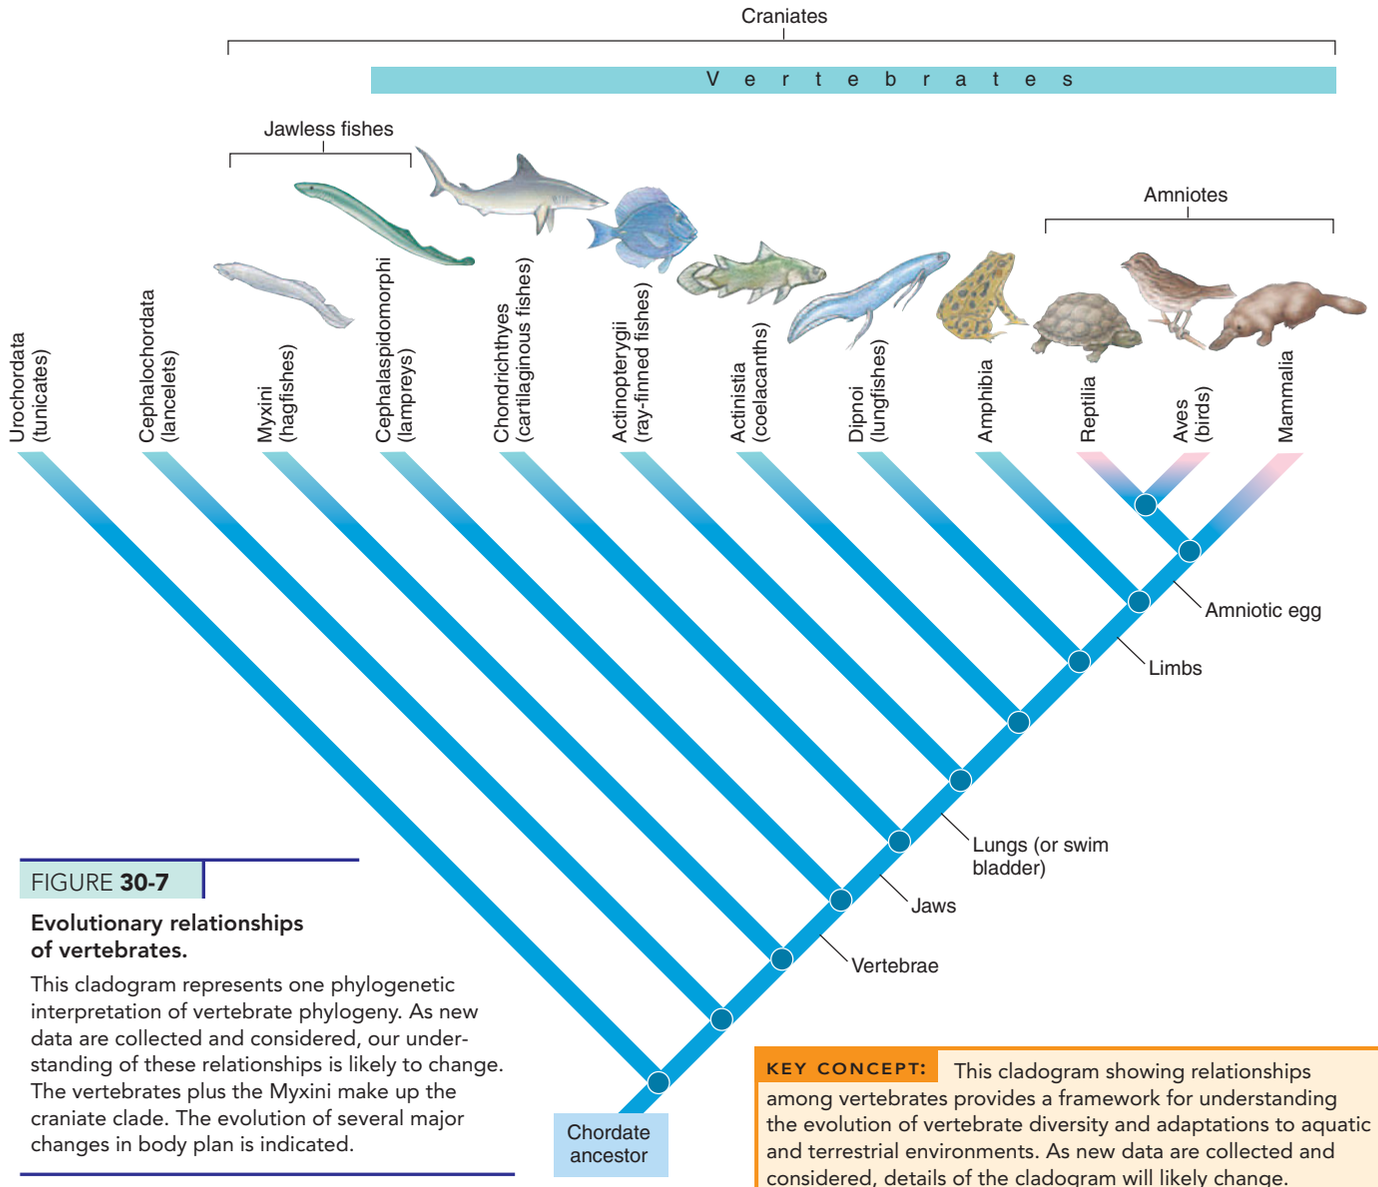

FIGURE **30-7**

Evolutionary relationships of vertebrates.

This cladogram represents one phylogenetic interpretation of vertebrate phylogeny. As new data are collected and considered, our understanding of these relationships is likely to change. The vertebrates plus the Myxini make up the craniate clade. The evolution of several major changes in body plan is indicated.

KEY CONCEPT: This cladogram showing relationships among vertebrates provides a framework for understanding the evolution of vertebrate diversity and adaptations to aquatic and terrestrial environments. As new data are collected and considered, details of the cladogram will likely change.

If we exclude the Myxini, the extant vertebrates are currently assigned to 9 classes: 5 classes of fishes and 4 of tetrapods (four-limbed vertebrates) (Fig. 30-7 and Table 30-2). Some biologists give these groups superclass status: superclass **Pisces** (fishes) and superclass **Tetrapoda.** In this classification scheme, the fishes include the lampreys and four classes of jawed fishes: Chondrichthyes, Actinopterygii, Actinistia, and Dipnoi.

The four-limbed land vertebrates, or tetrapods, include class Amphibia, the frogs, toads, and salamanders; class Reptilia, the lizards, snakes, turtles, and alligators; class Aves, the birds; and class Mammalia, the mammals. As we discuss later in the chapter, many cladists classify birds with reptiles, rather than assigning them to a separate class. The reptiles, birds, and mammals form a clade known as *amniotes,* animals fully adapted to life on land.

One approach to understanding the phylogenetic relationships of various taxa is to compare gene groups, such as *Hox* genes, of different animals. Recall that *Hox* genes are important in determining pattern development in embryos (see Chapter 16). Specifically, *Hox* genes determine the fate of cells in the anterior–posterior axis. These genes occur in clusters on specific chromosomes. All invertebrates and early chordates that have been studied have one *Hox* gene cluster. Investigators have suggested that duplication of *Hox* clusters may have contributed to the evolution of vertebrate body plans. Amphibians, reptiles, birds, and mammals have four *Hox* gene clusters, each containing about 10 different genes. Interestingly, the zebrafish and its close relatives have seven *Hox* clusters. We discuss the evolutionary implications of this fact later in the chapter.

Review

- What derived characters distinguish the vertebrates from the rest of the chordates?

BiologyNow™ Assess your understanding of **the vertebrates** by taking the pretest on your BiologyNow CD-ROM.

TABLE **30-1** Extant Vertebrate Classes

Class	Examples	Characteristics
Cephalaspidomorphi	Lampreys	Jawless, freshwater and marine fishes with skeleton of cartilage; complete cranium and rudimentary vertebrae; hatch as small larvae
Chondrichthyes	Sharks, rays, skates, chimeras	Jawed marine and freshwater fishes with skeleton of cartilage; notochord replaced by vertebrae in adult; gills; placoid scales; two pairs of fins; oviparous, ovoviparous, or viviparous (a few species); well-developed sense organs (including lateral line system)
Actinopterygii (ray-finned fishes)	Perch, salmon, tuna, trout	Bony, marine and freshwater fishes; gills; swim bladder; generally oviparous
Actinistia (lobe-finned fishes)	Coelacanths	Bony fishes; marine, nocturnal predators on fish; seven-lobed fins
Dipnoi (lungfishes)	Lungfishes	Bony freshwater fishes; four similarly sized limbs, which are similar in structure and position to those of tetrapods
Amphibia	Salamanders, frogs and toads, caecilians	Tetrapods; aquatic larva typically undergoes metamorphosis into terrestrial adult; gas exchange through lungs and/or moist skin; heart consists of two atria and single ventricle; systemic and pulmonary circulation
Reptilia Cladists divide this group into anapsid (turtles), diapsids (snakes, lizards, crocodiles, alligators), and birds.*	Turtles, lizards, snakes, alligators	Amniotes with horny scales; adapted for reproduction on land (internal fertilization, leathery shell, amnion); lungs; ventricles of heart partly divided
Aves	Robins, pelicans, eagles, ducks, penguins, ostriches	Amniotes with feathers; anterior limbs modified as wings; compact, streamlined body; four-chambered heart; endothermic; vocal calls and complex songs
Mammalia	Monotremes (Holotheria), marsupials (Metatheria), placental mammals (Eutheria)	Amniotes with hair; females nourish young with mammary glands; differentiation of teeth; 3 middle ear bones; diaphragm; four-chambered heart; endothermic; highly developed nervous system

*This classification of amniotes is illustrated in Figure 30-17.

JAWLESS FISHES

Learning Objective

7 Distinguish among the major groups of jawless fishes.

Some of the earliest known vertebrates, collectively referred to as **ostracoderms,** consisted of several groups of small, armored, jawless fishes that lived on the bottom and strained their food from the water (see Fig. 20-10). Their heads were protected from predators by thick bony plates, and their trunks and tails were covered with thick scales. Most ostracoderms lacked fins. Fragments of ostracoderm scales have been found in rocks from the Cambrian period, but most ostracoderm fossils are from the Ordovician and Silurian periods. They became extinct by the end of the Devonian period.

Like ostracoderms, present-day hagfishes and lampreys have neither jaws nor paired fins. They are eel-shaped animals, up to 1 m long. Their smooth skin lacks scales, and they are supported by a cartilaginous skeleton and well-developed notochord.

Hagfishes, assigned to class Myxini and no longer considered vertebrates, are marine scavengers. They burrow for worms and other invertebrates or prey on dead and disabled fishes. As a defense mechanism, hagfishes secrete large amounts of sticky slime.

Lampreys are jawless vertebrates assigned to class Cephalaspidomorphi. Some spend their adult lives in the ocean and return to fresh water to reproduce. Many species of adult lampreys are parasites on other fishes (Fig. 30-8). Adult parasitic lampreys have a circular sucking disk around the mouth, which lies on the ventral side of the anterior end of the body. Using this disk to attach to a fish, the lamprey bores through the skin of its host with horny (made of keratin rather than bone) teeth on the disk and tongue. Then the lamprey injects an anticoagulant into its host and sucks out blood and soft tissues.

As in hagfish, the notochord persists throughout life and is not replaced by a vertebral column. However, lampreys have rudiments of vertebrae, cartilaginous segments called *neural arches* that extend dorsally around the spinal cord.

Review

FISHES AND AMPHIBIANS

Learning Objective

8 Trace the evolution of jawed fishes and early tetrapods, and identify major taxa of jawed fishes and amphibians.

Fossil evidence suggests that jaws and paired fins evolved during the late Silurian and Devonian periods. Two early groups of jawed fishes, now extinct, were the **acanthodians,** armored fishes

FIGURE **30-8** **Lampreys.**

with paired spines and pectoral and pelvic fins, and **placoderms,** armored fishes with paired fins (Fig. 30-9).

The evolution of jaws from a portion of the gill arch skeleton and the development of fins enabled fishes to change from suspension-feeding bottom dwellers to active predators. This change afforded many new opportunities for finding food. The success of the jawed vertebrates may have contributed to the extinction of the ostracoderms.

FIGURE **30-9** **Early jawed fishes.**

Acanthodians and placoderms flourished in the Devonian period. **(a)** *Climatius,* a spiny-skinned acanthodian with large fin spines and five pairs of accessory fins between the pectoral and pelvic pairs. *Climatius* was a small fish that reached a length of 8 cm (3 in). **(b)** *Dinichthys,* a giant placoderm that grew to a length of 8 m (26 ft). (Most placoderms were only about 20 cm, or 8 in, long.) Its head and thorax were covered by bony armor, but the rest of the body and tail were naked.

(a) *Climatius*

(b) *Dinichthys*

Members of class Chondrichthyes are cartilaginous fishes

Members of class **Chondrichthyes,** the cartilaginous fishes, evolved as successful marine forms in the Devonian period. Class Chondricthyes, which is considered monophyletic, includes the sharks, rays, and skates (Fig. 30-10). Most species are ocean dwellers, but a few have invaded fresh water. Except for the whales, the sharks are the largest living vertebrates. Some whale sharks (*Rhincodon*) exceed 15 m (49 ft) in length, making them the largest fish.

Most rays and skates are sluggish, flattened creatures that live partly buried in the sand. Their enormous pectoral fins propel them along the bottom, where they feed on mussels and clams. The sting ray has a whiplike tail with a barbed spine at its base that can inflict a painful wound. The electric ray has electric organs on either side of the head. These modified muscles can discharge enough electric current (up to 2500 watts) to stun fairly large fishes, as well as human swimmers.

The chondrichthyes retain their cartilaginous embryonic skeleton. Although this skeleton is not replaced by bone, a deposit of calcium salts may strengthen it. All chondrichthyes have paired jaws and two pairs of fins. The skin contains **placoid scales.** Each scale is a toothlike structure consisting of an outer layer of enamel and an inner layer of dentine (Fig. 30-11). The lining of the mouth contains larger, but essentially similar, scales that serve as teeth. The teeth of other vertebrates are homologous with these scales. Shark teeth are embedded in the flesh and not attached to the jawbones; new teeth develop continuously in rows behind the functional teeth and migrate forward to replace any that are lost.

The shark body is adapted for swimming. Lift is provided by body shape and fins and by swimming swiftly. The shark stores a great deal of oil in its large liver (which may account

(a) Blue-spotted sting ray (*Taeniura lymma*). Sting rays typically feed on shellfish and bottom-dwelling fishes. **(b)** The great white shark (*Carcharodon carcharias*), photographed in Australia, is considered the most dangerous shark to humans. This shark is actually white only on its ventral aspect; the rest of the body is brownish-gray or bluish-gray.

for up to 30% of the body weight). Fats and oils decrease the overall density of fishes and contribute to buoyancy. Even so, the shark body is denser than water, so sharks tend to sink unless they are actively swimming.

Most sharks are streamlined predators that swim actively and catch and eat other fishes as well as crustaceans and mollusks. The largest sharks and rays, like the largest whales, are suspension feeders that strain plankton from the water. They gulp water through the mouth. Then, as the water passes through the pharynx and out the gill slits, food particles are trapped in a sievelike structure.

Predatory sharks are attracted to blood, so a wounded swimmer or a skin diver towing speared fish is a target. However, despite the common portrayal of sharks in books and films as monstrous enemies, most do not go out of their way to attack humans. In fact, of the approximately 350 known shark species, fewer than 30 are known to attack humans.

The shark has a complex brain, and a spinal cord protected by vertebrae. Their well-developed sense organs very effectively locate prey in the water. Sharks may detect other animals electrically before sensing them by sight or smell. **Electroreceptors** on the shark's head sense weak electric currents generated by the muscular activity of animals. The **lateral line organ,** found in all fishes, is a groove along each side of the body with many tiny openings to the outside. Sensory cells in the lateral line organ are sensitive to waves and other motion in the water, alerting the shark to the presence of predator or prey (see Fig. 41-5).

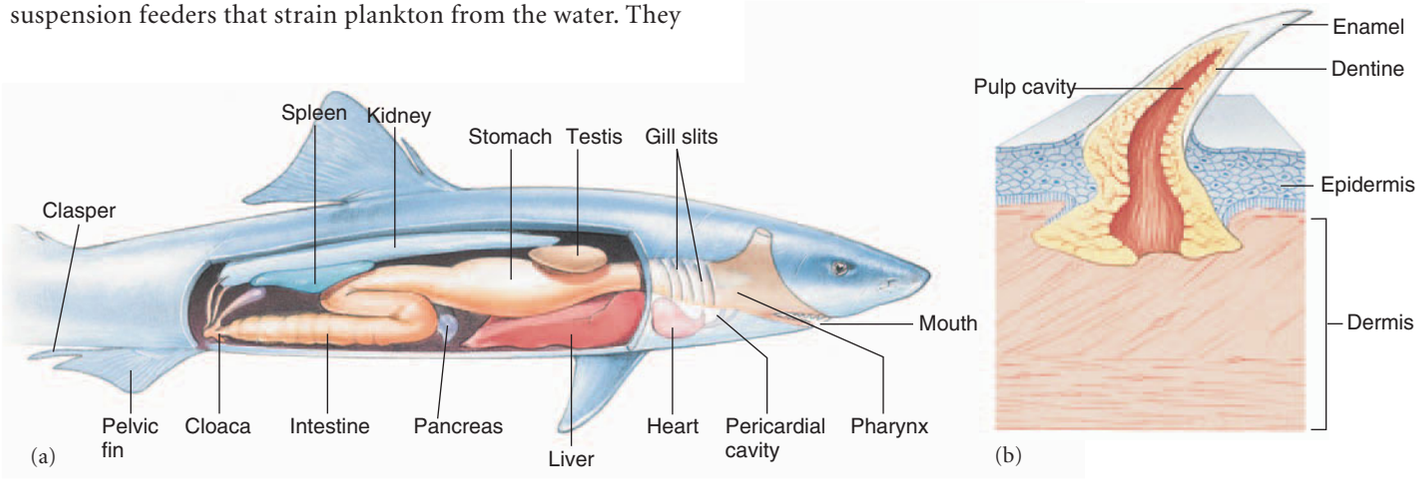
Cartilaginous fishes have no lungs. They have five to seven pairs of gills. A current of water enters the mouth and passes over the gills and out the gill slits, constantly providing the fish with a fresh supply of dissolved oxygen. Sharks that actively swim depend on their motion to enhance gas exchange. Sharks that spend time on the ocean floor, and rays and skates, use muscles of the jaw and pharynx to pump water over their gills.

The digestive tract of sharks consists of the mouth cavity; a long pharynx leading to the stomach; a short, straight intestine; and a **cloaca,** which opens on the underside of the body and is characteristic of many vertebrates. The liver and pancreas discharge digestive juices into the intestine. The cloaca receives digestive wastes, as well as metabolic wastes from the urinary system. In females, the cloaca also serves as a reproductive organ.

The sexes are separate, and fertilization is internal. In the mature male, each pelvic fin has a slender, grooved section, known as a **clasper,** used to transfer sperm into the female's cloaca. The

FIGURE **30-11** **Sharks.**

(a) Internal structure of a shark. **(b)** Structure of a placoid scale.



eggs are fertilized in the upper part of the female's oviducts. Part of the oviduct is modified as a shell gland, which secretes a protective coat around the egg.

Skates and some species of sharks are **oviparous;** that is, they lay eggs. Many species of sharks, however, are **ovoviviparous,** meaning their young are enclosed in eggs and incubated within the mother's body. During development, the young depend on stored yolk for their nourishment rather than on transfer of materials from the mother. The young are born after hatching from the eggs.

A few species of sharks are **viviparous.** Not only do the embryos develop within the uterus, but much of their nourishment is delivered to them by the mother's blood. Nutrients are transferred between the blood vessels in the lining of the uterus and the yolk sac surrounding each embryo.

The ray-finned fishes gave rise to modern bony fishes

Although bony fishes appear earlier in the fossil record than cartilaginous fishes, both groups may have evolved about the same time, during the Devonian period. The two groups share many characteristics (such as continuous tooth replacement), but they also differ in important ways.

Most bony fishes are characterized by a bony skeleton with many vertebrae. Bone has advantages over cartilage: It provides excellent support and serves as a very effective storage site for calcium. Most species have flexible median and paired fins, supported by long rays made of cartilage or bone. Overlapping, bony dermal scales cover the body. A lateral bony flap, the **operculum,** extends posteriorly from the head and protects the gills.

Unlike most sharks, bony fishes are oviparous. They lay an impressive number of eggs and fertilize them externally. The ocean sunfish, for example, lays more than 300 million eggs! Of course, most of the eggs and young become food for other animals. The probability of survival is increased by certain behavioral adaptations. For example, many species of fishes build nests for their eggs and protect them.

During the Devonian period, the bony fishes diverged into two major groups: the **Sarcopterygii** and the **ray-finned fishes,** class **Actinopterygii.** Fossils of the earliest sarcopterygians date back to the Devonian about 400 mya. Lungs and fleshy, **lobed fins** characterize these fishes. The flexible fins had a central appendage with many bones and muscles and could support the body. Early sarcopterygians evolved along two separate lines: the **lungfishes** (class **Dipnoi**) and **lobe-finned fishes** (class **Actinistia**). Three genera of lungfishes survive today in the rivers of tropical Africa, Australia, and South America.

The ray-finned fishes underwent two important adaptive radiations. The first gave rise during the late Paleozoic era to a group of fishes that are now mostly extinct. The second radiation began during the early Mesozoic era and gave rise to the modern bony fishes. The ancestors of the modern bony fishes had lungs, which were retained by the lobe-finned fishes and lungfishes. In the ray-finned fishes, however, the lungs became modified as a **swim bladder,** an air sac that helps regulate buoyancy (Fig. 30-12). Bones and muscles are heavier than water, and without the swim bladder the fish would sink. By regulating gas exchange between its blood and swim bladder, a fish can control the amount of gas in the swim bladder, changing the overall density of its body. This ability allows a bony fish, in contrast to a shark, to hover at a given depth of water without much muscular effort.

There are more species of bony fishes than any other group of vertebrates. Biologists have identified about 49,000 living species of freshwater and saltwater bony fishes, of many shapes and colors (Fig. 30-13). Bony fishes range in size from the Philippine goby, which is only about 1 cm (0.4 in) long, to the ocean sunfish (or *Mola;* see Fig. 19-13c), which may reach 4 m and weigh about 1500 kg (about 3300 lb).

The diversity of bony fishes may have resulted from the action of *Hox* genes. Early chordates have only one *Hox* cluster, but tetrapods have four clusters. The zebrafish has seven *Hox* clusters. During the radiation of ray-finned fishes, entire chromosomes duplicated, resulting in one or more additional clusters of *Hox* genes. These genes could have provided the genetic material for the evolution of the diverse species of ray-finned fish.

Did descendants of the lobe-finned fishes or lungfishes move onto the land?

PROCESS OF SCIENCE

Biologists thought the lobe-finned fishes were extinct by the end of the Paleozoic era, so in 1938 the scientific community

was very excited when a commercial fisherman caught one off the coast of South Africa. Since that time more than 200 specimens of these giant "living fossils" have been found in the deep waters off the east coast of Africa near the Comoro Islands (Fig. 30-14). These fishes, known as **coelacanths,** measure nearly 2 m (about 6 ft) in length. They are nocturnal predators on other fishes. Coelacanths have been discovered recently off the coasts of Indonesia and Kenya.

The pieces seemed to fit together perfectly. The coelacanths were surely the living fossil representatives of the group that gave rise to the land vertebrates. This was the prevailing hypothesis until the 1980s, when a few investigators began to question it because of morphological data. The external nasal openings of fossil and living lungfish suggested they, rather than the coelacanths, might be the ancestors of the land vertebrates. Other morphological similarities between lungfishes and land vertebrates are tooth enamel and four similarly sized limbs that have a similar structure and position. (Recall that the fins of lungfishes are also lobed.) During the 1990s, the lungfish hypothesis gained support from comparisons of mitochondrial DNA. Current data suggest lungfishes are probably the ancestors of tetrapods. Future sequencing of nuclear DNA may support or refute this hypothesis.

One hypothesis that explains the origin of tetrapod limbs is as follows. During the frequent seasonal droughts in the Devonian period, swamps became stagnant or even dried up completely. Fishes with lobed fins would have had a tremendous advantage for survival under those conditions. They were strikingly preadapted for moving onto the land. They had lungs for breathing air, and their sturdy, fleshy fins may have allowed them to "walk" along in shallow water. These fins could support the fish's weight, enabling it to emerge onto dry land and make its way to another pond or stream.

Some biologists question this account. A competing view holds that limbs may have evolved in a fully aquatic environ-

Image not available due to copyright restrictions

ment. Animals with more developed limbs could move along in shallow water or creep through dense aquatic vegetation more efficiently than their lobe-finned ancestors. Whichever view of the evolution of tetrapods is correct, natural selection favored those individuals adapted for making their way on land.

The ability to move about, however awkwardly, on dry land gave animals access to new food sources. Terrestrial plants were already established, and terrestrial insects and arachnids were rapidly evolving. A vertebrate that could survive on land had less competition for food. Laying eggs on land, away from the many ocean predators, also increased their chances for successful reproduction. The early vertebrate experience on land was so successful that their lineage gave rise to the amphibians and, later, the reptiles, birds, and mammals.

Amphibians were the first successful land vertebrates

The first successful **tetrapods,** or land vertebrates, were the **labyrinthodonts** (Fig. 30-15), clumsy animals with short necks and heavy, muscular tails. They had limbs strong enough to support the weight of their bodies on land. The largest labyrinthodonts were the size of crocodiles. They flourished during the late Paleozoic and early Mesozoic eras, then became extinct. Biologists hypothesize that the labyrinthodonts gave rise to frogs and salamanders.

Biologists classify modern amphibians (class **Amphibia**) in three orders: Order **Urodela** ("visible tail") includes salamanders, mudpuppies, and newts, all animals with long tails; order **Anura** ("no tail") is made up of frogs and toads, with legs adapted for hopping; and order **Apoda** ("no feet") contains the wormlike caecilians (Fig. 30-16). Although some adult amphibians are quite successful as land animals and live in dry environments, most return to the water to reproduce. Eggs and sperm are generally released in the water.

Amphibians undergo a complex change, or **metamorphosis,** from larva to adult. The embryos of most frogs and toads develop into larvae called **tadpoles.** These larvae have tails and gills, and most feed on aquatic plants. After a time, the tadpole undergoes metamorphosis, a process regulated by hormones secreted by the *thyroid gland.* During metamorphosis, gills and gill slits disappear, the tail is resorbed, and limbs emerge. The digestive tract shortens, and food preference shifts from plant material to a carnivorous diet; the mouth widens; a tongue develops; the tympanic membrane (ear drum) and eyelids appear; and the eye lens changes shape. Many biochemical changes also accompany the transformation from a completely aquatic life to an amphibious one.

Several salamanders, such as the mudpuppy *Necturus,* do not undergo complete metamorphosis; they retain many larval characteristics even when sexually mature adults. Recall from Chapter 19 that this is an example of **paedomorphosis** (see Fig. 19-14). This type of development permits these salamanders to remain aquatic rather than having to compete on land.

The coloration of amphibians may conceal them in their habitat or may be very bright and striking. Many of the brightly colored species are poisonous (Fig. 30-16a). Their distinctive

FIGURE **30-15** **An artist's conception of labyrinthodonts.**

(b)

colors warn predators they are not encountering an ordinary amphibian. Some frogs camouflage themselves by changing color.

Adult amphibians do not depend solely on their primitive lungs for the exchange of respiratory gases. Their moist, glandular skin, which lacks scales and is plentifully supplied with blood vessels, also serves as a respiratory surface. The numerous mucous glands within the skin help keep the body surface moist, which is important in gas exchange. The mucus also makes the animal slippery, facilitating its escape from predators. Some amphibians have glands in their skin that secrete poisonous substances harmful to predators.

The amphibian heart is divided into three chambers: Two **atria** receive blood, and a single **ventricle** pumps it into the arteries. A double circuit of blood vessels keeps oxygen-rich and oxygen-poor blood partially separate. Blood passes through the **systemic circulation** to the various tissues and organs of the body. Then, after returning to the heart, it is directed through the **pulmonary circulation** to the lungs and skin, where it is recharged with oxygen. The oxygen-rich blood returns to the heart to be pumped out into the systemic circulation again. We discuss the comparative anatomy of the heart and circulation of various vertebrate classes in Chapter 42.

Review

- From an evolutionary perspective, what is the significance of each of the following? (a) placoderms (b) lungfishes (c) labyrinthodonts?
- What changes allow amphibians to move from aquatic life as a tadpole to terrestrial life as an adult?
- Support the hypothesis that lungfishes gave rise to tetrapods.

FIGURE **30-17** **Phylogeny of the amniotes.**
This cladogram shows proposed evolutionary relationships among reptiles, birds, and mammals. Some of these relationships, for example, classification of the turtle as an anapsid, are currently being studied and may be reinterpreted.

AMNIOTES

Learning Objectives

9 Describe three vertebrate adaptations to terrestrial life.
10 Describe the reptiles and birds, and give an argument for including the birds in the reptile clade.
11 Contrast monotremes, marsupials, and placental mammals, and give examples of animals that belong to each group.

The evolution of reptiles from ancestral amphibians required many adaptations that allowed them to be completely terrestrial. Evolution of the **amniotic egg** was an extremely important event because it let terrestrial vertebrates complete their life cycles on land. This egg contains an **amnion,** a membrane that forms a fluid-filled sac around the embryo. The amnion provides the embryo with its own private "pond," permitting independence from a watery external environment. In addition to keeping the embryo moist, the amniotic fluid serves as a shock absorber, cushioning the developing embryo.

The evolution of the amniotic egg is so important to the success of terrestrial vertebrates—reptiles, birds, and mammals—that biologists refer to these animals as **amniotes.** Amniotes are a monophyletic group, because they have a common ancestor that was itself an amniote (Fig. 30-17).

In addition to the amnion, the amniotic egg has three other extraembryonic (not part of the developing body itself) membranes: yolk sac, chorion, and allantois. These membranes protect the developing embryo, store nutrients *(yolk sac)*, carry on gas exchange *(chorion and allantois)*, and store wastes *(allantois)*. We discuss development of the extraembryonic membranes in Chapter 49. Although most extant mammals do not lay eggs, their embryos have an amnion and other extraembryonic membranes.

Another important adaptation to terrestrial life is a body covering that minimizes water loss. However, such a covering severely decreases gas exchange across the body surface. Amniotes have efficient lungs and circulatory systems for exchange of oxygen and carbon dioxide. Amniotes also have physiological mechanisms for conserving water. For example, to avoid water loss during excretion of metabolic wastes, much of the fluid filtered from the blood by the kidneys is reabsorbed in the kidney tubules and urinary bladder.

Our understanding of amniote phylogeny is changing

Until recently, biology instructors taught that the three classes of amniotes were Reptilia, Aves, and Mammalia. However,

cladistic analysis indicates class Reptilia is not a monophyletic group. It is paraphyletic because it includes some, but not all, of its descendants (see Fig. 22-7). Our discussion of amniotes reflects the cladistic view, although we describe modern birds separately for convenience.

Biologists hypothesize that the earliest amniotes resembled lizards. By the late Carboniferous period, about 290 mya, amniotes had undergone an impressive adaptive radiation and diverged into two branches. One of these branches, the **synapsids,** gave rise to the mammals. The second branch, the **sauropsids,** gave rise to all the other reptiles and to the birds. The sauropsids divided to form two sub-branches: **anapsids** and **diapsids.** The turtles may be the only extant anapsids. The diapsids include the snakes, lizards, crocodilians, and many extinct reptiles, including the dinosaurs. Based on cladistic analysis, biologists also classify the birds as diapsids.

A second great amniote adaptive radiation occurred during the Mesozoic era that ended about 65 mya. In fact, the Mesozoic era is known as the Age of Reptiles. During that time reptiles were the dominant terrestrial animals (see Chapter 20). They had radiated into an impressive variety of ecological lifestyles (see Fig. 20-12). Some could fly, others became marine, and many filled terrestrial habitats. Two major groups were the **dinosaurs** and the **pterosaurs,** the flying reptiles.

Some of the dinosaurs were among the largest land animals to have ever walked on Earth (see Fig. 20-14). Some dinosaurs apparently traveled in social groups and took care of their young. Fossil evidence supports the hypothesis that at least some dinosaurs were **endothermic,** meaning they used metabolic energy to maintain a constant body temperature despite changes in the temperature of the environment. An advantage of endothermy is that it allows animals to be more active.

The reptiles were the dominant land animals for almost 200 million years. Then, toward the end of the Mesozoic era, many, including all the dinosaurs and pterosaurs, disappeared from the fossil record. In fact, more than half of all animal species became extinct at that time (see Chapter 20). As a result of this mass extinction, there are many more extinct reptiles than living species.

Reptiles have many terrestrial adaptations

Many reptilian characters are adaptations to terrestrial life. The female reptile secretes a protective leathery shell around the egg, which helps prevent the developing embryo from drying out. Sperm cannot penetrate this shell, and internal fertilization takes place within the body of the female before the shell is added. In this process, the male uses a copulatory organ (penis) to transfer sperm into the female reproductive tract. An amnion surrounds the embryo, as it develops within the protective shell.

The hard, dry, horny scales that retard drying are another adaptation to life on land. This scaly protective armor, which also protects the reptile from predators, is shed periodically. The dry reptilian skin does not allow effective gas exchange. Reptilian lungs are better developed than the saclike lungs of amphibians. Divided into many chambers, the reptilian lung provides a greatly increased surface area for gas exchange. Most reptiles have a three-chambered heart that is more efficient than the amphibian heart. The single ventricle has a partition, though incomplete, that separates oxygen-rich and oxygen-poor blood, facilitating oxygenation of body tissues. In crocodiles the partition is complete, and the heart has four chambers.

Like fishes and amphibians, reptiles generally lack metabolic mechanisms for regulating body temperature. They are **ectothermic,** meaning that their body temperature fluctuates with the temperature of the surrounding environment. Some reptiles have behavioral adaptations that let them maintain a body temperature higher than that of their environment. For example, you may have observed a lizard basking in the sun, which raises its body temperature and so increases its metabolic rate. This permits the lizard to hunt actively for food. When the body of a reptile is cold, its metabolic rate is low and it tends to be sluggish. Ectothermy may explain why reptiles are more successful in warm than in cold climates.

Many reptiles are carnivores (animals that eat meat). Their paired limbs, usually with five toes, are well adapted for running and climbing, and their well-developed sense organs enable them to locate prey.

Ignoring birds for the moment, biologists assign the extant reptiles to three main groups. Some consider these groups as classes, whereas others rank them as orders. The anapsids gave rise to the turtles, terrapins, and tortoises. These animals can be grouped in order Chelonia. Order Squamata includes lizards and snakes, and order Crocodilia contains crocodiles, alligators, caimans, and gavials (Fig. 30-18).

Members of order **Chelonia** are enclosed in a protective shell made of bony plates overlaid by horny scales. Some terrestrial species can withdraw their heads and legs completely into their shells. The size of adult turtles ranges from about 8 cm (3 in) long to that of the great marine species, which measure more than 2 m (6.5 ft) long and may weigh 450 kg (almost 1000 lb). Biologists usually refer to the land species as *tortoises,* whereas the aquatic forms are called *turtles;* freshwater types are sometimes called *terrapins.*

Lizards and snakes, assigned to order **Squamata,** are the most common of the modern reptiles. These animals have rows of scales that overlap like shingles on a roof, forming a continuous, flexible armor that is shed periodically. Lizards range in size from certain geckos, which weigh as little as 1 g, to the Komodo dragon of Indonesia, which may weigh 100 kg (220 lb). Their body sizes and shapes vary greatly. Some lizards, like the glass snake (it's really a lizard), are legless.

Snakes are characterized by a flexible, loosely jointed jaw structure that lets them swallow animals larger than the diameter of their own jaws. Snakes lack legs, and their bodies are elongated. (Remember that although not all the tetrapods have four limbs, all evolved from four-limbed ancestors.) Their eyes, covered by a transparent scale, do not have movable eyelids. Also absent are an external ear opening, a tympanic membrane (ear drum), and a middle ear cavity.

The snake uses its forked tongue as an accessory sensory organ for touch and smell. Chemicals from the ground or air adhere to the tongue. The snake rubs the tip of its tongue across the opening of a sense organ in the roof of the mouth that de-

tects odors. Pit vipers and some boas also have a prominent **pit organ** on each side of the head that enables them to detect heat from endothermic prey (see Fig. 41-1). These snakes use their pit organs to locate and capture small nocturnal mammals.

Some snakes, such as king snakes, pythons, and boa constrictors, kill their prey by rapidly wrapping themselves around the animal and squeezing so it cannot breathe. Others have fangs, which are hollow teeth connected to venom glands. When the snake bites, it pumps venom through the fangs into the prey. Some snake venoms cause the breakdown of red blood cells; others, such as that of the coral snake, are neurotoxins, which interfere with nerve function. Venomous snakes of the United States include rattlesnakes, copperheads, cottonmouths, and coral snakes. All these except the coral snakes are pit vipers.

Order **Crocodilia** includes three groups: (1) the crocodiles of Africa, Asia, and America; (2) the alligators of the southern United States and China, plus the caimans of Central America; and (3) the gavials of South Asia. Most species live in swamps, in rivers, or along sea coasts, feeding on various kinds of animals. Crocodiles are the largest living reptiles; some exceed 7 m (23 ft) in length. The cranial skeleton is adapted for aquatic life. The crocodile can be distinguished from the alligator or caiman by its long, slender snout and by the large fourth tooth on the bottom jaw that is visible when the mouth is closed.

Are birds really dinosaurs?

Cladistic analyses indicate that birds that evolved from saurischian dinosaurs (see Fig. 20-13a), specifically carnivorous theropods. Many theropods were long-tailed animals that moved about on two feet and had forelimbs with three clawed fingers. Many biologists now view birds as living dinosaurs!

Birds are the only extant animals with feathers. However, recent molecular and fossil evidence indicates that feathers evolved in dinosaurs before birds evolved. Biologists have suggested several hypotheses to explain the early functions of feathers. They may have been an adaptation that conserved body heat. Insulating feathers may have contributed to the evolution of endothermy (the ability to maintain a constant body temperature), permitting animals to be more active. Feathers may have been important in courtship rituals, or in camouflage.

Chinese, American, and Canadian paleontologists have discovered, in the Yixian formation in China, an amazing array of fossils from the early Cretaceous period (124 to 128 mya). They have identified a number of theropod dinosaur fossils that demonstrate the evolution of feathers from very simple, tubular structures to complex modern forms. One feathered dinosaur discovered there is *Caudipteryx,* which was about the size of a turkey. *Caudipteryx* has well-preserved imprints of complex feathers on its tail and forelimbs, and its bones show many bird characteristics (Fig. 30-19a). Analyzing fossil evidence and recent molecular data, biologists conclude that feather evolution took place in terrestrial, bipedal dinosaurs before the evolution of birds or flight.

In 2003, a team of paleontologists led by Xing Xu and Zhonghe Zhou of the Institute of Vertebrate Paleontology and Paleoanthropology in Beijing reported a new species of feathered dinosaur (*Microraptor gui*) with asymmetrical feathers on its forelimbs and hindlimbs. Modern birds use asymmetrical feathers for flight. These small dinosaurs, which lived about 126 mya, probably coexisted with early birds. Their small size and body structure supports the hypothesis that flying evolved from gliding; bird ancestors climbed trees and used their feathered limbs for gliding (see *On the Cutting Edge: Origin of Flight in Birds,* in Chapter 20).

Although the bones of birds are fragile and disintegrate quickly, a few fossils of early birds have been found. The first birds looked very much like reptiles. They had teeth (which

(a) *Caudipteryx* exhibits both dinosaur and bird characteristics. This fossil lacks a head, but the rest of its skeleton is well preserved. The bones in the foot and the shape and orientation of the pelvis are similar to those of the theropods, but the fossil also has bird characters, including impressions of feathers.

modern birds lack), a long tail, and bones with thick walls. Unlike reptiles, their jaws were elongated into beaks, and they had feathers and wings.

One of the earliest known birds, *Archaeopteryx* (meaning "ancient wing") was about the size of a pigeon. Several specimens of this genus have been found in the Jurassic limestone of Bavaria, which was laid down about 145 mya. Unlike extant birds, its jawbones were armed with reptilian-type teeth, and it had a long reptilian tail covered with feathers (Fig. 30-19b). Each *Archaeopteryx* wing had three claw-bearing digits. Like modern birds, *Archaeopteryx* had wings, feathers, reduced digits, and a **furcula,** or "wishbone." Its feathers were very similar to those of modern birds. Biologists do not think that *Archaeopteryx* gave rise to modern birds but, rather, that it shared a common ancestor with other birds.

Cretaceous rocks have yielded fossils of other early birds. *Hesperornis,* which lived in North America, was a toothed, aquatic diving bird with rudimentary wings and broad, webbed feet for swimming. *Ichthyornis* was a toothed, flying bird about the size of a sea gull. From the Tertiary period onward, the fossil record of birds shows an absence of teeth and progressive changes leading to the modern birds.

Modern birds are adapted for flight

About 9000 species of extant birds have been described, and they have been classified into about 23 monophyletic groups. Birds inhabit a wide variety of habitats and can be found on all continents, most islands, and even the open sea. Birds are a diverse group (Fig. 30-20). The largest living birds are the ostriches of Africa, which may be up to 2 m (6.5 ft) tall and weigh 136 kg (300 lb), and the great condors of the Americas, with wingspans of up to 3 m (10 ft). The smallest known bird is Helena's hummingbird of Cuba, with a length of less than 6 cm (2 in) and a weight of less than 4 g (0.14 oz).

Like their reptilian ancestors, modern birds lay eggs and have reptilian-type scales on their legs. Birds have evolved remarkable specializations for flight. Their feathers are very light, yet flexible and strong, and present a flat surface to the air. Feathers also protect the body and decrease water and heat loss. The anterior limbs of birds are wings, usually adapted for flight. The posterior limbs are modified for walking, swimming, or perching.

In addition to feathers and wings, birds have many other adaptations for flight. Their bodies are compact and streamlined, and the fusion of many bones gives them the rigidity needed for flying. Their bones are strong but very light. Many are hollow, containing large air spaces. The avian jaw is light and instead of teeth, birds have a light, horny beak. The breastbone is broad and keeled, for the attachment of the large flight muscles.

Birds have efficient lungs with thin-walled extensions, called **air sacs,** that occupy spaces between the internal organs and within certain bones. They have a unique "one-way" flow of air through their respiratory system (discussed in Chapter 44). Birds have a four-chambered heart and a double circuit of blood flow. Blood delivers oxygen to the tissues and then recharges with oxygen in the lungs before the heart pumps it into the systemic circulation again. The very effective respiratory and circulatory systems provide the cells with enough oxygen to permit a high metabolic rate, which is necessary for the tremendous muscular activity that flying requires. Some of the heat a bird gen-

FIGURE **30-20** **Modern birds.**

Although they are diverse, most birds are highly adapted for flight, and their basic structure is similar. **(a)** A male peacock (*Pavo cristatus*) impressively displaying his feathers. **(b)** This Atlantic puffin (*Fraterula arctica*) has caught several fish.

erates by metabolic activities helps it maintain a constant body temperature. Birds are endothermic, which permits them to remain active in cold climates.

Birds excrete nitrogenous wastes mainly as semisolid uric acid. Because birds typically do not have a urinary bladder, these solid wastes are delivered into the cloaca. They leave the body with the feces, which are dropped frequently. This adaptive mechanism helps maintain a light body weight.

Birds have become adapted to a variety of environments, and various species have very different types of beaks, feet, wings, tails, and behavioral patterns. Not all birds fly. Some, such as penguins, have small, flipper-like wings used in swimming. Ratites are a group of mainly large, flightless birds, including the ostriches, cassowarys, and kiwis. These birds have only vestigial wings, but they have well-developed legs, which they use for running.

Bills are specifically adapted for the type of food the bird eats. Although all birds must eat frequently (because they have a high metabolic rate and typically do not store much fat), the choice of food varies widely among species. Most birds eat energy-rich foods such as seeds, fruits, worms, mollusks, or arthropods. Warblers and some other species eat mainly insects. Owls and hawks eat rodents, rabbits, and other small mammals. Vultures feed on dead animals. Pelicans, gulls, terns, and kingfishers catch fish. Some hawks catch snakes and lizards.

An interesting feature of the bird digestive system is the **crop,** an expanded, saclike portion of the digestive tract below the esophagus, in which food is temporarily stored. The stomach is divided into a **proventriculus,** which secretes gastric juices, and a thick, muscular **gizzard,** which grinds food. The bird swallows small bits of gravel that act as "teeth" in the gizzard, mechanically breaking down food.

Birds have a well-developed nervous system, with a brain that is proportionately larger than that of reptiles. Birds rely heavily on vision, and their eyes are relatively larger than those of other vertebrates. Hearing is also well developed.

In striking contrast with the relatively silent reptiles, birds are very vocal. Most have short, simple *calls* that signal danger or influence feeding, flocking, or interaction between parent and young. *Songs* are usually more complex than calls and are performed mainly by males. Songs are related to attracting and keeping a mate, and to claiming and defending a territory.

One of the most fascinating aspects of bird behavior is the annual migration that many species make. Some birds, such as the golden plover and Arctic tern, fly from Alaska to Patagonia, South America, and back each year, covering perhaps 40,250 km (25,000 mi) en route. Migration and navigation are discussed in Chapter 50.

Many birds have beautiful and striking colors. The color is due partly to pigments deposited during the development of the feathers and partly to reflection and refraction of light of certain wavelengths. Many birds, especially females, are protectively colored by their plumage. During the breeding season the male often assumes brighter colors to help in attracting a mate.

Mammals are characterized by hair and mammary glands

Derived characters that distinguish mammals (class Mammalia) include hair, which insulates and protects the body; **mammary glands,** which produce milk for the young; differentiation of teeth into incisors, canines, premolars, and molars; and

three middle-ear bones (malleus, incus, and stapes) that conduct vibrations.

A muscular **diaphragm** helps move air into and out of the lungs. Like birds, mammals are *endotherms,* but biologists think mammals evolved endothermy independently of birds. Maintaining a constant body temperature is enhanced by the covering of insulating hair, by the four-chambered heart, and by separate pulmonary and systemic circulations. Red blood cells without nuclei serve as efficient oxygen transporters.

Contributing significantly to the success of the mammals, the complex nervous system is more highly developed than in any other group of animals. The cerebrum is especially large and complex, with an outer gray region called the **cerebral cortex.**

Fertilization is always internal, and, except for the primitive monotremes that lay eggs, mammals are viviparous. Most mammals develop a **placenta,** an organ of exchange between developing embryo and mother, through which the embryo receives its nourishment and oxygen and rids its blood of wastes. By carrying their developing young internally, mammals avoid the hazards of having their eggs consumed by predators. By nourishing the young and caring for them, the parents offer both protection and an "education" on how to obtain food and avoid being eaten.

The limbs of mammals are variously adapted for walking, running, climbing, swimming, burrowing, or flying. In four-legged mammals, the limbs are more directly under the body than they are in extant reptiles, which contributes to speed and agility.

Early mammals were small, endothermic animals

Mammals descended from **therapsids,** a group of synapsid reptiles, during the Triassic period some 200 mya. The therapsids were doglike carnivores with differentiated teeth and legs adapted for running (Fig. 30-21). The fossil record indicates that early mammals were small, about the size of a mouse or shrew. Some may have been endothermic, and some may have had fur.

How did mammals manage to coexist with reptiles during the 160 million years or so that reptiles ruled Earth? Many adaptations permitted early mammals to compete for a place on this planet. Perhaps one of the most important was their skill at being inconspicuous. They were **arboreal** (tree-dwelling) and **nocturnal** (active at night), searching for food (mainly insects and plant material, and perhaps reptile eggs) at night while the reptiles were inactive. Although their eyes may have been small, early mammals had well-developed sense organs for hearing and smell.

As many reptiles became extinct, the mammals adapted to their abandoned niches (lifestyles). During this time, the flowering plants, including many trees, underwent an adaptive radiation, providing new habitats, sources of food, and protection from predators. Larger forms and numerous varieties of mammals evolved. During the early Cenozoic era (more than 55 mya), the mammals underwent an adaptive radiation, becoming widely distributed and adapted to an impressive variety of ecological lifestyles (see Fig. 20-16).

The therapsids were synapsid reptiles. *Lycaenops,* a carnivore about the size of a coyote, lived in South Africa during the late Permian period.

Modern mammals are assigned to three subclasses By the end of the Cretaceous period, three main groups of mammals had evolved (Fig. 30-22). Today, mammals inhabit virtually every corner of Earth; they live on land, in fresh and salt water, and in the air. They range in size from the tiny pigmy

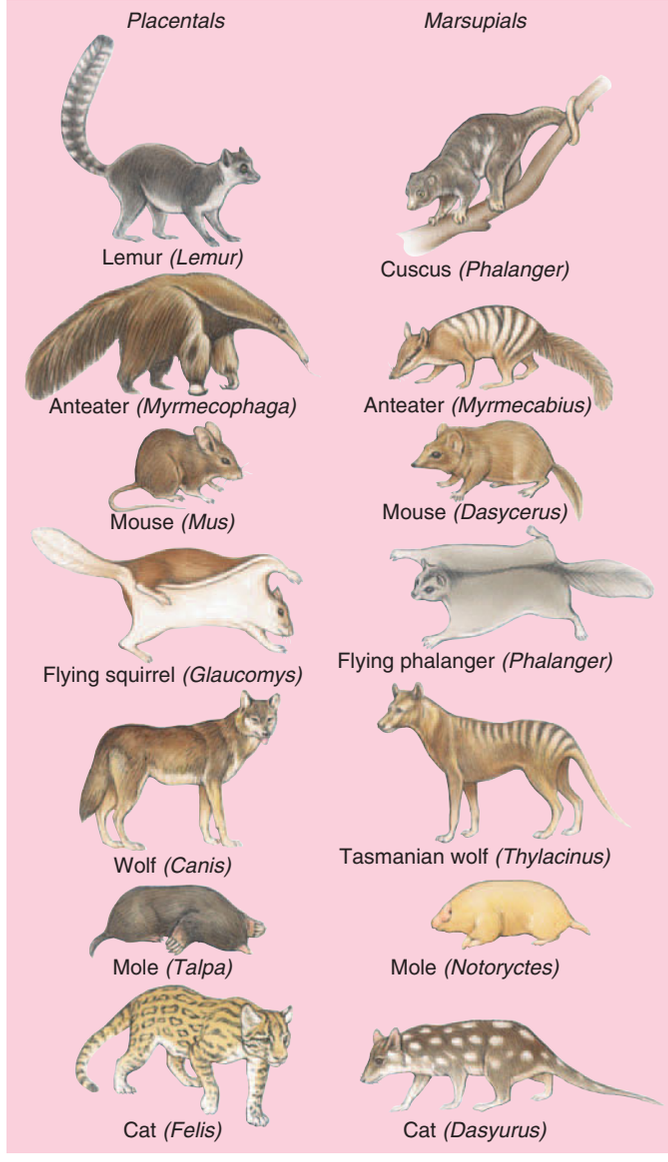
shrew, weighing about 2.5 g (less than 0.1 oz), to the blue whale, which may weigh up to 136,000 kg (150 tons) and which biologists think is one of the largest animals that has ever lived.

Modern mammals are classified in three subclasses: **Holotheria** includes the egg-laying mammals, or monotremes; **Metatheria** includes the marsupials, or pouched mammals; and **Eutheria** includes the placental mammals.

The **monotremes** are the only living order of subclass Holotheria. One genus includes the duck-billed platypus (*Ornithorhynchus*) and a second, the spiny anteaters or echidnas (*Tachyglossus*) (Fig. 30-23; see also Figs. 1-16 and 22-4). These animals live in Australia and Tasmania; two of the three spiny anteater species also live in New Guinea. The females lay eggs that they carry in a pouch on the abdomen or keep warm in a nest. When

FIGURE **30-25** **Convergent evolution in placental and marsupial mammals.**

For each mammal in one group, there is a counterpart in the other group. Their similarities include both lifestyles and structural features.



the young hatch, they lap up milk secreted by their mother's mammary glands. Unlike other mammals, nipples are absent.

With their long beaks and long, sticky tongues, spiny anteaters capture ants and termites The duck-billed platypus, which lives in burrows along river banks, preys on freshwater invertebrates. It has webbed feet and a flat, beaver-like tail, which helps it swim.

Marsupials include pouched mammals such as kangaroos and opossums (Fig. 30-24a). Embryos begin their development in the mother's uterus, where they are nourished by fluid and yolk. After a few weeks, still in a very undeveloped stage, the young are born. In many species, the young crawl to the **marsupium** (pouch), where they complete their development. The young marsupial attaches its mouth to a mammary gland nipple and is nourished by its mother's milk (Fig. 30-24b).

At one time, marsupials probably inhabited much of the world, but placental mammals largely outcompeted them. Now marsupials live mainly in Australia and in Central and South America. The only marsupial species that ranges into the United States is the Virginia opossum (*Didelphis virginiana*). Australia became geographically isolated from the rest of the world before placental mammals migrated there, and the marsupials remained the dominant mammals (see discussion of continental drift in Chapter 17). Australian marsupials underwent adaptive radiation, paralleling the evolution of placental mammals elsewhere. Thus, marsupials that live in Australia and adjacent islands correspond to North American placental wolves, bears, rats, moles, flying squirrels, and even cats (Fig. 30-25).

Most familiar to us are **placental mammals,** characterized by development of a placenta, an organ of exchange between the developing embryo and its mother (Fig. 30-26). The placenta forms from both embryonic membranes and the maternal uterine wall. In it the blood vessels of the embryo come very close to the blood vessels of the mother, so materials can be exchanged by diffusion. (The two circulations do not normally mix.) The placenta enables the young to remain within the mother's body until embryonic development is complete.

Placental mammals are born at a more mature stage than marsupials. Indeed, among some species the young can walk around and begin to interact with other members of the group within a few minutes after birth. Biologists classify extant placental mammals into about 16 orders. Table 30-3 gives a brief summary of some of these orders. Remember that aquatic mammals, such as dolphins, whales, and seals, evolved from terrestrial ancestors.

Review

- What vertebrate adaptations are important for terrestrial life?
- What are some arguments for classifying birds and reptiles in a single clade?
- What are the three main groups of mammals? How do they differ?
- Which amniotes are endothermic? What are some advantages of endothermy?

TABLE 30-2 Some Orders of Living Placental Mammals

Order, Representative Members, and Some Characteristics

Insectivora (moles, hedgehogs, shrews)

Nocturnal; eat insects; considered most primitive placental mammals. Shrew is smallest living mammal; some weigh less than 5 g.

African hedgehog

Chiroptera (bats)

Adapted for flying; fold of skin extends from elongated fingers to body and legs, forming wing. Guided in flight by type of biological sonar; they emit high-frequency squeaks and are guided by echoes from obstructions. Eat insects and fruit, or suck blood of other animals.

Bat

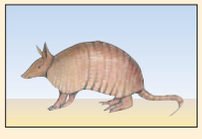
Carnivora (cats, dogs, wolves, foxes, bears, otters, mink, weasels, skunks)

Carnivores with sharp, pointed canine teeth and molars for shearing. Keen sense of smell; complex social interactions. Among fastest, strongest, and smartest animals.

Wolf

Xenarthra (sloths, anteaters, armadillos)

Teeth reduced or no teeth. Sloths are sluggish animals that hang upside down from branches; often protectively colored by green algae that grow on their hair. Armadillos are protected by bony plates; eat insects and small invertebrates.



Nine-banded armadillo

Rodentia (squirrels, beavers, rats, mice, hamsters, porcupines, guinea pigs)

Gnawing animals with chisel-like incisors. As they gnaw, teeth are worn down, and so must grow continually.

Flying squirrel

Lagomorpha (rabbits, hares, pikas)

Like rodents, have chisel-like incisors. Typically have long hind legs adapted for jumping. Many have long ears.

Pika

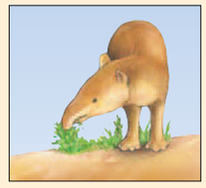
Primates lemurs, monkeys, apes, humans)

Highly developed brains and eyes. Nails instead of claws. Opposable thumb. Eyes directed forward. Omnivores. Most species arboreal. (Primate evolution discussed in Chapter 21.)

Ring-tailed lemur

Perissodactyla (horses, zebras, tapirs, rhinoceroses)

Herbivores. Hoofed with odd number of digits per foot; one or three toes. Teeth adapted for chewing. Usually large animals with long legs.



Tapir

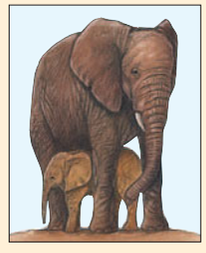
Artiodactyla (cattle, sheep, pigs, deer, giraffes)

Hoofed with even numbers of digits per foot; most have two toes, some have four. Most have antlers or horns. Herbivores; most are ruminants, chew a cud and have series of stomachs in which bacteria that digest cellulose.

American elk

Proboscidea (elephants)

Largest land animals; weigh up to 7 tons; large head; broad ears; long, muscular, flexible trunk (proboscis). Thick loose skin is characteristic. Two upper incisors are elongated as tusks. Includes extinct mastodons and wooly mammoths.



African elephant

Sirenia (sea cows, manatees)

Herbivorous, aquatic mammals with finlike forelimbs and no hind limbs. They are probably the basis for most tales about mermaids.

Manatee

Cetacea (whales, dolphins, porpoises)

Adapted for aquatic life with fish-shaped body and broad, paddle-like forelimbs (flippers). Posterior limbs absent. Many have thick layer of blubber under skin. Some are suspension feeders. Mate and bear young in the water. Very intelligent.

Humpback whale

Pinnipedia (seals, sea lions, walruses)

Marine; limbs adapted as flippers for swimming. Carnivores; eat fish.

Sea lions

SUMMARY WITH KEY TERMS

1 Identify the main branches of deuterostomes.

- **Deuterostomes** include echinoderms, hemichordates, and chordates. **Hemichordates** (acorn worms) are marine deuterostomes with a three-part body, including proboscis, collar, and trunk.

2 List three shared derived characters of echinoderms; and describe the main classes of echinoderms.

- Phylum **Echinodermata** includes marine animals with a spiny "skin," **water vascular system, tube feet,** and **endoskeleton.** The larvae have bilateral symmetry; most of the adults exhibit **pentaradial symmetry.**
- Class **Crinoidea** includes sea lilies and feather stars. The **oral surface** of crinoids is turned upward; some crinoids are sessile.
- Class **Asteroidea** consists of the sea stars. They have a central disk with five or more arms. They use tube feet for locomotion.
- Class **Ophiuroidea** includes the brittle stars, which resemble sea stars but have longer, more slender arms that are set off more distinctly from the central disk. They use their arms for locomotion. Their tube feet lack suckers and are not used in locomotion.
- Class **Echinoidea** includes the sea urchins and sand dollars. Echinoids lack arms; they have a solid shell and are covered with spines.
- Class **Holothuroidea** consists of sea cucumbers, animals with elongated flexible bodies. The mouth is surrounded by a circle of modified tube feet that serve as tentacles.

3 Describe four shared derived characters of chordates

- Phylum **Chordata** has three subphyla: Urochordata, Cephalochordata, and Vertebrata. At some time in its life cycle, a chordate has a flexible, supporting **notochord;** a **dorsal, tubular nerve cord; pharyngeal (gill) slits;** and a **muscular postanal tail.**

4 Describe the invertebrate chordate subphyla.

- The **tunicates,** which belong to subphylum **Urochordata,** are suspension-feeding, marine animals with **tunics.** Larvae have typical chordate characteristics and are free-swimming. Adults of most groups are sessile suspension feeders.
- Subphylum **Cephalochordata** consists of the **lancelets,** small, segmented, fishlike animals that exhibit chordate characteristics.

5 Discuss the evolution of chordates.

- The urochordates (tunicates) were probably the first chordates to evolve. Subphyla Cephalochordata and **Vertebrata** to be **sister taxa,** groups that diverged from a recent common ancestor.

6 Describe four shared derived characters of vertebrates.

- The vertebrates have a **vertebral column** that forms the chief skeletal axis of the body, and a braincase called a **cranium. Neural crest cells** give rise to or influence the development of many structures, including the cranium and jaws. Vertebrates have pronounced cephalization, a complex brain, and muscles attached to the **endoskeleton** for movement.

7 Distinguish among the major groups of jawless fishes.

- Some of the earliest known vertebrates, called **ostracoderms,** were jawless fishes that are now extinct.
- The extant jawless fishes, or **agnathans,** are the hagfishes, assigned to class **Cephalaspidomorphi** and the lampreys, class **Myxini.** Systematists no longer consider hagfishes vertebrates, because they have no trace of vertebrae. They classify the vertebrates plus the hagfishes as **craniates** (Craniata).

8 Trace the evolution of jawed fishes and early tetrapods, and identify major taxa of jawed fishes and amphibians.

- Class **Chondrichthyes,** the cartilaginous fishes, includes the sharks, rays, and skates. These fishes have jaws, two pairs of fins, and **placoid scales.** Skates and some species of sharks are **oviparous,** that is, they lay eggs. Many species of sharks are **ovoviparous;** their young are enclosed by eggs that are incubated in the mother's body. A few shark species are **viviparous;** the young develop in the mother's uterus and are nourished by transfer of nutrients from the mother's blood.
- The bony fishes are assigned to three classes: **Actinopterygii,** ray-finned fishes; **Actinistia,** coelancanths; and **Dipnoi,** lungfishes.
- During the Devonian, bony fishes gave rise to two evolutionary lines: the Actinopterygii, or **ray-finned fishes,** and the **Sarcopterygii,** or **lobe-finned fishes.**
- The ray-finned fishes gave rise to the modern bony fishes. In these fishes, the lungs have been modified as a **swim bladder,** an air sac for regulating buoyancy.
- The sarcopterygii probably gave rise to the **lungfishes** (class **Dipnoi**) and **coelacanths** (class **Actinistia**).
- Both coelancanths and lungfishes were apparently preadapted for life on land. Biologists think the lungfish gave rise to the **tetrapods,** the land vertebrates.
- The first successful tetrapods were the now-extinct **labyrinthodonts,** which may be the ancestors of frogs and salamanders.
- Class **Amphibia** includes salamanders, frogs and toads, and wormlike caecilians. Most amphibians return to the water to reproduce. Frog embryos develop into **tadpoles,** which undergo **metamorphosis** to become adults.
- Amphibians use their moist skin as well as lungs for gas exchange. They have a three-chambered heart and **systemic** and **pulmonary circulations.**

9 Describe three vertebrate adaptations to terrestrial life.

- Terrestrial vertebrates, or **amniotes,** include reptiles, birds, and mammals. The evolution of the **amniotic egg** with its shell and amnion was an important adaptation for life on land. The **amnion** is a membrane that forms a fluid-filled sac around the embryo. Amniotes have a body covering that retards water loss. They also have physiological mechanisms that conserve water.

10 Describe the reptiles and birds, and give an argument for including the birds in the reptile clade.

- Class **Reptilia,** as traditionally defined, is paraphyletic. It includes dinosaurs, turtles, lizards, snakes, and alligators. Many biologists now include the birds in the dinosaur clade.
- In reptiles, fertilization is internal and most reptiles secrete a leathery protective shell around the egg. The embryo develops protective membranes, including an amnion that keeps it moist.
- Reptiles have dry skin with horny scales, lungs with many chambers, and a three-chambered heart with some separation of oxygen-rich and oxygen-poor blood.
- Paleontologists have discovered feathered dinosaurs, and many biologists now consider the birds as feathered dinosaurs; they classify the birds and most of the reptiles as **diapsids.**
- Birds have many adaptations for powered flight, including feathers, wings, and light, hollow bones containing air spaces. Birds have a four-chambered heart, very efficient lungs, a high metabolic rate, and a constant body temperature; they excrete solid metabolic wastes (uric acid). They have a well-developed nervous system and excellent vision and hearing.

SUMMARY WITH KEY TERMS *(continued)*

11 Contrast monotremes, marsupials, and placental mammals, and give examples of animals that belong to each group.

- **Mammals** have hair, **mammary glands,** differentiated teeth, and three middle-ear bones. They maintain a constant body temperature and have a highly developed nervous system and a muscular **diaphragm.**
- **Monotremes,** which belong to subclass **Holotheria,** include the duck-billed platypus and spiny anteaters. Monotremes lay eggs.
- **Marsupials** (subclass **Metatheria**) include pouched mammals, such as kangaroos and opossums. The young are born in an embryonic stage and complete their development in their mother's **marsupium,** where they are nourished with milk from the mammary glands.
- **Placental mammals** (subclass **Eutheria**) are characterized by the **placenta,** an organ of exchange that develops between the embryo and the mother.

POST-TEST

1. Which of the following is *not* a deuterostome? (a) echinoderm (b) chordate (c) hemichordate (d) arthropod (e) hagfish
2. Which of the following belongs to subphylum Vertebrata? (a) lophophorate (b) lamprey (c) lancelet (d) tunicate (e) crinoid
3. Which of the following is/are found in tunicates? (a) notochord (b) tube feet (c) anal gill slits (d) two pairs of appendages (e) vertebral column
4. Which of the following was an early jawed fish? (a) placoderm (b) crinoid (c) therapsid (d) labyrinthodont (e) ostracoderm.
5. Arrange the following animals to reflect an accepted sequence of evolution: 1. lungfish 2. reptile 3. amphibian 4. bird. (a) 3, 1, 2, 4, (b) 1, 3, 2, 4 (c) 2, 1, 3, 4 (d) 1, 2, 3, 4
6. Which of the following characteristics is *not* associated with sea stars? (a) tube feet (b) water vascular system (c) central disk with five or more arms (d) spiny skeleton (e) notochord
7. Which of the following characteristics is associated with amphibians? (a) mantle (b) placoid scales (c) three-chambered heart (d) swim bladder (e) amnion
8. Which of the following is *not* characteristic of birds? (a) feathers (b) ectothermic (c) amnion (d) high metabolic rate (e) reptilian-like scales on legs
9. Which of the following is *not* true of the duck-billed platypus? (a) classified as a marsupial (b) lays eggs (c) embryo has a notochord (d) embryo has pharyngeal slits (e) is a predator
10. Which of the following is *not* a placental mammal? (a) shrew (b) human (c) dolphin (d) spiny anteater (e) bat
11. Which of the following is *true* of mammals? (a) all have placentas (b) evolved from saurischian dinosaurs (c) three middle-ear bones (d) most are ovoviviparous (e) evolved during the Devonian period
12. The vertebral column (a) is characteristic of all chordates (b) forms the skeletal axis of the chordate body (c) may consist of cartilaginous or bony segments (d) is well developed in lancelets (e) three of the preceding answers are correct
13. A shark is characterized by (a) placoid scales (b) bony skeleton (c) water vascular system (d) amnion (e) muscular diaphragm
14. Reptiles (a) have dry, scaly skin (b) are amniotes (c) gave rise to the birds and mammals (d) answers a, b, and c are correct (e) answers a and c only are correct
15. Amniotes (a) include amphibians, reptiles, birds, and mammals (b) are especially well adapted for fresh water (c) typically have physiological mechanisms for conserving water (d) typically excrete ammonia (e) gave rise to the amphibians
16. Which of the following is *not* true? (a) feathers evolved in dinosaurs (b) birds are endothermic (c) birds excrete uric acid (d) birds have an amniotic egg (e) *Archaeopteryx* was the ancestor of feathered dinosaurs

CRITICAL THINKING

1. Discuss the relationships among the echinoderms, hemichordates, and chordates, describing shared derived characters that support grouping them together as deuterostomes.
2. Some paleontologists consider monotremes to be therapsid reptiles rather than mammals. Give arguments for and against this position.
3. Which are more specialized, birds or mammals? Explain your answer.
4. Imagine you discover an interesting new animal. You find it has a dorsal, tubular nerve cord, a cranium, moist skin, and a heart with two atria and a ventricle. How would you classify the animal? Explain each step in your decision.

Plant Structure, Growth, and Differentiation

Runk/Schoenberger from Grant Heilman

Oak seedling. A massive oak tree may grow from this young basket oak (*Quercus prinus*) seedling.

CHAPTER OUTLINE

- Plant Structure and Life Span
- The Plant Body
- Plant Meristems

About 90% of the approximately 262,000 species of plants are flowering plants. These vascular plants are characterized by flowers, double fertilization, endosperm, and seeds enclosed within fruits (see Chapter 27). Because flowering plants are the largest, most successful group of plants, they are the focus of much of this chapter and of Chapters 32 to 36. Let us begin our study of the structure and functions of plants by examining a familiar species, the oak, and its fruit, the acorn.

Squirrels often temporarily store acorns in holes in the ground to provide winter food. Many of these are never retrieved, and so a new oak often begins its life after a squirrel has buried an acorn in the soil. The seed within the acorn first absorbs water from the surrounding soil. Then germination occurs as a root emerges and works its way down into the soil, absorbing additional water and anchoring the young plant. A miniature shoot begins to grow upward and breaks through the soil. At this point the young oak, shown in the photograph, is a seedling—it has just emerged from the seed and is still dependent on the food supply stored within the seed.

The stem continues to elongate, and small leaves develop, expand, and begin to photosynthesize. The young plant is now independently established: It is anchored in the ground, absorbs water and dissolved nutrient minerals from the soil, and uses energy from organic molecules, such as glucose, that it produces by photosynthesis.

Smaller roots branch off the original root, and the young tree grows taller, always by growth at the tips of its branches. The roots likewise elongate at their tips. As it ages, the tree also increases in girth (thickness) by forming additional wood and bark. This growth occurs along the sides of the more mature stems and roots. Thus, the oak progressively accumulates more wood and bark, more stem and root tissues, and more leaves.

Growth and expansion of both the root and shoot systems continue throughout the life of the oak. As in all plants, growth is flexible and dynamic, enabling the oak to respond to its environment. For example, the young oak may grow very slowly for

several years, particularly if shaded by mature trees. When conditions change, perhaps when an older tree nearby dies and falls to the ground, permitting direct sunlight to reach the young tree, it is poised for rapid growth.

After several years of growth, the oak tree becomes reproductively mature. Oaks reproduce by forming separate male and female flowers in spring. The minute male flowers, more conspicuous than the female flowers, are found together on slender, drooping, caterpillar-shaped catkins (clusters); in contrast, the tiny female flowers are often solitary. After pollen from a male flower is blown by the wind to a female flower, a sperm cell fertilizes the egg, and an acorn develops, partially enclosed by a scaly cup. First green in color, the acorn fruit turns a deep brown as it matures. Within the acorn is a seed containing an embryo of a miniature oak, along with a supply of stored food. Thus the cycle of life repeats itself, as squirrels busily collect these acorns and cache them for later retrieval.

PROCESS OF SCIENCE

In this chapter we examine the external structure of the flowering plant body; the organization of its cells, tissues, and tissue systems; and its basic growth patterns. Information of this type, which is based on observation and description, rarely receives as much attention as experimental science. However, observation and description are crucial aspects of the scientific process. ■

FIGURE **31-1** **Size variation in plants.**

(a) Duckweeds (*Spirodela*), the larger green plants in the photograph, are tiny floating aquatic plants about 1 cm (3/8 in) across. If you look closely at the frog's body, you will see minute green dots. Each is a water-meal (*Wolffia*) plant. These tiny floating herbs, about 1.5 mm (1/16 in) wide, are the smallest known flowering plants. **(b)** This giant gum tree (*Eucalyptus regnans*) was photographed in Bushy Park, Australia. Although most giant gums grow to 75 m (246 ft), some specimens have been measured at heights of 100 m (328 ft) and are the world's tallest flowering plants.

PLANT STRUCTURE AND LIFE SPAN

Learning Objectives

1. Distinguish between herbaceous and woody plants.
2. Discuss the differences among annuals, biennials, and perennials, and give an example of each.
3. Contrast two different life history strategies in plants.

Plants range in size from the minute floating water-meal (*Wolffia microscopica*), the smallest flowering plant known, to Australian gum trees (*Eucalyptus*), some of Earth's tallest trees (Fig. 31-1). The 235,000 or so species of flowering plants that live in and are adapted to the many environments offered by our planet represent remarkable variety. Yet all of these—from desert cacti with enormously swollen stems, to cattails partly submerged in marshes, to orchids growing in the uppermost tree branches of lush tropical rain forests—are recognizable as plants. Almost all plants have the same basic body plan, which consists of roots, stems, and leaves.

Plants are either herbaceous or woody. *Herbaceous* plants are nonwoody. In temperate climates, the aerial parts (stems and leaves) of herbaceous plants die back to the ground at the end of the growing season. In contrast, the aerial parts of *woody* plants (trees and shrubs) persist. Botanically speaking, woody plants produce hard, lignified secondary tissues (the cell walls of secondary tissues contain lignin), and herbaceous plants do not. Lignin and the production of secondary tissues are discussed later in the chapter.

Annuals are herbaceous plants (such as corn, geranium, and marigold) that grow, reproduce, and die in one year or less. Other herbaceous plants (such as carrot, Queen Anne's lace, cabbage, and foxglove) are **biennials;** they take two years to complete their life cycles before dying. During their first season biennials produce extra carbohydrates, which they store and use during their second year when they typically form flowers and reproduce. **Perennials** are herbaceous and woody plants that have the potential to live for more than two years. In temperate climates, the aerial (aboveground) stems of herbaceous perennials such as iris, rhubarb, onion, and asparagus die back each winter. Their underground parts (roots and underground stems)

become dormant during the winter and send out new growth each spring. (In **dormancy,** an organism reduces its metabolic state to a minimum level to survive unfavorable conditions.) Similarly, in certain tropical climates with pronounced wet and dry seasons, the aerial parts of herbaceous perennials die back and the underground parts become dormant during the unfavorable dry season. Other tropical plants, such as orchids, are herbaceous perennials that grow year-round.

All woody plants are perennials, and some of them live for hundreds or even thousands of years. In temperate climates, the aboveground stems of woody plants become dormant during the winter. Many temperate woody perennials are **deciduous;** that is, they shed their leaves before winter and produce new stems with new leaves the following spring. Other woody perennials are **evergreen** and shed their leaves over a long period, so that some leaves are always present. Because they have permanent woody stems that are the starting points for new growth the following season, many trees attain massive sizes.

Plants have different life history strategies

Plants exhibit a variety of patterns of growth, reproduction, and longevity. Woody perennials often live for hundreds of years, whereas some herbaceous annuals may live for only a few weeks or months. Such characteristic features of an organism's life cycle, particularly as they relate to its survival and successful reproduction, are known as **life history strategies.** Biologists try to understand the relative advantages of each life history strategy, including any tradeoffs involved in the allocation of various resources. It appears that in some environments a longer life span is advantageous, whereas in other environments a shorter life span increases a species' chances for reproductive success—that is, for long-term survival.

When an environment is relatively favorable, it is filled with plants competing for available space. Because such an environment is so crowded, it has few open spots in which new plants can become established. When a plant dies, the empty area is quickly filled by another plant, but not necessarily by the same species as before. Thus an adult perennial survives well, but young plants, whether perennials or annuals, do not. A plant with a long life span thrives in this type of environment because it can occupy a piece of soil and continue to produce seeds for many years. In a tropical rain forest, for example, competition prevents most young plants from becoming established, and woody perennials predominate.

In a relatively unfavorable environment, many possible sites are usually available. This type of environment is not crowded, and young plants usually do not have to compete against large, fully established plants. Here, smaller, short-lived plants have the reproductive advantage. These plants are opportunists: They grow and mature quickly during the brief periods when environmental conditions are most favorable. As a result, all their resources are directed into producing as many seeds as possible before dying. In deserts following a rainy spell, for example, annuals are more prevalent than woody perennials.

Thus each species has its own characteristic life history strategy, with some plants adapted to variable environments and others adapted to stable environments. The longer life span characteristic of woody perennials is just one of several successful life history plans. We return to life history strategies in our discussion of population ecology (see Chapter 51).

Review

- Consider a common plant such as a marigold. Is it herbaceous or woody? An annual, biennial, or perennial? Explain your answers.
- Consider a common plant such as a carrot. Is it herbaceous or woody? An annual, biennial, or perennial? Explain.
- Consider a common plant such as an oak. Is it herbaceous or woody? An annual, biennial, or perennial? Explain.

BiologyNow™ Review your understanding of **plant structure and life span** by taking the pretest on your BiologyNow CD-ROM.

THE PLANT BODY

Learning Objectives

4 Discuss the functions of various parts of the vascular plant body, including the nutrient- and water-absorbing root system and the photosynthesizing shoot system.

5 Describe the structure and functions of the ground tissue system (parenchyma tissue, collenchyma tissue, and sclerenchyma tissue).

6 Describe the structure and functions of the vascular tissue system (xylem and phloem).

7 Describe the structure and functions of the dermal tissue system (epidermis and periderm).

The plant body of flowering plants (and other vascular plants) is usually organized into a root system and a shoot system (Fig. 31-2). The **root system** is generally underground. The aboveground portion, the **shoot system,** generally consists of a vertical stem that bears leaves, and, in flowering plants, flowers and fruits that contain seeds.

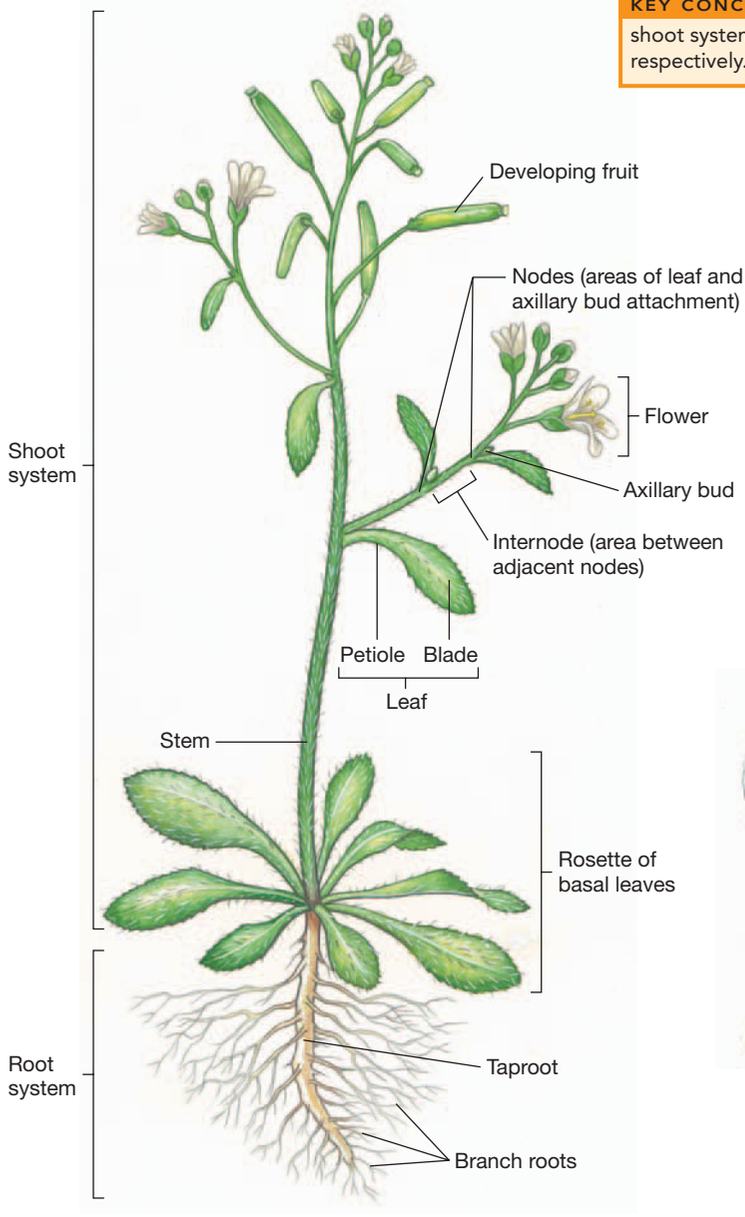
Each plant typically grows in two different environments: the dark, moist soil and the illuminated, relatively dry air. Plants usually have both roots and shoots because they require resources from both environments. Thus, roots branch extensively through the soil, forming a network that anchors the plant firmly in place and absorbs water and dissolved nutrient minerals from the soil. Leaves, the flattened organs of photosynthesis, are attached more or less regularly on the stem, where they absorb the sun's light and atmospheric CO_2 used in photosynthesis.

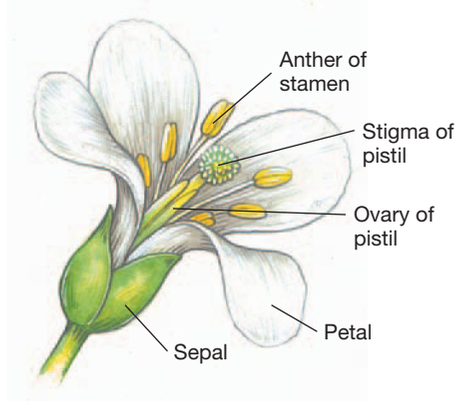
The plant body consists of cells and tissues

As in other organisms, the basic structural and functional unit of plants is the cell. During the course of evolution, plants have developed a diversity of cell types, each specialized for particular functions.

Like animal cells, plant cells are organized into tissues. A **tissue** is a group of cells that form a structural and functional unit. *Simple tissues* are composed of only one kind of cell, whereas *complex tissues* have two or more kinds of cells.

KEY CONCEPT: During the evolution of plants, the root and shoot systems specialized to obtain resources from the soil and air, respectively.





ACTIVE FIGURE 31-2 **The plant body.**

A plant body consists of a root system, usually underground, and a shoot system, usually aboveground. Shown is mouse-ear cress (*Arabidopsis thaliana*), a small plant in the mustard family that is a model plant for biological research. *Arabidopsis* is native to North Africa and Eurasia and has been naturalized (was introduced and is now growing in the wild) in California and the eastern half of the United States.

BiologyNow™ Learn more about **the plant body** by clicking on this figure on your BiologyNow CD-ROM.

In vascular plants, tissues are organized into three tissue systems, each of which extends throughout the plant body (Fig. 31-3). Each tissue system contains two or more kinds of tissues (Table 31-1). Most of the plant body is composed of the **ground tissue system,** which has a variety of functions, including photosynthesis, storage, and support. The **vascular tissue system,** an intricate conducting system that extends throughout the plant body, is responsible for conduction of various substances, including water, dissolved nutrient minerals, and food (dissolved sugar). The vascular tissue system also functions in strengthening and supporting the plant. The **dermal tissue system** provides a covering for the plant body.

Roots, stems, leaves, flower parts, and fruits are **organs,** because each is composed of all three tissue systems. The tissue systems of different plant organs form an interconnected network throughout the plant. For example, the vascular tissue system of a leaf is continuous with the vascular tissue system of the stem to which it is attached, and the vascular tissue system of the stem is continuous with the vascular tissue system of the root.

The ground tissue system is composed of three simple tissues

The bulk of an herbaceous plant is its ground tissue system, which is composed of three tissues: parenchyma, collenchyma, and sclerenchyma (Table 31-2). These tissues can be distinguished by their cell wall structures. Recall that plant cells are surrounded by a cell wall that provides structural support (see Chapter 4). A growing plant cell secretes a thin **primary cell wall,** which stretches and expands as the cell increases in size. After the cell stops growing, it sometimes secretes a thick, strong **secondary cell wall,** which is deposited *inside* the primary cell

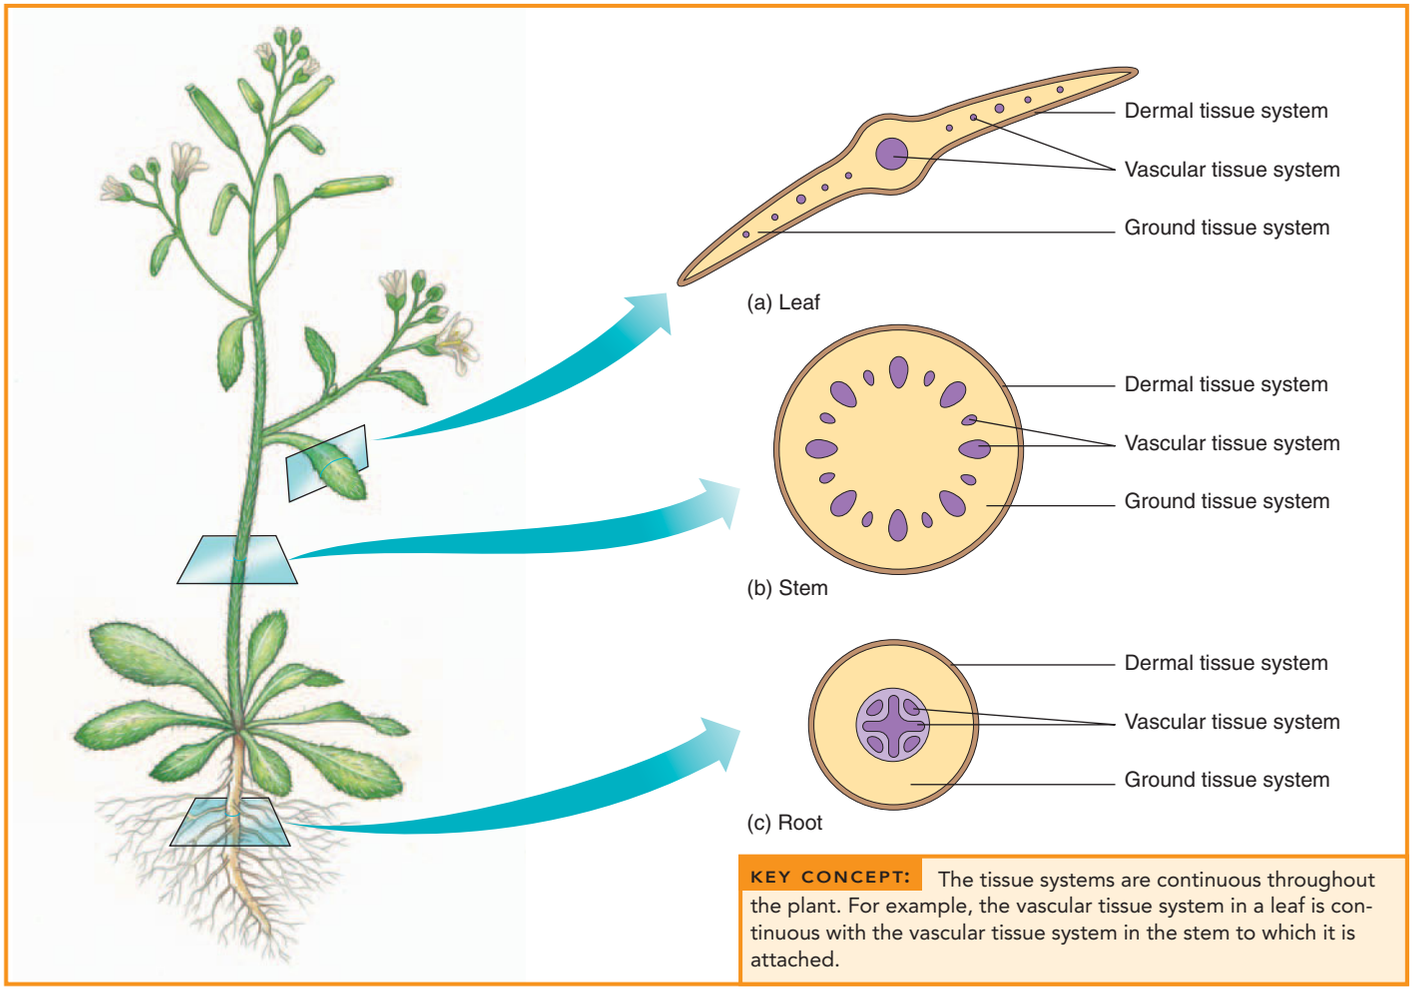


FIGURE **31-3** **The three tissue systems in the plant body.**

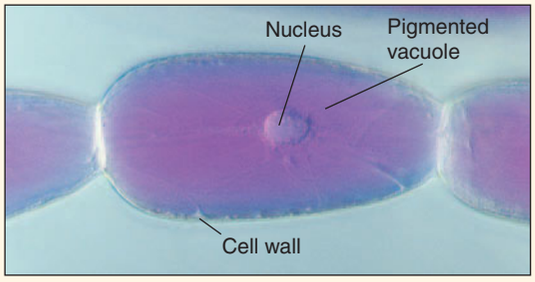
This figure shows the distribution of the ground tissue system, vascular tissue system, and dermal tissue system in the (a) leaves, (b) stems, and (c) roots of a herbaceous dicot such as *Arabidopsis*.

TABLE **31-1** **Tissue Systems, Tissues, and Cell Types of Flowering Plants**

Tissue System	Tissue	Cell Types	Main Functions of Tissue
Ground tissue system	Parenchyma tissue	Parenchyma cells	Storage, secretion, photosynthesis
	Collenchyma tissue	Collenchyma cells	Support
	Sclerenchyma tissue	Sclerenchyma cells (sclereids or fibers)	Support, strength
Vascular tissue system	Xylem	Tracheids	Conduction of water and nutrient minerals, support
		Vessel elements	Conduction of water and nutrient minerals, support
		Xylem parenchyma cells	Storage
		Fibers (sclerenchyma cells)	Support, strength
	Phloem	Sieve tube elements	Conduction of sugar in solution, support
		Companion cells	May control functioning of sieve tube elements
		Phloem parenchyma cells	Storage, loading sugar into sieve tube elements
		Fibers (sclerenchyma cells)	Support, strength
Dermal tissue system	Epidermis	Epidermal cells	Protective covering over surface of plant body
		Guard cells	Regulate stomata
		Trichomes	Variable functions
	Periderm	Cork cells	Protective covering over surface of plant body
		Cork cambium cells	Meristematic (form new cells)
		Cork parenchyma cells	Storage

TABLE 31-2 Cell Types in the Ground Tissue System

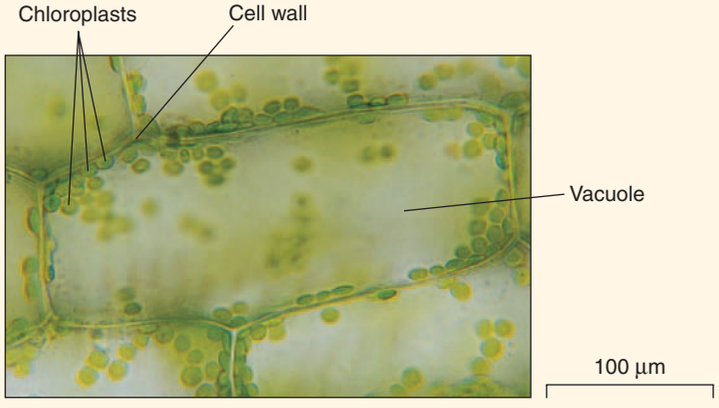


Parenchyma cell

Description
Living, actively metabolizing; thin primary cell walls

Functions
Storage; secretion, and/or photosynthesis

Location and comments
Throughout the plant body; shown is an LM of a stamen hair of a spiderwort (*Tradescantia virginiana*) flower; note the large pigmented vacuole; the nucleus is not inside the vacuole but is lying on *top* of the vacuole
(Phil Gates/Biological Photo Service)

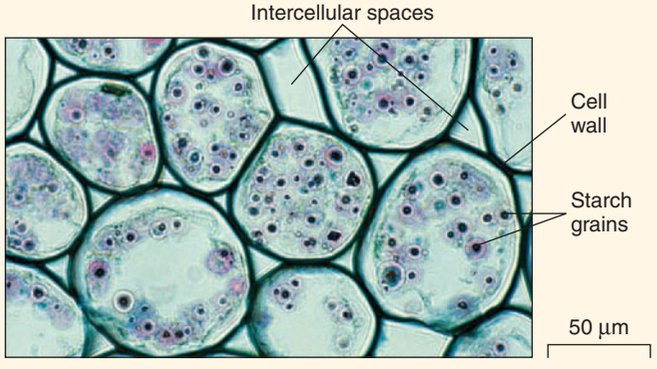


Parenchyma cell

Description
Living, actively metabolizing; thin primary cell walls

Functions
Storage; secretion; photosynthesis

Location and comments
Throughout the plant body; shown is an LM of leaf cells from an aquatic plant (*Elodea);* note the many chloroplasts in the thin layer of cytoplasm surrounding the large, transparent vacuole
(Dennis Drenner)

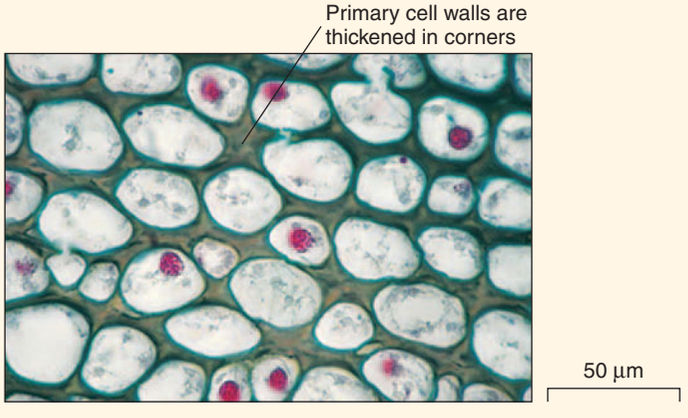


Parenchyma cell

Description
Living, actively metabolizing; thin primary cell walls

Functions
Storage; secretion; photosynthesis

Location and comments
Throughout the plant body; shown is an LM of a cross section of part of a buttercup (*Ranunculus*) root; note the starch grains filling the cells
(Dennis Drenner)



Collenchyma cell

Description
Living; unevenly thickened primary cell walls

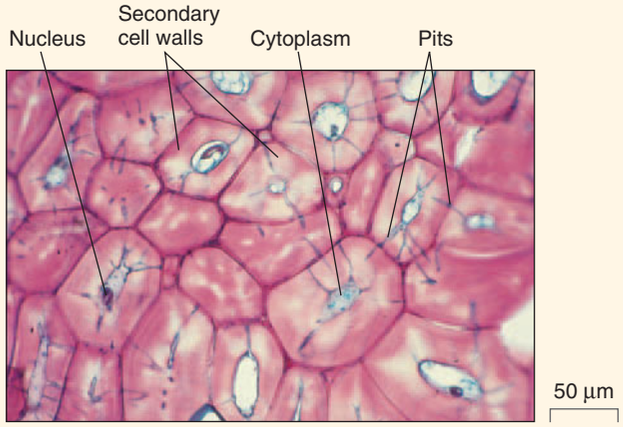
Function
Elastic support

Location and comments
Just under stem epidermis; shown is an LM of a cross section of an elderberry (*Sambucus*) stem; note the unevenly thickened cell walls that are especially thick in the corners, making the cell contents assume a spherical shape
(Ed Reschke)

wall—that is, between the primary cell wall and the plasma membrane (see Fig. 4-28).

Plant cell walls have several important roles in plants. Cell walls are involved in growth; the ability of primary cell walls to expand allows cells to increase in size. Scientists are increasingly aware that **signal transduction** takes place in plant cell walls, because many carbohydrate and protein molecules in plant cell walls communicate with other molecules both inside

TABLE **31-2** **Continued**

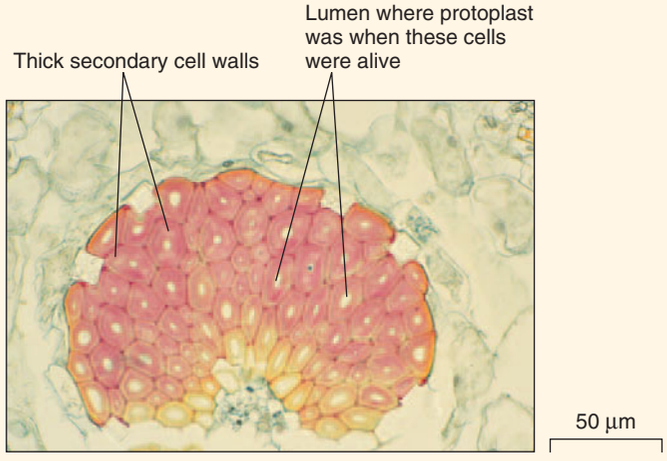


Sclereid (Sclerenchyma cell)

Description
May be living or dead at maturity; thick secondary cell walls; lacks secondary wall at pits

Functions
Strength; sclereid-rich tissue is hard and inflexible

Location and comments
Shells of walnuts and coconuts; pits of cherries and peaches; shown is an LM of living sclereids in a section through a cherry (*Prunus avium*) pit *(James Mauseth, University of Texas)*



Fiber (Sclerenchyma cell)

Description
Often dead at maturity; thick secondary cell walls; fewer pits than in sclereids

Functions
Support; provides strength

Location and comments
Throughout the plant body; common in stems and certain leaves; shown is an LM of a cross section through a clump of fibers from a century plant (*Agave*) leaf
(James Mauseth, University of Texas)

and outside the cell. The cell wall is also the first line of defense against disease-causing organisms.

Parenchyma cells have thin primary walls

Parenchyma tissue, a simple tissue composed of parenchyma cells, is found throughout the plant body and is the most common type of cell and tissue (Fig. 31-4a). The soft parts of a plant, such as the edible part of an apple or a potato, consist largely of parenchyma.

Parenchyma cells perform several important functions, such as photosynthesis, storage, and secretion. Parenchyma cells that function in photosynthesis contain green chloroplasts, whereas nonphotosynthetic parenchyma cells lack chloroplasts and are often colorless. Materials stored in parenchyma cells include starch grains, oil droplets, water, and salts, which are sometimes visible as crystals. Resins, tannins, hormones, enzymes, and sugary nectar are examples of substances that may be secreted by parenchyma cells. The various functions of parenchyma require that they be living, metabolizing cells.

Parenchyma cells have the ability to *differentiate* into other kinds of cells, particularly when a plant has been injured. If xylem (water-conducting) cells are severed, for example, adjacent parenchyma cells may divide and differentiate into new xylem cells within a few days. (Recall from Chapter 16 that it is possible to induce certain plant cells to become the equivalent of embryonic cells that can then differentiate into specialized cells.)

Collenchyma cells have unevenly thickened primary walls

Collenchyma tissue, a simple plant tissue composed of collenchyma cells, is an extremely flexible structural tissue that provides much of the support in soft, nonwoody plant organs (Fig. 31-4b). Support is crucial for plants, in part because it lets them grow upward to compete with other plants for available sunlight in a plant-crowded area. Plants lack the bony skeletal system typical of many animals; instead, individual cells, including collenchyma cells, support the plant body.

Collenchyma cells, which are usually elongated, are alive at maturity. Their primary cell walls are unevenly thickened and are especially thick in the corners. Collenchyma is not found uniformly throughout the plant and often occurs as long strands near stem surfaces and along leaf veins. The "strings" in a celery stalk, for example, consist of collenchyma tissue.

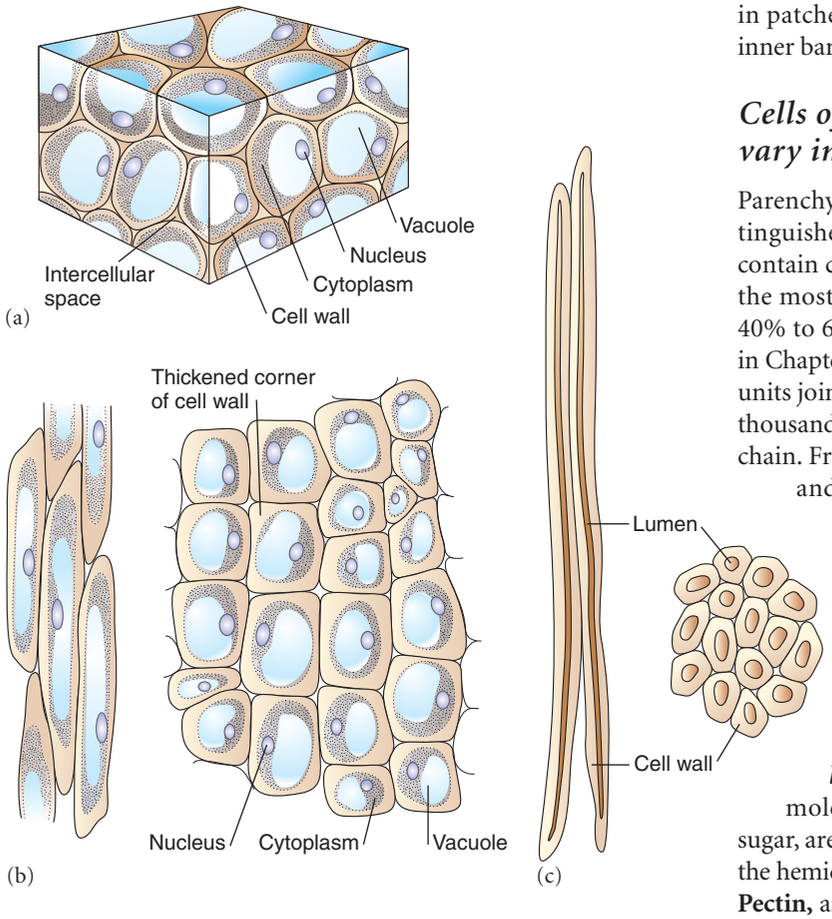


FIGURE **31-4** **Cell types: parenchyma, collenchyma, and sclerenchyma.**

(a) 3-D view of parenchyma cells. Parenchyma cells vary in size and structure, depending on their various functions within the plant body. **(b)** Collenchyma cells in longitudinal section *(left)* and cross section. Note the elongated cells, evident in longitudinal section, and the unevenly thickened cell walls, evident in cross section. **(c)** Sclerenchyma cells (fibers) in longitudinal section *(left)* and cross section. Mature fibers are often dead at functional maturity and therefore lack nuclei and cytoplasm; the lumen is the space formerly occupied by the living cell.

Sclerenchyma cells have both primary walls and thick secondary walls

Another simple plant tissue specialized for structural support is **sclerenchyma** tissue, whose cells have both primary and secondary cell walls. The root of the word *sclerenchyma* is derived from a Greek word *(sclero)* meaning "hard." The secondary cell walls of sclerenchyma cells become strong and hard because of extreme thickening. Thus sclerenchyma cells are unable to stretch or elongate. At functional maturity, when sclerenchyma tissue is providing support for the plant body, its cells are often dead.

Sclerenchyma tissue may be located in several areas of the plant body. Two types of sclerenchyma cells are sclereids and fibers. **Sclereids** are cells of variable shape common in the shells of nuts and in the pits of stone fruits such as cherries and peaches. Pears owe their slightly gritty texture to the presence of clusters of sclereids. **Fibers,** which are long, tapered cells that often occur in patches or clumps, are particularly abundant in the wood, inner bark, and leaf ribs (veins) of flowering plants (Fig. 31-4c).

Cells of the three simple tissues vary in their cell wall chemistry

Parenchyma, collenchyma, and sclerenchyma cells can be distinguished by the chemistry of their cell walls. Cell walls may contain cellulose, hemicelluloses, pectin, and lignin. **Cellulose,** the most abundant polymer in the world, accounts for about 40% to 60% of the dry weight of plant cell walls. As discussed in Chapter 3, cellulose is a **polysaccharide** composed of glucose units joined by β-1,4 bonds. Each cellulose molecule consists of thousands of glucose subunits joined to form a flat, ribbon-like chain. From 40 to 70 of these chains lie parallel to one another and connect by hydrogen bonding to form a **cellulose microfibril,** a strong, tiny strand visible under the electron microscope (see Fig. 3-10a).

Cellulose microfibrils are cemented together by a matrix of hemicelluloses and pectins. **Hemicelluloses** are a group of polysaccharides that are more soluble than cellulose. Hemicelluloses vary in their chemical composition from one species to another. Some hemicelluloses are composed of *xyloglucan,* which consists of a backbone of β-1,4-glucose molecules to which side chains of *xylose,* a five-carbon sugar, are attached. Despite their name, the chemical structure of the hemicelluloses is significantly different from that of cellulose. **Pectin,** another cementing polysaccharide, is less variable in its monomer composition than are the hemicelluloses. Pectin monomer units are *α-galacturonic acid,* a six-carbon molecule that is a derivative of glucose.

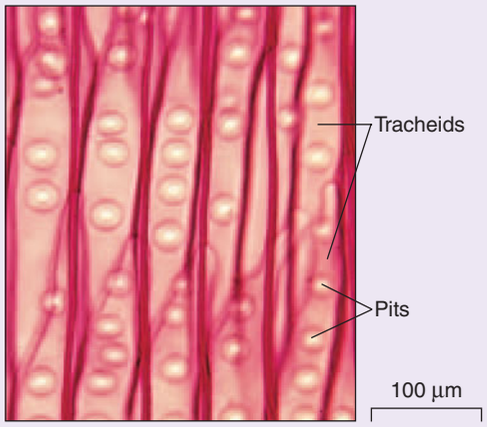
An important component of secondary plant cell walls, particularly those of wood, is **lignin.** Comprising as much as 35% of the dry weight of the secondary cell wall, lignin is an extremely complex strengthening polymer composed of monomers derived from certain amino acids. The chemical structure of lignin has not been completely determined, because it is hard to remove from cellulose and other cell wall materials to which it is covalently bound.

Having examined four main components in plant cell walls, we can now generalize about the cell chemistry of parenchyma, collenchyma, and sclerenchyma cells. The thin primary cell walls of parenchyma cells contain predominantly cellulose, although they also contain hemicelluloses and pectin. Both parenchyma and collenchyma cells have primary cell walls, but their walls are chemically distinct because the thickened areas of collenchyma walls contain large quantities of pectin in addition to cellulose and hemicelluloses. The thick secondary walls of sclerenchyma cells are chemically different because they are rich in lignin, in addition to cellulose, hemicelluloses, and pectin.

The vascular tissue system consists of two complex tissues

The vascular tissue system, which is embedded in the ground tissue, transports needed materials throughout the plant via two complex tissues: xylem and phloem (Table 31-3). Both xylem and

TABLE 31-3 Selected Cell Types in the Vascular Tissue System

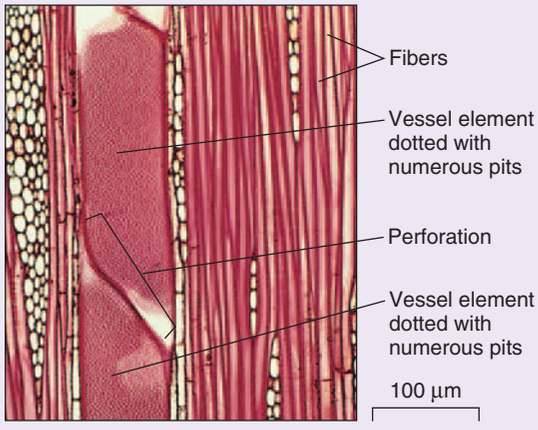


Tracheid

Description
Dead at maturity; lacks secondary wall at pits

Functions
Conduction of water and nutrient minerals, support

Location and comments
Occurs in clumps in xylem throughout plant body; shown is an LM of a longitudinal section of tracheids from white pine (*Pinus strobus*) wood
(John D. Cunningham/Visuals Unlimited)

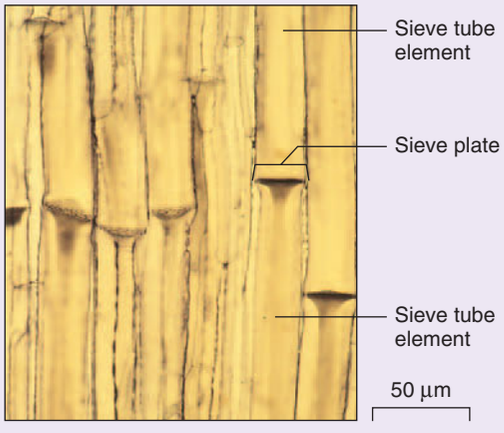


Vessel element

Description
Dead at maturity; end walls have perforations; lacks secondary wall at pits

Functions
Conduction of water and nutrient minerals, support

Location and comments
Xylem throughout plant body; vessel elements are more efficient than tracheids in conduction; shown is an LM of a longitudinal section of two vessel elements from an unknown woody dicot
(James Mauseth, University of Texas)

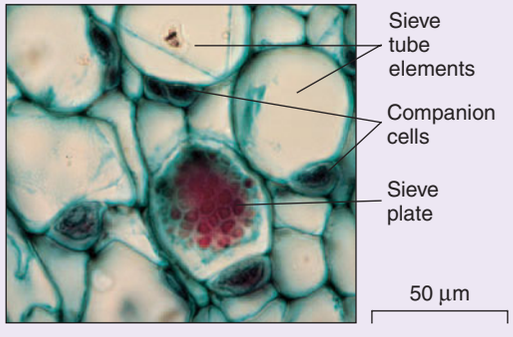


Sieve tube element

Description
Living but lacks nucleus and other organelles at maturity; end walls are sieve plates

Function
Conduction of sugar in solution

Location and comments
Phloem throughout plant body; shown is an LM of a longitudinal section through a clump of sieve tube elements in a squash (*Cucurbita*) petiole (leaf stalk)
(James Mauseth, University of Texas)



Companion cell

Description
Living; has cytoplasmic connections with sieve tube element

Function
Assists in moving sugars into and out of sieve tube element

Location and comments
Phloem throughout plant body; shown is an LM of phloem from a squash (*Cucurbita*) petiole (leaf stalk) in cross section
(J. Robert Waaland/Biological Photo Service)

phloem are continuous throughout the plant body. (Chapter 33 discusses the mechanisms of transport in xylem and phloem.)

The conducting cells in xylem are tracheids and vessel elements

Xylem conducts water and dissolved nutrient minerals from the roots to the stems and leaves and provides structural support. In flowering plants, xylem is a complex tissue composed of four different cell types: tracheids, vessel elements, parenchyma cells, and fibers. Two of the four cell types found in xylem, the **tracheids** and **vessel elements,** conduct water and dissolved nutrient minerals. In addition to these cells, xylem also contains parenchyma cells, known as *xylem parenchyma,* that perform storage functions, and fibers that provide support.

Tracheids and vessel elements are highly specialized for conduction. When mature, both cell types are dead and therefore hollow; only their cell walls remain. Tracheids, the chief water-conducting cells in gymnosperms (such as pine) and seedless vascular plants (such as ferns), are long, tapering cells located in patches or clumps (Fig. 31-5a). Water is conducted upward, from roots to shoots, passing from one tracheid into another through *pits,* thin areas in the tracheids' cell walls where a secondary wall did not form.

In addition to a relatively few tracheids, flowering plants possess extremely efficient water-conducting cells called *vessel elements* (Fig. 31-5b). The cell diameters of vessel elements are usually greater than those of tracheids. Vessel elements are hollow, but unlike tracheids, the end walls have holes, known as *perforations,* or are entirely dissolved away. Vessel elements are stacked one on top of the other, and water is conducted readily from one vessel element into the next. A stack of vessel elements, called a **vessel,** resembles a miniature water pipe. Vessel elements also have pits in their side walls that permit the lateral transport (sideways movement) of water from one vessel to another.

Sieve tube elements are the conducting cells of phloem

Phloem conducts food materials, that is, carbohydrates formed in photosynthesis, throughout the plant and provides structural support. In flowering plants, phloem is a complex tissue composed of four different cell types: sieve tube elements, companion cells, fibers, and phloem parenchyma cells (Fig. 31-5c, d). Fibers are frequently extensive in the phloem of herbaceous plants, providing additional structural support for the plant body.

Food materials are conducted in *solution,* that is, dissolved in water, through the **sieve tube elements,** which are among the most specialized cells. Sieve tube elements are joined end-on-end to form long **sieve tubes.** The cells' end walls, called *sieve plates,* have a series of holes through which cytoplasm extends from one sieve tube element into the next. Sieve tube elements are living at maturity, but many of their organelles, including the nucleus, vacuole, mitochondria, and ribosomes, disintegrate or shrink as they mature.

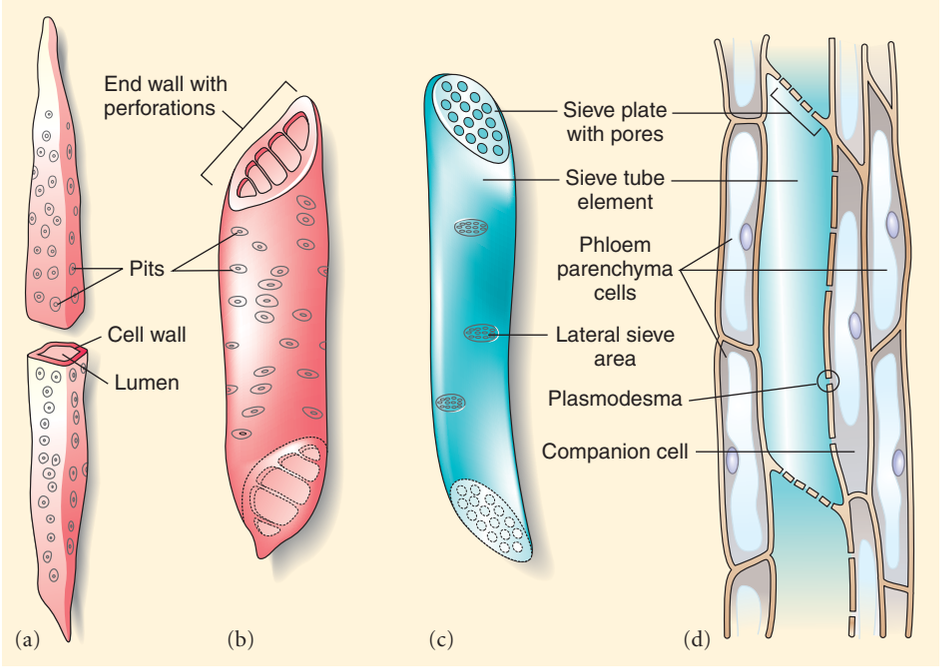
Sieve tube elements are among the few eukaryotic cells that can function without nuclei. These cells typically live for less than a year. There are, however, notable exceptions: Certain palms have sieve tube elements that remain alive for approximately 100 years!

Adjacent to each sieve tube element is a **companion cell** that assists in the functioning of the sieve tube element. The companion cell is a living cell, complete with a nucleus. This nucleus is thought to direct the activities of both the companion cell and sieve tube element. Numerous **plasmodesmata**—cytoplasmic connections through which cytoplasm extends from one cell to another (see Chapter 5)—occur between a companion cell and its adjoining sieve tube element. The companion cell plays an essential role in moving sugar into the sieve tube elements for transport to other parts of the plant.

FIGURE **31-5**

Longitudinal views of cell types in xylem and phloem tissues.

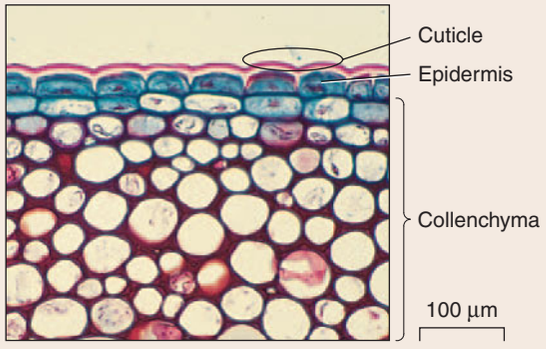
(a) 3-D view of a tracheid (xylem cell). The tracheid is opened to reveal the cell's appearance in cross section. At maturity, tracheids are usually dead. **(b)** 3-D view of a vessel element (xylem cell). The end walls of vessel elements have a variety of openings, or perforations, depending on the species. Vessel elements are joined end-to-end to produce minute "water pipes" that run the length of the plant, from roots to leaves and other shoot parts. **(c)** 3-D view of a sieve tube element, showing the sieve plate. **(d)** Longitudinal section of phloem tissue, showing sieve tube elements, companion cells, and phloem parenchyma cells. Fiber cells are not shown.



The dermal tissue system consists of two complex tissues

The dermal tissue system, the epidermis and periderm, provides a protective covering over plant parts (Table 31-4). In herbaceous plants, the dermal tissue system is a single layer of cells called the epidermis. Woody plants initially produce an epidermis, but it splits apart as the plant increases in girth owing to the production of additional woody tissues inside the epidermis. Periderm, a tissue several to many cell layers thick, forms under the epidermis to provide a new protective covering as the epidermis is destroyed. Periderm, which replaces the epidermis in the stems and roots of older woody plants, composes the outer bark.

TABLE **31-4** Selected Cell Types in the Dermal Tissue System

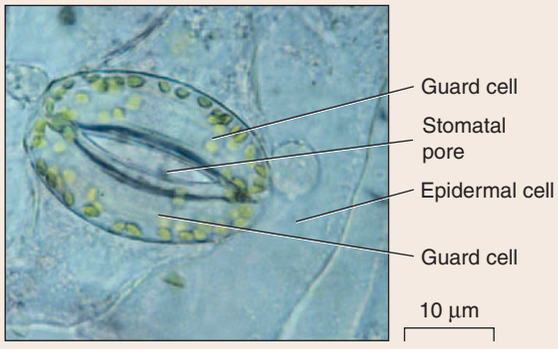


Epidermal cell

Description
Relatively unspecialized cell with thin primary wall; outer wall often thicker and covered by a noncellular waxy layer (cuticle)

Functions
Protective covering over surface of plant body; helps reduce water loss

Location and comments
Epidermis is usually one cell thick; shown is an LM of a cross section through epidermis of an ivy (*Hedera helix*) stem
(James Mauseth, University of Texas)



Guard cell

Description
Chloroplast-containing cell that occurs in pairs; pair changes shape to open and close stomatal pore

Function
Opens and closes stomatal pore

Location and comments
Epidermis of stems and leaves; shown is an LM of the epidermis of a spiderwort (*Tradescantia virginiana*) leaf
(Dwight R. Kuhn)

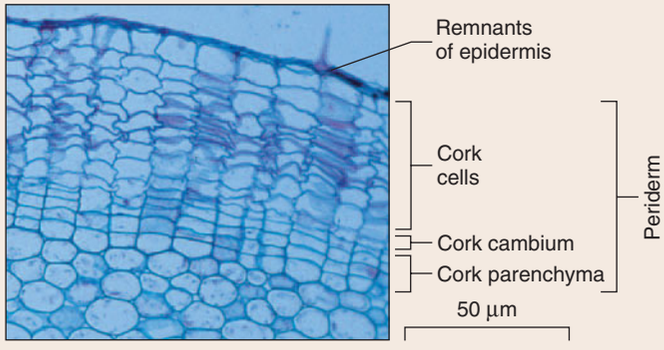
Image not available due to copyright restrictions

Trichome

Description
Hair or other epidermal outgrowth; may be unicellular or multicellular; occurs in variety of sizes and shapes

Functions
Varied; absorption; secretion; excretion; protection; reduces water loss

Location and comments
Epidermis; shown is an SEM of a nettle (*Solanum carolinense*) leaf, which has trichomes that break off inside the skin of animals and inject irritating substances that cause a stinging sensation
(Biophoto Associates)



Cork cell

Description
Dead at maturity; cell walls are impregnated with waterproof material (suberin)

Functions
Reduces water loss and prevents disease-causing organisms from penetrating

Location and comments
Produced in large numbers; cork often forms just under the epidermis; replaces epidermis in older stems and roots; shown is an LM of a cross section through periderm of a geranium (*Pelargonium*) stem
(Dennis Drenner)

Epidermis is the outermost layer of a herbaceous plant

The **epidermis** is a complex tissue composed primarily of relatively unspecialized living cells. Dispersed among these cells are more specialized guard cells and outgrowths called trichomes (discussed shortly). In most plants, the epidermis consists of a single layer of flattened cells (Fig. 31-6). Epidermal cells generally contain no chloroplasts and are therefore transparent, allowing light to penetrate into the interior tissues of stems and leaves. In both stems and leaves, photosynthetic tissues lie *beneath* the epidermis.

An important requirement of the aerial parts (stems, leaves, flowers, and fruits) of a plant is the ability to control water loss. Epidermal cells of aerial parts secrete a waxy **cuticle** over the surface of their exterior walls; this waxy layer greatly restricts water loss from plant surfaces.

Although the cuticle is extremely efficient at preventing most water loss through epidermal cells, it also slows the diffusion of carbon dioxide, needed for photosynthesis, from the atmosphere into the leaf or stem. The diffusion of carbon dioxide is facilitated by **stomata** (singular, *stoma*). Stomata are minute pores in the epidermis, surrounded by two cells called **guard cells** (see Figure 32-5). Many gases, including carbon dioxide, oxygen, and water vapor, pass through the stomata by diffusion. Stomata are generally open during the day when photosynthesis is occurring, and the water loss that also takes place when stomata are open provides some evaporative cooling. During the night, stomata usually close. During drought conditions, the need to conserve water overrides the need to cool the leaves and exchange gases. Thus, during a drought, the stomata close in the daytime. Stomata are discussed in greater detail in Chapter 32.

The epidermis also contains special outgrowths, or hairs, called **trichomes,** which occur in many sizes and shapes and have a variety of functions (see Figure 32-4). Plants that tolerate salty environments such as the seashore often have specialized trichomes on their leaves to remove excess salt that accumulates in the plant. The presence of trichomes on the aerial parts of desert plants may increase the reflection of light off the plants, thereby keeping the internal tissues cooler and decreasing water loss. Other trichomes have a protective function. For example, the trichomes on stinging nettle leaves and stems contain irritating substances that may discourage herbivorous animals from eating the plant. **Root hairs** are simple, unbranched trichomes that increase the surface area of the root epidermis (which comes into contact with the soil) for more effective water and nutrient mineral absorption.

Epidermis is replaced by periderm in woody plants

As a woody plant begins to increase in girth, its epidermis is sloughed off and replaced by **periderm.** Periderm forms the outer bark of older stems and roots. It is a complex tissue composed mainly of cork cells and cork parenchyma cells. **Cork cells** are dead at maturity, and their walls are heavily coated with a waterproof substance called *suberin,* which helps reduce water loss. **Cork parenchyma** cells function primarily in storage.

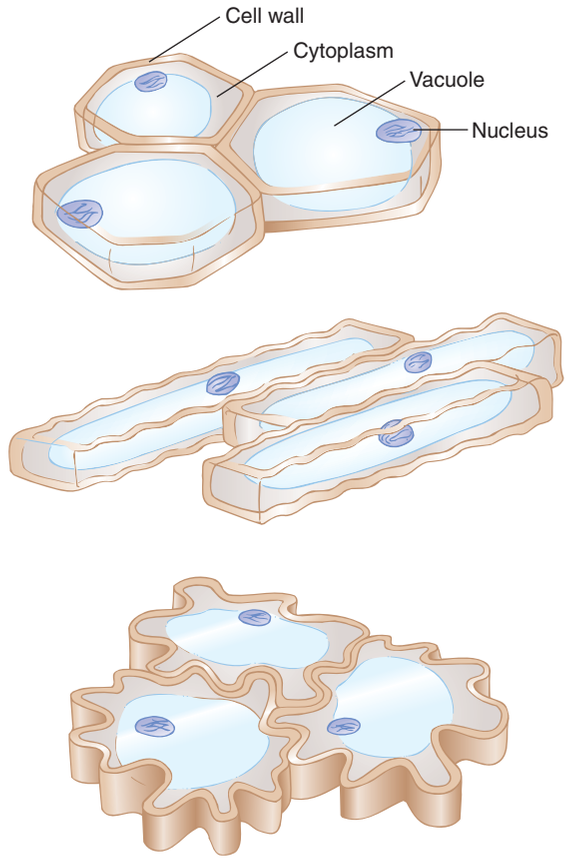


FIGURE **31-6** **Cell types: epidermal cells.**
3-D views of epidermal cells from three different plants. Note that, regardless of the cell shape, epidermal cells fit tightly together.

Review

- What are some of the functions of roots? Of shoots?
- What are the three tissue systems in plants? Describe the functions of each.
- How do parenchyma, collenchyma, and sclerenchyma tissues differ in cellular structure and function?
- What are the functions of xylem and phloem? Describe the conducting cells that occur in each of these complex tissues.
- How are epidermis and periderm alike? How are they different?

BiologyNow™ Assess your understanding of **the plant body** by taking the pretest on your BiologyNow CD-ROM.

PLANT MERISTEMS

Learning Objectives

8 Discuss what is meant by growth in plants, and state how it differs from growth in animals.
9 Distinguish between primary and secondary growth.
10 Distinguish between apical meristems and lateral meristems.

Plant growth involves three different processes: cell division, cell elongation (the lengthening of a cell), and cell differentia-

tion. Cell division is an essential part of plant growth that results in an increase in the number of cells. These new cells elongate as the cytoplasm grows and the vacuole fills with water, which exerts pressure on the cell wall and causes it to expand. In an onion root cell, the vacuole increases in size by some 30 to 150 times during elongation. Plant cells also differentiate, or specialize, into the various cell types just discussed. These cell types constitute the mature plant body and perform the various functions required in a multicellular organism. Although differentiation does not contribute to an increase in size, it is an important aspect of growth and development because it is essential for tissue formation.

One difference between plants and animals is the *location* of growth. When a young animal is growing, all parts of its body grow, although not necessarily at the same rate. However, when plants grow, their cells divide only in specific areas, called **meristems,** which are composed of cells whose primary function is the formation of new cells by mitotic division. Meristematic cells do not differentiate. Instead, they retain the ability to divide by mitosis, a trait that many differentiated cells lose. The persistence of mitotically active meristems means that plants, unlike most animals, can grow throughout their entire life span.

Two kinds of meristematic growth may occur in plants. **Primary growth** is an increase in stem and root length. All plants exhibit primary growth, which produces the entire plant body in herbaceous plants and the young, soft shoots and roots in woody trees and shrubs. **Secondary growth** is an increase in the girth of a plant. For the most part, only gymnosperms and woody dicots have secondary growth.[1] Tissues produced by secondary growth comprise the wood and bark, which make up most of the bulk of trees and shrubs. A few annuals—geranium and sunflower, for example—have limited secondary growth despite the fact that they lack obvious wood and bark tissues.

Primary growth takes place at apical meristems

Primary growth occurs as a result of the activity of **apical meristems,** areas located at the tips of roots and shoots, including within the buds of stems. (**Buds** are dormant embryonic shoots that eventually develop into branches.)

Primary growth is evident when a root tip (Fig. 31-7) is examined. A protective layer of cells called a **root cap** covers the root tip. Directly behind the root cap is the root apical meristem, which consists of meristematic cells. Meristematic cells, which are quite small and cube-shaped, remain small because they are continually dividing. (In meristems, as daughter cells begin to enlarge, one or both will divide again.)

Farther from the root tip, just behind the area of cell division, is an area of cell elongation where the cells have been displaced from the meristem. Here the cells are no longer dividing but instead are growing longer, pushing the root tip ahead of them, deeper into the soil. Some differentiation also begins to occur in the area of cell elongation, and immature tissues such as differentiating xylem and phloem, become evident. The tissue systems continue to develop and differentiate into primary tissues (epidermis, xylem, phloem, and ground tissues) of the adult plant. Farther from the tip, behind the area of cell elongation, most cells have completely differentiated and are fully mature. Root hairs are evident in this area.

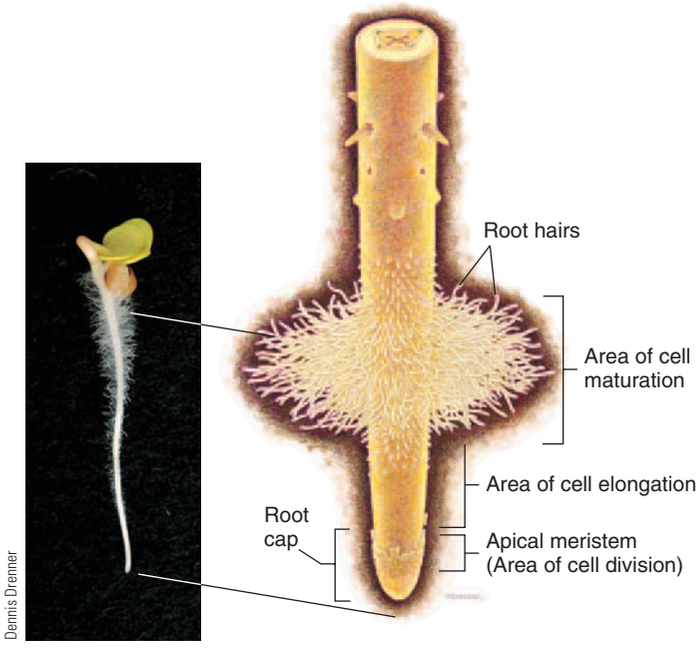

FIGURE **31-7** **A root tip.**

The root apical meristem (where cells divide and thus increase in number) is protected by a root cap. Farther from the tip is an area of cell elongation, where cells enlarge and begin to differentiate. The area of cell maturation has fully mature, differentiated cells. Note the young root hairs in this area and on the root of a young radish (*Raphanus sativus*) seedling, which is approximately 5 cm (2 in) long *(left)*.

A shoot apex (such as the terminal bud) is quite different in appearance from a root tip (Fig. 31-8). A dome of minute, regularly arranged meristematic cells—the shoot apical meristem—is located in each shoot apex. **Leaf primordia** (developing leaves) and **bud primordia** (developing buds) arise from the shoot apical meristem. The tiny leaf primordia cover and protect the shoot apical meristem. As the cells formed by the shoot apical meristem elongate, the shoot apical meristem is pushed upward. Subsequent cell divisions produce additional stem tissue and cause new leaf and bud primordia to appear. Farther from the stem tip, the immature cells differentiate into the three tissue systems of the mature plant body.

Secondary growth takes place at lateral meristems

In addition to primary growth, trees and shrubs have secondary growth. These plants increase in length by primary growth and

[1] Recall from Chapter 27 that, on the basis of structural features, flowering plants are divided into two groups, informally called dicots and monocots. Oak, sycamore, ash, cherry, apple, and maple are examples of woody dicots, whereas bean, daisy, and snapdragon are herbaceous dicots. Palm, corn, bluegrass, lily, and tulip are monocots.

ACTIVE FIGURE **31-8**

A shoot apex.

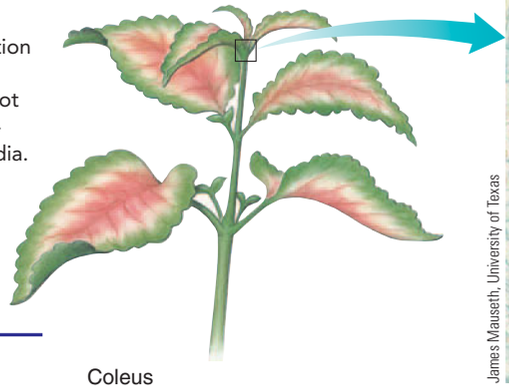
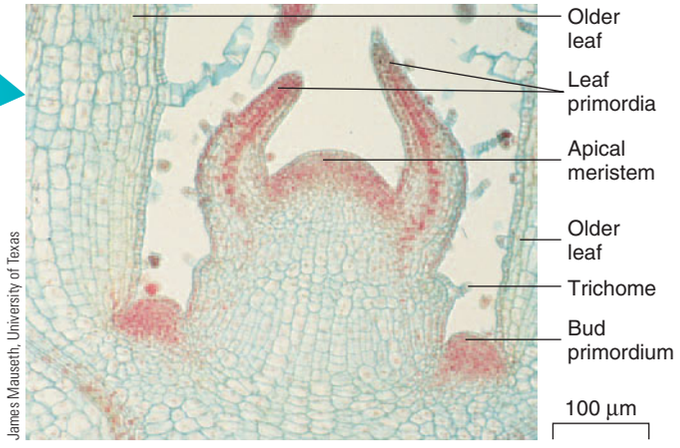
BiologyNow™ See **shoot development in action** by clicking on this figure on your BiologyNow CD-ROM.



Coleus

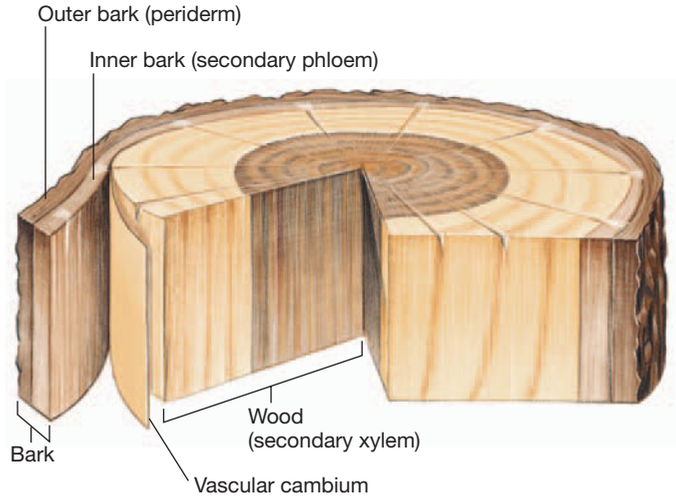


increase in girth by secondary growth. This increase in girth, which occurs in areas that are no longer elongating, is due to cell divisions that take place in **lateral meristems,** areas extending along the entire length of the stems and roots, except at the tips. Two lateral meristems, the vascular cambium and the cork cambium, are responsible for secondary growth, which is the formation of secondary tissues: secondary xylem, secondary phloem, and periderm (Fig. 31-9).

The **vascular cambium** is a layer of meristematic cells that forms a long, thin, continuous cylinder within the stem and root. It is located between the wood and bark of a woody plant. Cells of the vascular cambium divide, adding more cells to the wood (secondary xylem) and inner bark (secondary phloem).

The **cork cambium** is composed of a thin cylinder or irregular arrangement of meristematic cells and is located in the outer bark. Cells of the cork cambium divide and form **cork cells** toward the outside and one or more underlying layers of **cork parenchyma** cells that function in storage. Collectively, cork cells, cork cambium, and cork parenchyma make up the periderm (discussed previously).

We are now ready to give a more precise definition of bark. **Bark,** the outermost covering over woody stems and roots, consists of all plant tissues located outside the vascular cambium. Bark has two regions, a living inner bark composed of secondary phloem and a mostly dead outer bark composed of periderm. A more comprehensive discussion of secondary growth is given in Chapters 33 and 34.



ACTIVE FIGURE **31-9** **Secondary growth.**

The vascular cambium, a thin layer of cells sandwiched between the wood and bark, produces the secondary vascular tissues: the wood, which is secondary xylem, and the inner bark, which is secondary phloem. The cork cambium produces the periderm, the outer bark tissue that replaces the epidermis in a plant with secondary growth.

BiologyNow™ Experiment with **tree-ring development** by clicking on this figure on your BiologyNow CD-ROM.

Review

- What is the role of plant meristems? Does animal growth involve meristems?
- What is primary growth? Secondary growth?
- What are apical meristems? Lateral meristems?

BiologyNow™ Assess your understanding of **plant meristems** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Distinguish between herbaceous and woody plants.

- Plants are either herbaceous (nonwoody) or woody. In temperate climates, the aerial parts of herbaceous plants die back, whereas the aerial parts of woody plants persist.

2 Discuss the differences among annuals, biennials, and perennials, and give an example of each.

- **Annuals** such as corn, geranium, and marigold are herbaceous plants that grow, reproduce, and die in one year or less.

SUMMARY WITH KEY TERMS *(continued)*

- **Biennials** such as carrot and Queen Anne's lace take two years to complete their life cycles before dying.
- **Perennials** such as asparagus and oak trees are herbaceous and woody plants that have the potential to live for more than two years.

3 Contrast two different life history strategies in plants.

- Plants have a variety of life history strategies to ensure their successful reproduction and survival.
- Long-lived trees thrive in a tropical rain forest where competition prevents most small, short-lived plants from becoming established. Small, short-lived plants thrive in a relatively unfavorable environment such as a desert following a rainy spell.

4 Discuss the functions of various parts of the vascular plant body, including the nutrient- and water-absorbing root system and the photosynthesizing shoot system.

- The vascular plant body typically consists of a root system and a shoot system. The **root system** is generally underground and obtains water and dissolved nutrient minerals for the plant. Roots also anchor the plant firmly in place.
- The **shoot system** is generally aerial and obtains sunlight and exchanges gases such as carbon dioxide, oxygen, and water vapor. The shoot system consists of a vertical stem that bears leaves (the main **organs** of photosynthesis) and reproductive structures (flowers and fruits in flowering plants). **Buds,** undeveloped embryonic shoots, develop on stems.
- Although separate organs (roots, stems, leaves, flower parts, and fruits) exist in the plant, tissue systems are integrated throughout the plant body, providing continuity from organ to organ. The plant body is composed of three tissue systems: ground, vascular, and dermal.

5 Describe the ground tissue system (parenchyma tissue, collenchyma tissue, and sclerenchyma tissue).

- The **ground tissue system** consists of three tissues with a variety of functions. **Parenchyma** tissue is composed of living parenchyma cells that have thin **primary cell walls.** Functions of parenchyma tissue include photosynthesis, storage, and secretion.
- **Collenchyma** tissue consists of collenchyma cells with unevenly thickened primary cell walls. This tissue provides flexible structural support.
- **Sclerenchyma** tissue is composed of sclerenchyma cells—**sclereids** or **fibers**—that have both primary cell walls and **secondary cell walls.** Sclerenchyma cells are often dead at maturity, but provide structural support.

6 Describe the structure and function of the vascular tissue system (xylem and phloem).

- The **vascular tissue system** conducts materials throughout the plant body and provides strength and support.
- **Xylem** is a complex tissue that conducts water and dissolved nutrient minerals. The actual conducting cells of xylem are **tracheids** and **vessel elements.**
- **Phloem** is a complex tissue that conducts sugar in solution. **Sieve tube elements** are the conducting cells of phloem; they are assisted by **companion cells.**

7 Describe the dermal tissue system (epidermis and periderm).

- The **dermal tissue system** is the outer protective covering of the plant body.
- The **epidermis** is a complex tissue that covers the herbaceous plant body. The epidermis that covers aerial parts secretes a waxy **cuticle** that reduces water loss. **Stomata** permit gas exchange between the interior of the shoot system and the surrounding atmosphere. **Trichomes** are outgrowths, or hairs, that occur in many sizes and shapes and have a variety of functions.
- The **periderm** is a complex tissue that covers the woody parts of the plant body in woody plants.

8 Discuss what is meant by growth in plants, and state how it differs from growth in animals.

- Growth in plants, unlike animals, is localized in specific regions, called **meristems,** and involves three processes: cell division, cell elongation, and cell differentiation.

9 Distinguish between primary and secondary growth.

- **Primary growth** is an increase in stem or root length. Primary growth occurs in all plants.
- **Secondary growth** is an increase in stem or root girth (thickness). Secondary growth is localized, typically occurring in long cylinders of meristematic cells throughout the length of older stems and roots.

10 Distinguish between apical meristems and lateral meristems.

- Primary growth results from the activity of **apical meristems** that are localized at the tips of roots and shoots and within the buds of stems.
- The two **lateral meristems** responsible for secondary growth are the **vascular cambium** and the **cork cambium.**

POST-TEST

1. Plants that complete their life cycles in one year are called _____; those that complete them in two years are _____; and those that live year after year are _____. (a) annuals; perennials; biennials (b) biennials; annuals; perennials (c) annuals; biennials; perennials (d) perennials; annuals; biennials (e) perennials; biennials; annuals
2. Which of the following plant life history strategies would be successful in a relatively favorable environment such as a tropical rain forest? (a) long life span with flowers and seeds produced each year (b) long life span with flowers and seeds produced only when the plant is very young (c) short life span with flowers and seeds produced each year (d) short life span with flowers and seeds produced only when the plant is very young (e) very short life span with flowering at end of life
3. Most of the plant body consists of the _____ tissue system. (a) ground (b) vascular (c) periderm (d) dermal (e) cortex
4. The cell walls of parenchyma cells: (a) contain large quantities of pectin in the thickened corners (b) are rich in lignin but do not contain hemicelluloses and pectin (c) are predominantly cellulose, although they also contain hemicelluloses and pectin (d) contain cellulose, hemicelluloses, and lignin in approximately equal amounts (e) contain hemicelluloses, pectin, and lignin but no cellulose

POST-TEST *(continued)*

5. Which tissue system provides a covering for the plant body? (a) ground (b) vascular (c) periderm (d) dermal (e) cortex
6. Storage, secretion, and photosynthesis are the functions of (a) collenchyma (b) vessel elements (c) lateral meristems (d) sclerenchyma (e) parenchyma
7. The two simple tissues that are specialized for support are (a) parenchyma and collenchyma (b) collenchyma and sclerenchyma (c) sclerenchyma and parenchyma (d) parenchyma and xylem (e) xylem and phloem
8. Sclereids and fibers are examples of which plant tissue? (a) parenchyma (b) collenchyma (c) sclerenchyma (d) xylem (e) epidermis
9. Which of the following statements about the vascular tissue system is *not* true? (a) Xylem and phloem are continuous throughout the plant body. (b) Xylem not only conducts water and dissolved nutrient minerals, but also provides support. (c) Four different cell types occur in phloem: sieve tube elements, companion cells, tracheids, and vessel elements. (d) Sieve tube elements lack nuclei. (e) Vessel elements are hollow, and their end walls have perforations or are entirely dissolved away.
10. Conduction of water and nutrient minerals in xylem occurs in vessel elements and (a) sieve tube elements (b) tracheids (c) collenchyma (d) cork cells (e) phloem
11. Conduction of sugar in solution in the sieve tube elements is aided by (a) cork cells (b) sclerenchyma (c) parenchyma (d) guard cells (e) companion cells
12. The outer tissue that covers plants with primary growth is _____, whereas plants with secondary growth are covered by _____. (a) cuticle; cork parenchyma (b) periderm; phloem (c) epidermis; periderm (d) epidermis; collenchyma (e) cellulose; lignin
13. The noncellular waxy layer secreted by the epidermis over its aerial surface is called (a) lignin (b) cuticle (c) periderm (d) cellulose (e) trichome
14. Minute pores known as _____ dot the surface of the epidermis of leaves and stems; each pore is bordered by two _____. (a) stomata; guard cells (b) stomata; fibers (c) sieve tube elements; companion cells (d) sclereids; guard cells (e) cuticle; guard cells
15. Localized areas within the plant body where cell divisions occur are known as (a) organs (b) fibers (c) meristems (d) cork parenchyma (e) stomata
16. Primary growth, an increase in the length of a plant, occurs at the (a) cork cambium (b) apical meristem (c) vascular cambium (d) lateral meristem (e) periderm
17. The two lateral meristems responsible for secondary growth are the (a) cork cambium and apical meristem (b) apical meristem and cork parenchyma (c) vascular cambium and apical meristem (d) vascular cambium and cork cambium (e) cork cambium and cork parenchyma

CRITICAL THINKING

1. Grasses have a special meristem situated at the base of the leaves. Relate this information to what you know about the growth of grass after you mow the lawn.
2. A couple carved a heart with their initials into a tree trunk 4 feet above ground level; the tree was 25 feet tall at the time. Twenty years later the tree was 50 feet tall. How far above the ground were the initials? Explain your answer.
3. Sclerenchyma in plants is the functional equivalent of bone in humans (both sclerenchyma and bone provide support). However, sclerenchyma is dead, whereas bone is living tissue. What are some of the advantages of a plant having dead support cells? Can you think of any disadvantages?

Leaf Structure and Function

David Sieren/Visuals Unlimited

Leaves. Note how the red maple (*Acer rubrum*) leaves are arranged to efficiently capture light.

CHAPTER OUTLINE

- Leaf Form and Structure
- Stomatal Opening and Closing
- Transpiration and Guttation
- Leaf Abscission
- Modified Leaves

Suppose for a moment that you are taking a course in engineering and have been asked to design an efficient solar collector capable of converting the radiant energy it collects into chemical energy of organic compounds. Where would you start? It might be helpful to check library books and periodicals to see how solar collectors/energy converters have been designed in the past. In this instance, it would also be wise to ask a biologist, or even a biology student like yourself, whether anything comparable exists in nature. The answer, of course, is yes. Plants have organs that are effective solar collectors and energy converters; they are called *leaves.*

Plants allocate many resources to the production of leaves. According to John E. Dale, a University of Edinburgh botanist who specializes in leaf development, a large maple tree annually produces 46.5 m^2 (500 ft^2) of leaves, which weigh more than 113 kg (250 lb). The metabolic cost of producing so many leaves is high, but leaves are essential to the tree's survival.

Leaves gather the sunlight necessary for **photosynthesis,** the biological process that converts radiant energy into the chemical energy of carbohydrate molecules (see Chapter 8). Plants then use these molecules as starting materials to synthesize all other organic compounds (such as starch and cellulose, amino acids, lipids, and nucleic acids) and as fuel to provide energy for their metabolic processes. During a single summer, the leaves of the red maple shown here will "fix" about 454 kg (1000 lb) of carbon dioxide into sugars and other organic compounds.

Leaves are the main photosynthetic organs of most plants, and the structure of a leaf is superbly adapted for its primary function of photosynthesis (see Chapter 26 for a discussion of how leaves evolved). Most leaves are thin and flat, a shape that allows maximum absorption of light energy and the efficient internal diffusion of gases such as CO_2 and O_2. As a result of their ordered arrangement on the stem, leaves efficiently catch the sun's rays. The leaves of plants form an intricate green mosaic, bathed in sunlight and atmospheric gases.

Leaves possess several features that help reduce or control water loss, the most important of which is a thin, transparent layer of wax that covers the leaf surface. Structural adaptations are compromises between competing needs, and some features that optimize photosynthesis actually *promote* water loss. Plants have minute pores that allow an exchange of gases for photosynthesis, but these tiny openings also allow water to escape into the atmosphere as water vapor. Thus, leaf structure represents a tradeoff between photosynthesis and water conservation. ■

LEAF FORM AND STRUCTURE

Learning Objectives

1. Discuss variation in leaf form, including simple versus compound leaves, leaf arrangement on the stem, and venation patterns.
2. Describe the major tissues of the leaf (epidermis, photosynthetic ground tissue, xylem, and phloem), and label them on a diagram of a leaf cross section.
3. Compare leaf anatomy in dicots and monocots.
4. Relate leaf structure to its function of photosynthesis.

Foliage leaves are the most variable of plant organs, so much so that plant biologists developed specific terminology to describe their shapes, margins (edges), vein patterns, and the way they attach to stems. Because each leaf is characteristic of the species on which it grows, many plants can be identified by their leaves alone. Leaves may be round, needle-like, scalelike, cylindrical, heart-shaped, fan-shaped, or thin and narrow. They vary in size from those of the raffia palm (*Raphia ruffia*), whose leaves often grow more than 20 m (65 ft) long, to those of water-meal (*Wolffia*), whose leaves are so small that 16 of them laid end-to-end measure 2.5 cm (1 in) (see Fig. 31-1a).

The broad, flat portion of a leaf is the **blade;** the stalk that attaches the blade to the stem is the **petiole.** Some leaves also have **stipules,** which are leaflike outgrowths usually present in pairs at the base of the petiole (Fig. 32-1). Some leaves do not have petioles or stipules.

Leaves may be *simple* (having a single blade) or *compound* (having a blade divided into two or more leaflets) (Fig. 32-2a). Sometimes it is difficult to tell whether a plant has formed one compound leaf or a small stem bearing several simple leaves. One easy way to determine if a plant has simple or compound leaves is to look for axillary buds, so called because each develops in a leaf *axil* (the angle between the stem and petiole). Axillary buds form at the base of a leaf, whether it is simple or compound. However, axillary buds never develop at the base of leaflets. Also, the leaflets of a compound leaf lie in a single plane (you can lay a compound leaf flat on a table), whereas simple leaves usually are not arranged in one plane on a stem.

Leaves are arranged on a stem in one of three possible ways (Fig. 32-2b). Plants such as beeches and walnuts have an *alternate leaf arrangement,* with one leaf at each **node,** the area of the stem where one or more leaves are attached. In an *opposite leaf arrangement,* as occurs in maples and ashes, two leaves grow at each node. In a *whorled leaf arrangement,* as in catalpa trees, three or more leaves grow at each node.

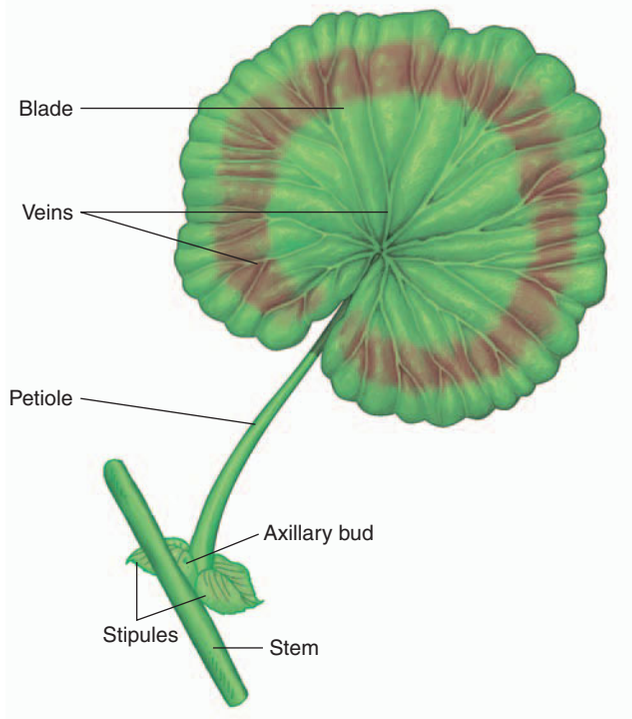

FIGURE **32-1** **Parts of a leaf.**
A geranium leaf consists of a blade, a petiole, and two stipules at the base of the leaf. Note the axillary bud in the leaf axil.

Leaf blades may possess *parallel venation,* in which the primary **veins**—strands of vascular tissue—run approximately parallel to one another (generally characteristic of monocots), or *netted venation,* in which veins are branched in such a way that they resemble a net (generally characteristic of dicots; Fig. 32-2c).[1] Netted veins can be *pinnately netted,* in which major veins branch off along the entire length of the **midvein** (main or central vein of a leaf), or *palmately netted,* in which several major veins radiate out from one point.

Leaf structure consists of an epidermis, photosynthetic ground tissue, and vascular tissue

The leaf is a complex organ composed of several tissues organized to optimize photosynthesis (Fig. 32-3). The leaf blade has upper and lower surfaces that are covered by an epidermal layer. The **upper epidermis** covers the upper surface, and the **lower epidermis** covers the lower surface. Most cells in these layers lack chloroplasts and are relatively transparent. One interesting

[1] Recall that flowering plants, the focus of this chapter, are divided into two groups, informally called *dicots* and *monocots* (see Chapter 27). Dicots include well-known plants such as beans, petunias, oaks, cherry trees, roses, and snapdragons; examples of monocots include corn, lilies, grasses, palms, tulips, orchids, and bananas.

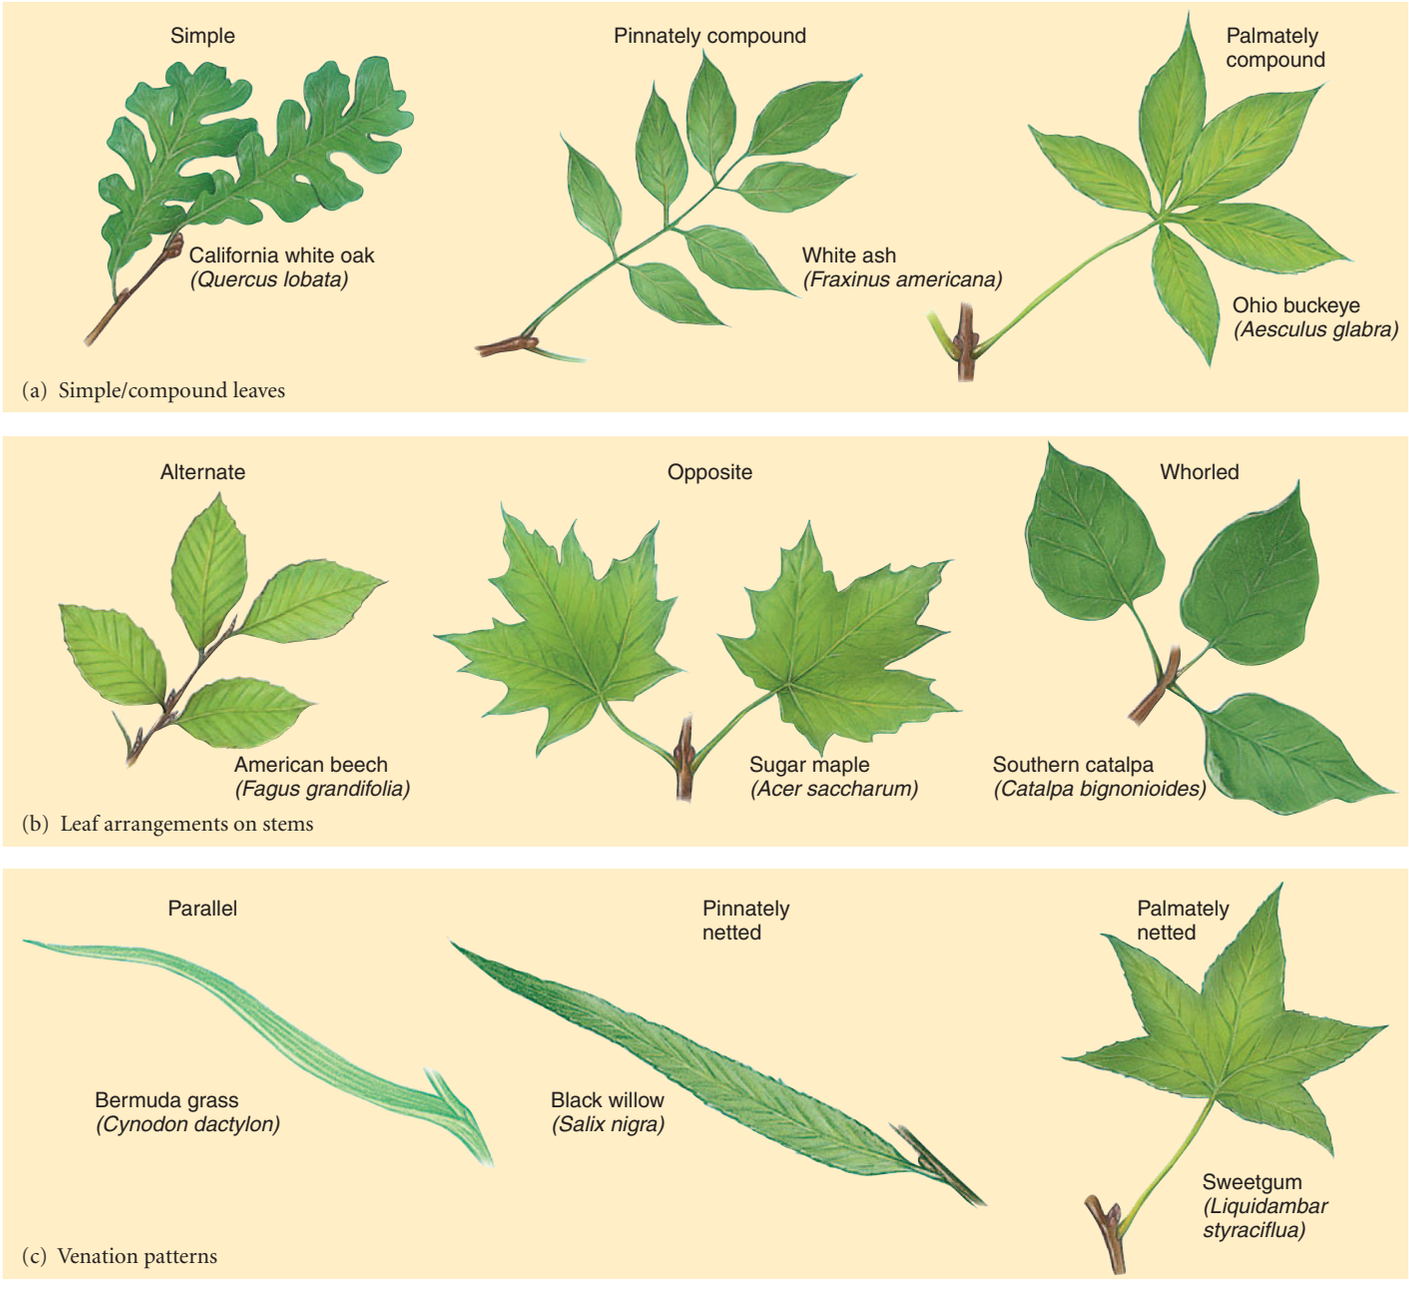

FIGURE **32-2** **Leaf morphology.**

(a) Simple, pinnately compound, and palmately compound leaves. **(b)** Leaf arrangement may be alternate, opposite, or whorled. **(c)** Venation patterns include parallel, pinnately netted, and palmately netted. feature of leaf epidermal cells is that the cell wall facing toward the outside environment is somewhat thicker than the cell wall facing inward. This extra thickness may provide the plant with additional protection against injury or water loss.

Because leaves have such a large surface area exposed to the atmosphere, water loss by evaporation from the leaf's surface is unavoidable. However, epidermal cells secrete a waxy layer, the **cuticle,** that reduces water loss from their exterior walls (see Table 31-4). The cuticle, which consists primarily of a waxy substance called **cutin,** varies in thickness in different plants, in part owing to environmental conditions. As one might expect, the leaves of plants adapted to hot, dry climates have extremely thick cuticles. Furthermore, a leaf's exposed (and warmer) upper epidermis generally has a thicker cuticle than its shaded (and cooler) lower epidermis.

The epidermis of many leaves is covered with various hair-like structures called **trichomes** (see Table 31-4). Some leaves, such as those of the popular cultivated plant called lamb's ear, have so many trichomes that they feel fuzzy (Fig. 32-4). Trichomes have several functions. Trichomes of some plants help

KEY CONCEPT: Leaves contain all three tissue systems found in plants: The dermal tissue system, represented by the upper and lower epidermis; the ground tissue system, represented by the mesophyll; and the vascular tissue system, represented by the xylem and phloem in the veins.

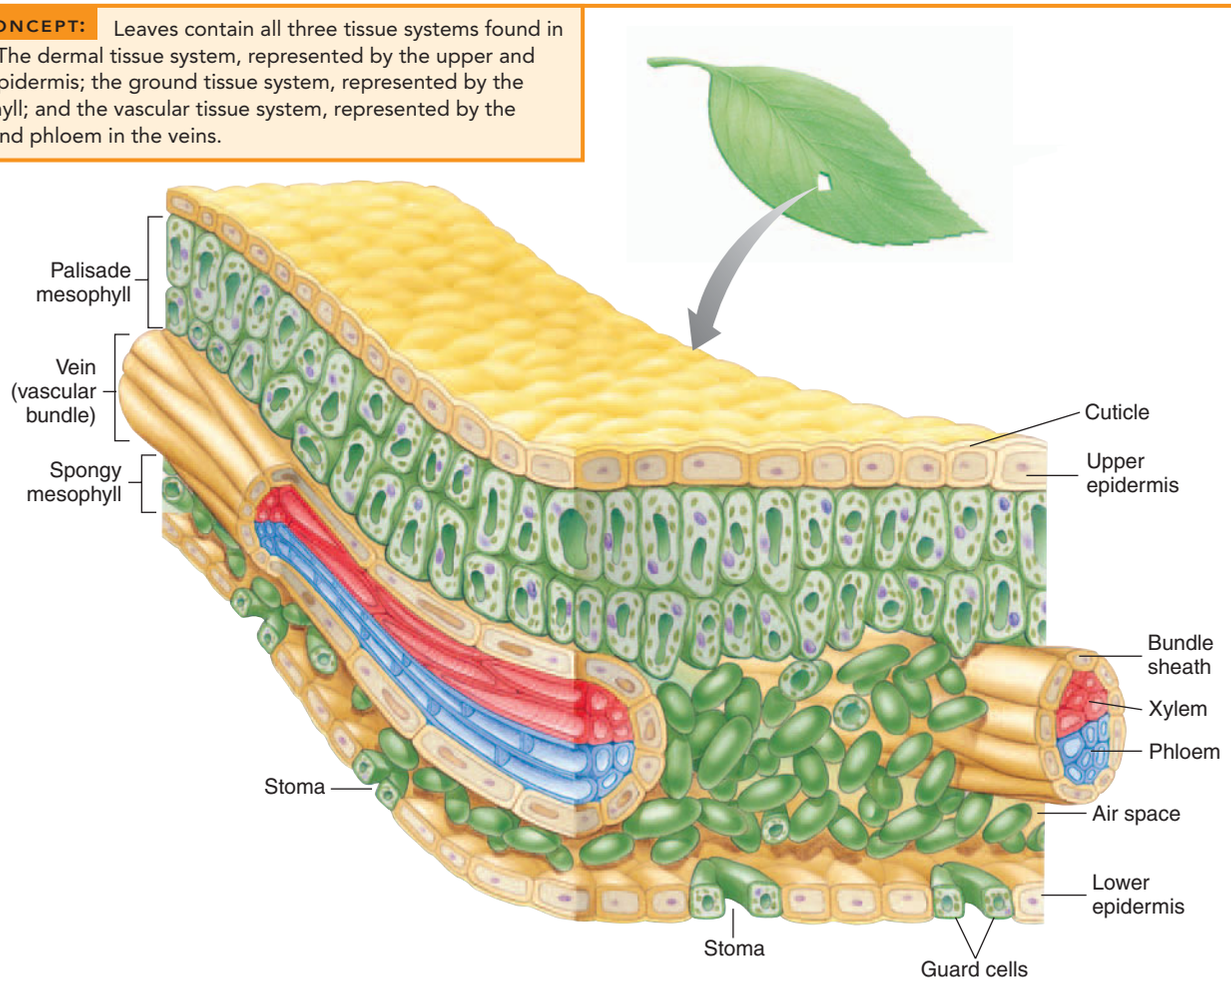

FIGURE **32-3** **Tissues in a typical leaf blade.**

An upper epidermis and lower epidermis cover the blade. The photosynthetic ground tissue, called *mesophyll*, is often arranged into palisade and spongy layers. Veins branch throughout the mesophyll.

reduce water loss from the leaf surface by retaining a layer of moist air next to the leaf and by reflecting sunlight, thereby protecting the plant from overheating. Some trichomes secrete stinging irritants for deterring **herbivores,** animals that feed on plants. In addition, a leaf covered with trichomes is difficult for an insect to walk over or eat. Other trichomes excrete excess salts absorbed from a salty soil.

The leaf epidermis contains minute openings, or **stomata** (sing., *stoma*), for gas exchange. Each stoma is flanked by two specialized epidermal **guard cells** (Fig. 32-5). The guard cells are responsible for opening and closing the stoma. Guard cells are usually the only epidermal cells with chloroplasts.

Stomata are especially numerous on the lower epidermis of horizontally oriented leaves (an average of about 100 stomata per mm^2), and in many species are located *only* on the lower surface. The lower epidermis of apple (*Malus sylvestris*) leaves, for example, has almost 400 stomata per mm^2, whereas the upper epidermis has none. This adaptation reduces water loss because stomata on the lower epidermis are shielded from direct sunlight and are therefore cooler than those on the upper epidermis. In

FIGURE **32-5** **Stoma.**

LM of an open stoma from the leaf epidermis of inch plant (*Zebrina pendula*). Note the chloroplasts present in the guard cells and the thicker inner wall of each guard cell.

contrast, floating leaves of aquatic plants such as water lilies have stomata only on the upper epidermis.

Guard cells are associated with special epidermal cells called **subsidiary cells** that are often structurally different from other epidermal cells. Subsidiary cells provide a reservoir of water and ions that move into and out of the guard cells as they change shape during stomatal opening and closing (discussed later in this chapter).

The photosynthetic ground tissue of the leaf, called the **mesophyll** (from the Greek *meso,* "the middle of," and *phyll,* "leaf"), is sandwiched between the upper epidermis and the lower epidermis. Mesophyll cells, which are parenchyma cells (see Chapter 31) packed with chloroplasts, are loosely arranged, with many air spaces between them that facilitate gas exchange. These intercellular air spaces account for as much as 70% of the leaf's volume.

In many plants, the mesophyll is divided into two sublayers. Toward the upper epidermis, the columnar cells are stacked closely together in a layer called **palisade mesophyll.** In the lower portion, the cells are more loosely and irregularly arranged, in a layer called **spongy mesophyll.** The two layers have different functions. Palisade mesophyll is the main site of photosynthesis in the leaf. Photosynthesis also occurs in the spongy mesophyll, but the primary function of the spongy mesophyll is to allow diffusion of gases, particularly CO_2, within the leaf.

Palisade mesophyll may be further organized into one, two, three, or even more layers of cells. The presence of additional layers of palisade mesophyll is at least partly an adaptation to environmental conditions. Leaves exposed to direct sunlight contain more layers of palisade mesophyll than do shaded leaves on the same plant. In direct sunlight, the light is strong enough to effectively penetrate multiple layers of palisade mesophyll, allowing all layers to photosynthesize efficiently.

The veins, or **vascular bundles,** of a leaf extend through the mesophyll. Branching is extensive, and no mesophyll cell is more than two or three cells away from a vein. Therefore, the slow process of diffusion does not limit the movement of needed resources between mesophyll cells and veins. Each vein contains two types of vascular tissue: xylem and phloem (see Chapter 31). **Xylem,** which conducts water and dissolved nutrient minerals, is usually located in the upper part of a vein, toward the upper epidermis, whereas **phloem,** which conducts dissolved sugars, is usually confined to the lower part of a vein.

One or more layers of nonvascular cells surround the larger veins and make up the **bundle sheath.** Bundle sheaths are composed of parenchyma or sclerenchyma cells (see Chapter 31). Frequently the bundle sheath has support columns, called **bundle sheath extensions,** that extend through the mesophyll from the upper epidermis to the lower epidermis (Fig. 32-6). Bundle sheath

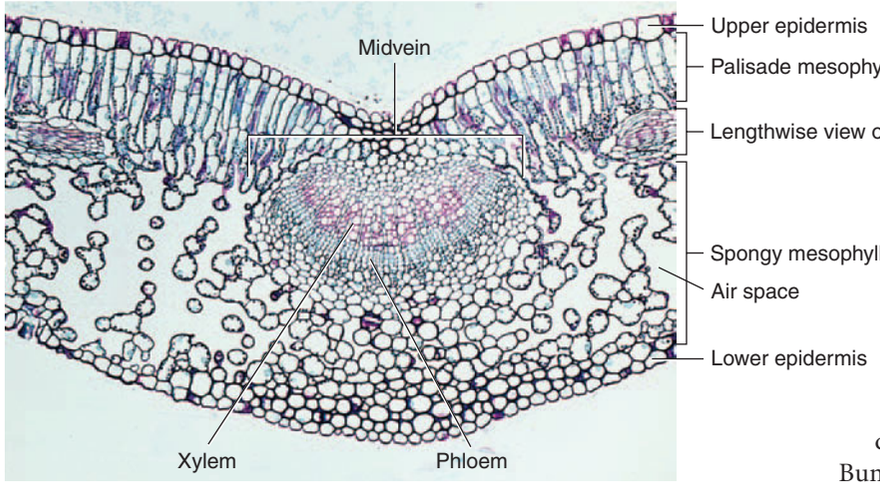
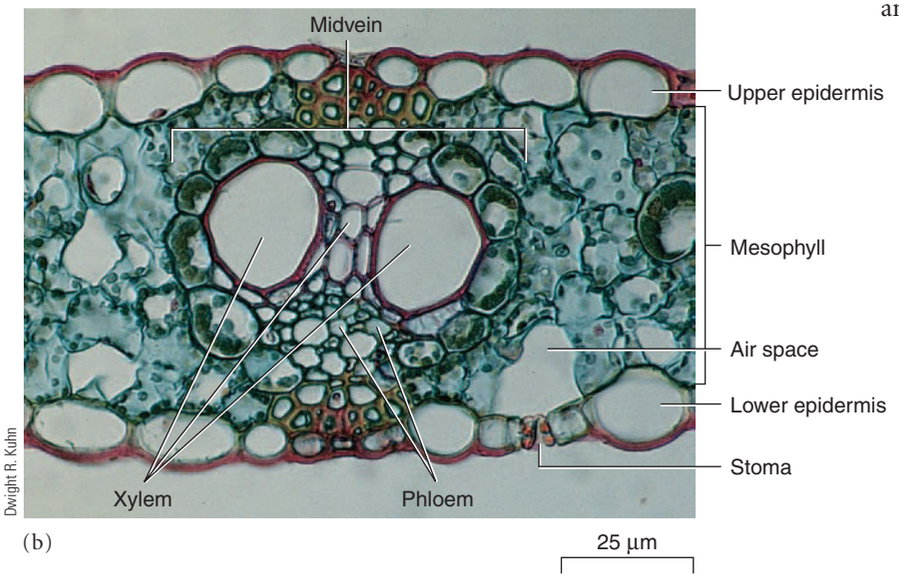
extensions may be composed of parenchyma, collenchyma, or sclerenchyma cells.

Leaf structure differs in dicots and monocots

A dicot leaf is usually composed of a broad, flattened blade and a petiole. As mentioned previously, dicot leaves typically have netted venation. In contrast, monocot leaves often lack a petiole; they are narrow and the base of the leaf often wraps around the stem, forming a sheath. Parallel venation is characteristic of monocot leaves.

Dicots and certain monocots also differ in internal leaf anatomy (Fig. 32-7). Although most dicots and monocots have both palisade and spongy layers, some monocots (corn and other grasses) do not have mesophyll differentiated into distinct palisade and spongy layers. Because dicots have netted veins, a cross section of a dicot blade often shows veins in both cross-sectional and lengthwise views. In a cross section of a monocot leaf, in contrast, the parallel venation pattern produces evenly spaced veins, all of which appear in cross section.





Differences between the guard cells in dicot and certain monocot leaves also occur (Fig. 32-8). The guard cells of dicots and many monocots are shaped like kidney beans. Other monocot leaves (those of grasses, reeds, and sedges) have guard cells shaped like dumbbells. These structural differences affect how the cells swell or shrink to open or close the stoma.

Leaf structure is related to function

How is leaf structure related to its primary function of photosynthesis? The epidermis of a leaf is relatively transparent and allows light to penetrate to the interior of the leaf where the photosynthetic ground tissue, the mesophyll, is located. Stomata, which dot the leaf surfaces, permit the exchange of gases between the atmosphere and the leaf's internal tissues. Carbon dioxide, a raw material of photosynthesis, diffuses into the leaf through stomata, and the oxygen produced during photosynthesis diffuses rapidly out of the leaf through stomata. Stomata also permit other gases, including air pollutants, to enter the leaf (see *Focus On: Air Pollution and Leaves*).

Water required for photosynthesis is obtained from the soil and transported in the xylem to the leaf, where it diffuses into the mesophyll and moistens the surfaces of mesophyll cells. The loose arrangement of the mesophyll cells, with air spaces between cells, allows for rapid diffusion of carbon dioxide to the mesophyll cell surfaces; there it dissolves in a film of water before diffusing into the cells.

The veins not only supply the photosynthetic ground tissue with water and minerals (from the roots, by way of the xylem) but also carry (in the phloem) dissolved sugar produced during photosynthesis to all parts of the plant. Bundle sheaths and bundle sheath extensions associated with the veins provide additional support to prevent the leaf, which is structurally weak because of the large amount of air space in the mesophyll, from collapsing under its own weight.

Leaves are adapted to help a plant survive in its environment

Leaf structure reflects the environment to which a particular plant is adapted. Although

both aquatic plants and those adapted to dry conditions perform photosynthesis and have the same basic leaf anatomy, their leaves are modified to enable them to survive different environmental conditions. The leaves of water lilies have petioles long enough to allow the blade to float on the water's surface. Large air spaces in the mesophyll make the floating blade buoyant. The petioles and other submerged parts have an internal system of air ducts; oxygen moves through these ducts from the floating leaves to the underwater roots and stems, which live in a poorly aerated environment.

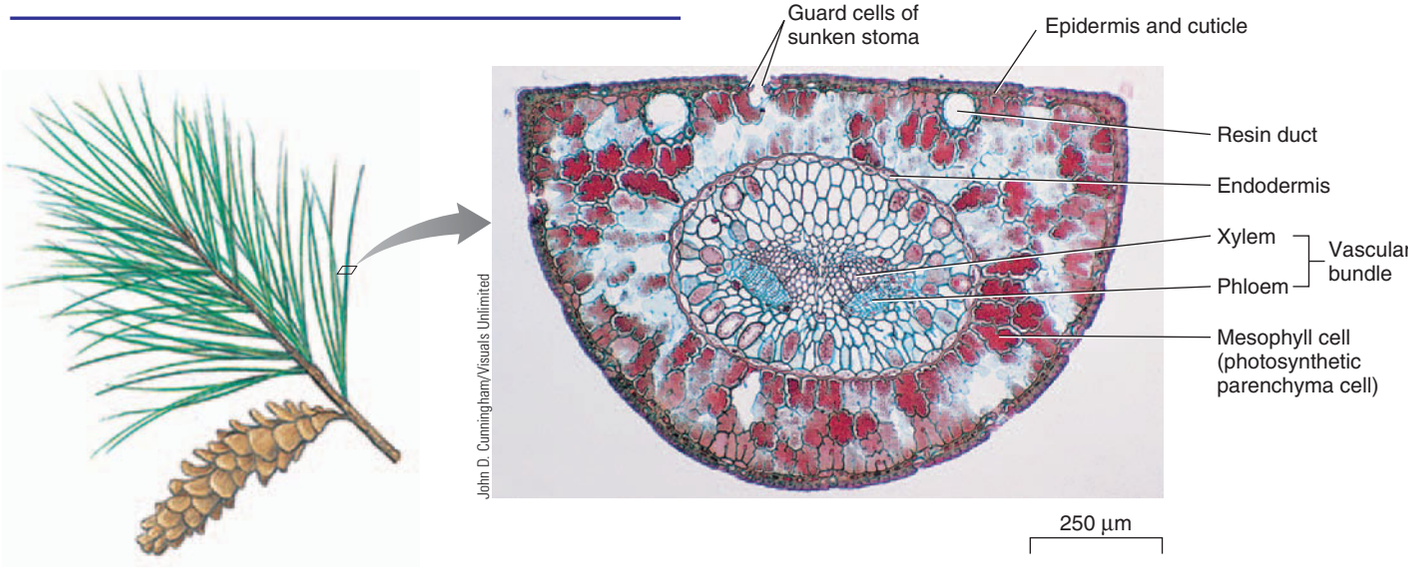
Conifers are an important group of woody trees and shrubs that includes pine, spruce, fir, redwood, and cedar.[2] Most conifers are evergreen, which means they produce and lose leaves throughout the year rather than during certain seasons. Conifers dominate a large portion of Earth's land area, particularly in northern forests and mountains. The leaves of most conifers are waxy needles. Their needles have structural adaptations that help them survive winter, the driest part of the year. (Winter is arid even in areas of heavy snows because roots cannot absorb water from soil when the soil temperature is very low.) Indeed, many of the structural features of needles are also found in many desert plants.

[2] As discussed in Chapter 27, conifers are gymnosperms, one of the two groups of seed plants (the other group is the flowering plants, or angiosperms). Unlike flowering plants, whose seeds are enclosed in fruits, conifers bear "naked" seeds on the scales of female cones.

Figure 32-9 shows a cross section of a pine needle. Note that the needle is somewhat thickened rather than thin and blade-like. The needle's relative thickness, which results in less surface area exposed to the air, reduces water loss. Other features that help conserve water include the thick, waxy cuticle and sunken stomata; these permit gas exchange while minimizing water loss. Thus needles help conifers tolerate the dry (low relative humid-

FIGURE 32-9 LM of a pine needle in cross section.

The thick, waxy cuticle and sunken stomata are two structural adaptations that enable pine (*Pinus*) to retain its needles throughout the winter.



Focus On Air Pollution and Leaves

The air we breathe is often dirty and contaminated with many pollutants, particularly in urban areas. Air pollution consists of gases, liquids, or solids present in the atmosphere in levels high enough to harm humans and other organisms as well as nonliving materials. Although air pollutants can come from natural sources, as, for example, a lightning-caused fire or a volcanic eruption, human activities are a major cause of global air pollution. Motor vehicles and industry are the two main human sources of air pollution.

All parts of a plant can be damaged by air pollution, but leaves are particularly susceptible because of their structure and function. The thin blade provides a large surface area that comes into contact with the surrounding air. The thousands of stomatal pores that dot the epidermis and allow gas exchange with the atmosphere also permit pollutants to diffuse into the leaf. Just as lungs, the organs of gas exchange in humans and other terrestrial vertebrates are affected by air pollution, so too the leaves of a plant are most affected.

Many studies have shown that high levels of most forms of air pollution reduce the overall productivity of crop plants. The worst pollutant in terms of yield loss is ozone, a toxic gas produced when sunlight catalyzes a reaction between pollutants emitted by motor vehicles and industries. Ozone has been observed to reduce soybean yields by as much as 35%, and the average yield reduction from exposure to ozone is 15%. Ozone inhibits photosynthesis because it damages the mesophyll cells, probably by altering the permeability of their cell membranes. Exposure to low levels of air pollution often causes a decline in photosynthesis without other symptoms of injury. Lesions on leaves and other obvious symptoms appear at much higher levels of air pollution.

When air pollution is combined with other environmental stressors (such as low winter temperatures, prolonged droughts, insects, and bacterial, fungal, and viral diseases), it causes plants to decline and die. More than half of the red spruce trees in the mountains of the northeastern United States have died since the mid-1970s, and sugar maples in eastern Canada and the United States are also dying. Many still-living trees are exhibiting symptoms of **forest decline,** characterized by gradual deterioration and eventual death of trees. The general symptoms of forest decline are reduced vigor and growth, but some plants exhibit specific symptoms, such as yellowing of needles in conifers. Forest decline is more pronounced at higher elevations, possibly because most trees growing at high elevations are at the limit of their normal range and are therefore more susceptible to wind and low temperatures.

Many factors can interact to decrease the health of trees, and no single factor accounts for the recent instances of forest decline. Several air pollutants have been implicated, including acid rain, ozone, and toxic heavy metals such as lead, cadmium, and copper. Power plants, ore smelters, refineries, and motor vehicles produce these pollutants. Insects and weather factors such as drought and severe winters may also be important. To complicate matters further, the actual causes of forest decline may vary from one tree species to another and from one location to another. Thus forest decline appears to result from the combination of multiple stressors. When one or more stressors weaken a tree, then an additional stressor may be enough to cause its death.

ity) winds that occur during winter. With the warming of spring, soil water again becomes available, and the needles quickly resume photosynthesis.

Review

- Sketch two shoots, one with simple leaves, palmate venation, and alternate leaf arrangement; and the second with palmately compound leaves, pinnate venation, and opposite leaf arrangement.

STOMATAL OPENING AND CLOSING

Learning Objectives

5 Explain the role of blue light in the opening of stomata.

6 Outline the physiological changes that accompany stomatal opening and closing.

Stomata are adjustable pores that are usually open during the day when carbon dioxide is required for photosynthesis and closed at night when photosynthesis is shut down (see the section on CAM photosynthesis in Chapter 8 for an interesting exception). The opening and closing of stomata are controlled by changes in the shape of the two guard cells that surround each pore. When water moves into guard cells from surrounding cells, they become turgid (swollen) and bend, producing a pore. When water leaves the guard cells, they become flaccid (limp) and collapse against one another, closing the pore. What causes water to move into and out of guard cells?

Blue light triggers stomatal opening

Data from numerous experiments and observations are beginning to explain the complexities of stomatal movements. Let us begin with stomatal opening, which occurs when the plant detects light from the rising sun. You already know that light is a form of energy; plants absorb light and convert it to chemical energy in the process of photosynthesis. However, light is also an important *environmental signal* for plants—that is, light provides plants with information about their environment that they use to modify various activities at the molecular and cellular levels.

In stomatal opening and several other plant responses, **blue light,** which has wavelengths from 400 to 500 nm, is an environmental signal. Any plant response to light must involve a **pigment,** a molecule that absorbs the light before the induction of a particular biological response. Data such as the responses of stomata to different colors of light suggest the pigment involved in stomatal opening and closing is yellow (yellow pigments strongly absorb blue light). The yellow pigment is thought to be located in the guard cells, probably in their plasma membranes.

In step ① of Figure 32-10, blue light, which is a component of sunlight, triggers the activation of an enzyme, **ATP synthase,** located in the guard cell plasma membrane. Blue light also triggers the synthesis of malic acid and the **hydrolysis** (splitting) of starch, about which we say more shortly.

In step ② ATP synthase actively pumps protons (H^+) out of the guard cells. The H^+ that are pumped are formed when malic acid produced in the guard cells ionizes to form H^+ and negatively charged malate ions. The enzyme ATP synthase may be familiar to you, because ATP synthase is also involved in pumping protons in mitochondria (for aerobic respiration; see Chapter 7) and in chloroplasts (for photosynthesis; see Chapter 8). As ATP synthase in guard cells pumps protons out of the guard cell plasma membranes, an **electrochemical gradient**—that is, a charge and concentration difference—forms on the two sides of the guard cell plasma membrane.

In step ③ the resulting electrochemical gradient of H^+ drives the facilitated diffusion of large numbers of potassium ions *into* guard cells. This movement occurs through **voltage-activated potassium channels,** which open when a certain voltage (difference in charge between the two sides of the guard cell plasma membrane) is attained. This movement of potassium ions has been experimentally measured by **patch clamp techniques** (see Figure 5-16). (Interestingly, in animals, voltage-activated ion channels are found in the plasma membranes of nerve cells and are involved in transmitting neural impulses; see Chapter 39.) As shown in step ④, chloride ions are also taken into the guard cells through ion channels in the guard cell plasma membrane. The negatively charged chloride and malate ions help to electrically balance the positively charged potassium ions.

The potassium, chloride, and malate ions accumulate in the vacuoles of the guard cells, increasing the solute concentration in the vacuoles. You may recall from the discussion of osmosis in Chapter 5 that when a cell has a solute concentration greater than that of surrounding cells, water flows *into* the cell. Thus in step ⑤, water enters the guard cells from surrounding epidermal cells by osmosis. The increased turgidity of the guard cells changes their shape, because the thickened inner cell walls do not expand as much as the outer walls, causing the stoma to open.

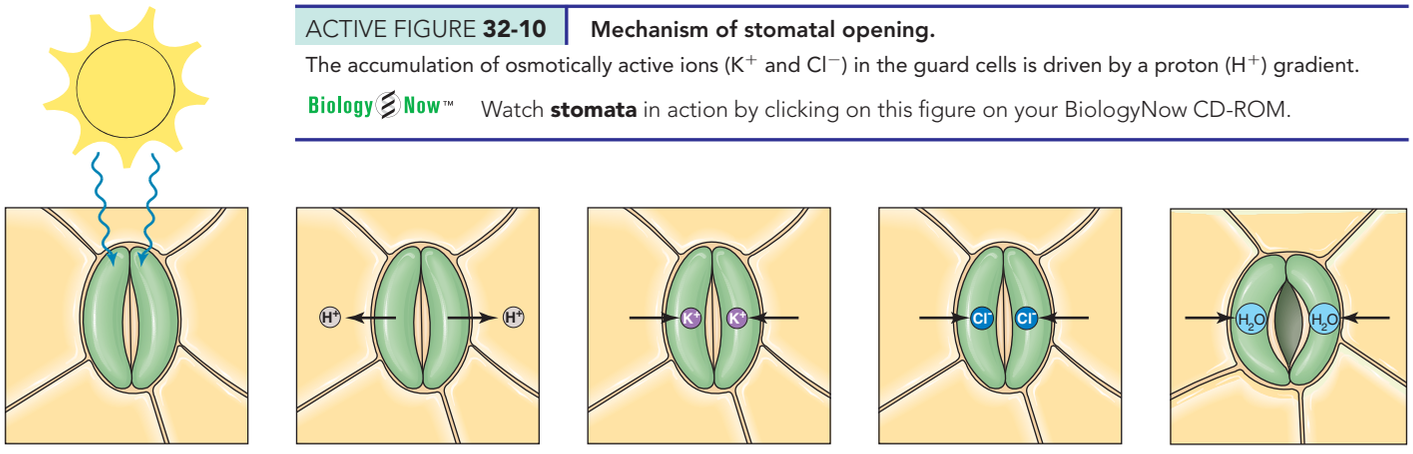
Blue light activates ATP synthase ⟶ proton pump moves H^+ out of guard cells ⟶ K^+ and Cl^- move into guard cells through voltage-activated ion channels ⟶ water diffuses by osmosis into guard cells ⟶ guard cells change shape and stoma opens

In the late afternoon or early evening, stomata close, but not by an exact reversal of the opening process. Recent studies have demonstrated that the concentration of potassium ions in guard cells slowly decreases during the day. However, the guard-cell concentration of sucrose, another osmotically active substance, increases during the day—maintaining the open pore—and then

ACTIVE FIGURE **32-10** **Mechanism of stomatal opening.**

The accumulation of osmotically active ions (K^+ and Cl^-) in the guard cells is driven by a proton (H^+) gradient.

BiologyNow™ Watch **stomata** in action by clicking on this figure on your BiologyNow CD-ROM.



① Blue light activates ATP synthase.

② Protons are pumped out of guard cells, forming electrochemical gradient.

③ Potassium ions enter guard cells through voltage-activated ion channels.

④ Chloride ions also enter guard cells through ion channels.

⑤ Water enters guard cells by osmosis, and stoma opens.

slowly decreases as evening approaches. This sucrose comes from the hydrolysis of the polysaccharide, starch, which is stored in the guard cell chloroplasts. As evening approaches, the sucrose concentration in the guard cells declines as sucrose is converted back to starch (which is osmotically inactive), water leaves by osmosis, the guard cells lose their turgidity, and the pore closes.

To summarize, different mechanisms appear to regulate the opening and closing of stomata. The uptake of potassium and chloride ions is mainly associated with stomatal opening, and the declining concentration of sucrose is mainly associated with stomatal closing. In Chapter 36, we discuss other blue light responses in plants.

Other factors also affect stomatal opening and closing

Although light and darkness trigger the opening and closing of stomata, other environmental factors are also involved, including carbon dioxide concentration. A low concentration of CO_2 in the leaf induces stomata to open even in the dark. The effects of light and CO_2 concentration on stomatal opening are interrelated. Photosynthesis, which occurs in the presence of light, reduces the internal concentration of CO_2 in the leaf, triggering stomatal opening. Another environmental factor that affects stomatal opening and closing is dehydration (water stress). During a prolonged drought, stomata remain closed even during the day. Stomatal opening and closing are under hormonal control, particularly by the plant hormone *abscisic acid* (see Chapter 36).

The opening and closing of stomata also appear to be regulated by an internal biological clock that in some way measures time. For example, after plants are placed in continual darkness, their stomata continue to open and close at more or less the same time each day. Such biological rhythms that follow an approximate 24-hour cycle are known as **circadian rhythms.** Other examples of circadian rhythms are provided in Chapter 36.

Review

TRANSPIRATION AND GUTTATION

Learning Objectives

7 Discuss transpiration and its effects on plants.
8 Distinguish between transpiration and guttation.

Despite leaf adaptations such as the cuticle, approximately 99% of the water that a plant absorbs from the soil is lost by evaporation from the leaves and, to a lesser extent, the stems. Loss of water vapor by evaporation from aerial plant parts is called **transpiration.**

The cuticle is extremely effective in reducing water loss by transpiration. It is estimated that only 1% to 3% of the water lost from a plant passes directly through the cuticle. Most transpiration occurs through open stomata. The numerous stomatal pores that are so effective in gas exchange for photosynthesis also provide openings through which water vapor escapes. In addition, the loose arrangement of the spongy mesophyll cells provides a large surface area within the leaf from which water can evaporate.

Several environmental factors influence the rate of transpiration. More water is lost from plant surfaces at higher temperatures. Light increases the transpiration rate, in part because it triggers stomatal opening and in part because it increases the leaf's temperature. Wind and dry air increase transpiration, but humid air *decreases* transpiration because the air is already saturated, or nearly so, with water vapor.

Although transpiration may seem wasteful, particularly to farmers in arid lands, it is an essential process that has adaptive value. Transpiration is responsible for water movement in plants, and without it water would not reach the leaves from the soil (see Chapter 33, discussion of the tension-cohesion model). The large amount of water that plants lose by transpiration may provide some additional benefits. Transpiration, like sweating in humans, cools the leaves and stems. When water passes from a liquid state to a vapor, it absorbs a great deal of heat. When the water molecules leave the plant as water vapor, they carry this heat with them. Thus the cooling effect of transpiration may prevent the plant from overheating, particularly in direct sunlight.

A second benefit of transpiration is that it distributes essential minerals throughout the plant. The water a plant transpires is initially absorbed from the soil, where it is present, not as pure water, but as a dilute solution of dissolved mineral salts. The water and dissolved nutrient minerals are then transported in the xylem throughout the plant, including its leaves. Water moves from the plant to the atmosphere during transpiration, but minerals remain in plant tissues. Many of these minerals are required for the plant's growth. It has been suggested that transpiration enables a plant to take in sufficient water to provide enough essential minerals, and that plants cannot satisfy their mineral requirements if the transpiration rate is not high enough.

There is no doubt, however, that under certain circumstances excessive transpiration can be harmful to a plant. On hot summer days, plants frequently lose more water by transpiration than they can take in from the soil. Their cells experience a loss of turgor, and the plant wilts (Fig. 32-11). If a plant is able to recover overnight, because of the combination of negligible transpiration (recall that stomata are closed) and absorption of water from the soil, the plant is said to have experienced *temporary wilting.* Most plants recover from temporary wilting with no ill effects. In cases of prolonged drought, however, the soil may not contain sufficient moisture to permit recovery from wilting. A plant that cannot recover is said to be *permanently wilted* and will die.

Transpiration is an important part of the **hydrologic cycle** (see Chapter 53), in which water cycles from the ocean and land to the atmosphere, and then back to the ocean and land. As a result of transpiration, water evaporates from leaves and stems to form clouds in the atmosphere. Thus, transpiration eventu-

FIGURE 32-11 Temporary wilting.

Shown are the same squash (*Cucurbita pepo*) leaves **(a)** in the late afternoon of a hot day, after the leaves have wilted owing to water loss, and **(b)** the following morning, after water in the leaves has been replenished from the soil. Note that wilting helps reduce the surface area from which transpiration occurs. During the night while transpiration is negligible, the plants recover by absorbing water from the soil.

FIGURE 32-12 Guttation.

Shown is a compound leaf of strawberry (*Fragaria*). Many people mistake guttation for early morning dew.

Ed Reschke/Peter Arnold, Inc.

ally results in precipitation. As you might expect, forest trees release substantial amounts of moisture into the air by transpiration. Researchers have determined that at least half the rain that falls in the Amazon rainforest basin is recycled again and again by transpiration and precipitation.

Some plants exude liquid water

Many leaves have special structures through which liquid water is literally forced out. This loss of liquid water, known as **guttation,** occurs when transpiration is negligible and available soil moisture is high. Guttation typically occurs at night because the stomata are closed, but water continues to move into the roots by osmosis. People sometimes think erroneously that the early morning water droplets on leaf margins are dew rather than guttation (Fig. 32-12). Unlike dew, which condenses from cool night air, guttation droplets come from within the plant. (The mechanism for guttation is discussed in Chapter 33.)

Review

- What is transpiration? How is leaf structure related to transpiration?
- How do environmental factors (sunlight, temperature, humidity, and wind) influence the rate of transpiration?
- How does guttation differ from transpiration?

BiologyNow™ Assess your understanding of **transpiration and guttation** by taking the pretest on your BiologyNow CD-ROM.

LEAF ABSCISSION

Learning Objective

9 Define leaf *abscission,* explain why it occurs, and describe the physiological and anatomical changes that precede it.

All trees shed leaves. Many conifers shed their needles in small numbers year-round. The leaves of deciduous plants turn color and **abscise,** or fall off, once a year—as winter approaches in temperate climates or at the beginning of the dry period in tropical climates with pronounced wet and dry seasons. In temperate forests, most woody plants with broad leaves shed their leaves to survive the low temperatures of winter. During winter, the plant's metabolism, including its photosynthetic machinery, slows down or halts temporarily.

Another reason for abscission is related to a plant's water requirements, which become critical during the physiological drought of winter. As mentioned previously, as the ground chills, absorption of water by the roots is inhibited. When the ground freezes, *no* absorption occurs. If the broad leaves were to stay on the plant during the winter, the plant would continue to lose water by transpiration but would be unable to replace it with water absorbed from the soil.

Leaf abscission is a complex process that involves many physiological changes, all initiated and orchestrated by changing levels of plant hormones, particularly **ethylene** (see Chapter 36). Briefly, the process is this: As autumn approaches, sugars, amino acids, and many essential minerals (such as nitrogen, phosphorus, and possibly potassium) are mobilized and transported from the leaves to other plant parts. Chlorophyll breaks down, allowing the **carotenoids** (orange carotenes and yellow xanthophylls), some of the accessory pigments in the chloroplasts of leaf cells, to become evident (see Fig. 3-14b). Recall from Chapter 8 that accessory pigments are always present in the leaf but are masked by the green of the chlorophyll. In addition, red water-soluble pigments called **anthocyanins** may accumulate in the vacuoles of epidermal leaf cells in some species; anthocyanins may protect leaves against damage by ultraviolet radiation. The various combinations of carotenoids and anthocyanins are responsible for the brilliant colors found in autumn landscapes in temperate climates.

In many leaves, abscission occurs at an abscission zone near the base of the petiole

The area where a petiole detaches from the stem is a structurally distinct area called the **abscission zone.** Composed primarily of thin-walled parenchyma cells, it is anatomically weak because it contains few fibers (Fig. 32-13). A protective layer of cork cells develops on the stem side of the abscission zone. These cells have a waxy, waterproof material impregnated in their walls. Enzymes then dissolve the **middle lamella** (the "cement" that holds the primary cell walls of adjacent cells together) in the abscission zone (see Fig. 4-28). Once this process is completed, nothing holds the leaf to the stem but a few xylem cells. A sudden breeze is enough to make the final break, and the leaf detaches. The protective layer of cork remains, sealing off the area and forming a leaf scar.

Although the structure of abscission zones and the physiological changes associated with abscission are well known, the genes responsible for the development of an abscission zone have been investigated only recently. In 2000, researchers from Clemson University and the University of Iowa reported in the journal *Nature* that they had isolated a gene involved in the development of an abscission zone on tomato flowers and fruits. (Like leaves, flowers and fruits have abscission zones and are also shed.) Tomato plants with a mutated version of the gene did not develop normal abscission zones on their flower stalks.

Review

- Why do many woody plants living in temperate zones lose their leaves in autumn?
- What physiological changes occur during leaf abscission?
- What is the abscission zone?

BiologyNow™ Assess your understanding of **leaf abscission** by taking the pretest on your BiologyNow CD-ROM.

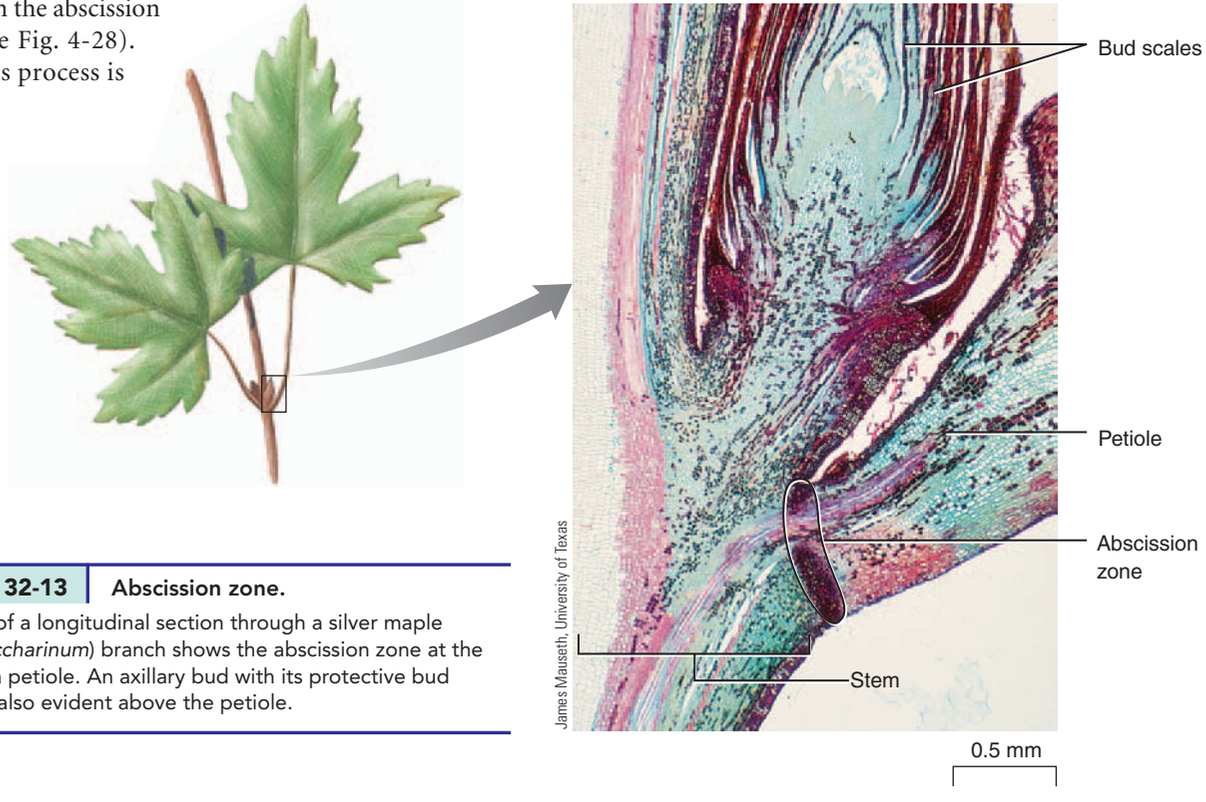

FIGURE **32-13** **Abscission zone.**
This LM of a longitudinal section through a silver maple (*Acer saccharinum*) branch shows the abscission zone at the base of a petiole. An axillary bud with its protective bud scales is also evident above the petiole.

MODIFIED LEAVES

Learning Objective

10 List at least four examples of modified leaves, and give the function of each.

Although photosynthesis is the main function of leaves, certain leaves have special modifications for other functions. Some plants have leaves specialized for deterring herbivores. **Spines,** modified leaves that are hard and pointed, are found on many desert plants such as cacti (Fig. 32-14a). In the cactus, the main organ of photosynthesis is the stem rather than the leaf. Spines discourage animals from eating the succulent stem tissue.

Vines are climbing plants whose stems cannot support their own weight, so they often possess **tendrils** that help keep the vine attached to the structure on which it is growing. The tendrils of many vines, such as peas, cucumbers, and squash, are specialized leaves (Fig. 32-14b). However, some tendrils, such as those of ivy, Virginia creeper, and grape, are specialized stems.

The winter buds of a dormant woody plant are covered by **bud scales,** modified leaves that protect the delicate meristematic tissue of the bud from injury, freezing, or drying out (Fig. 32-14c).

Leaves may also be modified for storage of water or food. For example, a **bulb** is a short underground stem to which large, fleshy leaves are attached (Fig. 32-14d). Onions and tulips form bulbs. Many plants adapted to arid conditions, such as jade

(a) The leaves of this pincushion cactus (*Mammilaria*) are modified as spines for deterring herbivores. Photographed in Arizona. **(b)** Tendrils of bur cucumber (*Echinocystis lobata*) are modified leaves. Tendrils, which wind around objects and aid vines in climbing, may be modified leaves or stems. **(c)** A terminal bud and two axillary buds of a maple (*Acer*) twig have overlapping bud scales to protect buds. **(d)** The leaves of bulbs such as the onion (*Allium cepa*) are fleshy for storage of food materials and water. **(e)** Some plants have thick, succulent leaves modified for water storage as well as photosynthesis. The succulent leaves of the string-of-beads plant (*Senecio rowleyanus*) are spherical to minimize surface area, thereby conserving water.

plant, medicinal aloe, and string-of-beads, have succulent leaves for water storage (Fig. 32-14e). These leaves are usually green and also function in photosynthesis.

Some leaves are modified for sexual reproduction (see discussion of flower evolution in Chapter 27, including Fig. 27-13) or asexual reproduction (see Fig. 35-17).

Modified leaves of insectivorous plants capture insects

Insectivorous plants are plants that capture insects. Most insectivorous plants grow in poor soil that is deficient in certain essential minerals, particularly nitrogen. These plants meet some of their mineral requirements by digesting insects and other small animals. The leaves of insectivorous plants are adapted to attract, capture, and digest their animal prey.

Some insectivorous plants have passive traps. The leaves of a pitcher plant, for example, are shaped so that rainwater collects and forms a reservoir that also contains acid secreted by the plant (Fig. 32-15). Some pitchers are quite large; in the tropics pitcher plants may be large enough to hold 1 L (approximately 1 qt) or more of liquid. An insect attracted by the odor or nectar of the pitcher may lean over the edge and fall in. Although it may make repeated attempts to escape, the insect is prevented from crawling out by the slippery sides and the rows of stiff hairs that point downward around the lip of the pitcher. The insect eventually drowns, and part of its body eventually disintegrates and is absorbed.

Although most insects are killed in pitcher plants, the larvae of several insects (certain fly, midge, and mosquito species), as well as a large community of microorganisms, actually live inside the pitchers. These insect species obtain their food from the insect carcasses, and the pitcher plant digests what remains. It is not known how these insects survive the acidic environment inside the pitcher.

The Venus flytrap is an insectivorous plant with active traps. Its leaf blades resemble tiny bear traps (see Fig. 1-3). Each side of the leaf blade contains three small, stiff hairs. If an insect alights and brushes against two of the hairs, or against the same hair twice in quick succession, the trap springs shut with amazing rapidity. The spines along the margins of the blades fit closely together to prevent the insect from escaping. Digestive glands on the surface of the trap secrete enzymes in response to the insect pressing against them. After the insect has died and been digested, the trap reopens and the indigestible remains fall out.

Bill Lea/Dembinsky Photo Associates

FIGURE **32-15** **A common pitcher plant.**
This species (*Sarracenia purpurea*), whose pitchers grow to 30.5 cm (12 in), is widely distributed in acidic bogs and marshes in eastern North America. Young pitchers are green but turn red as they age. Note the dead beetle in the "pitcher."

Review

- What are the primary functions of each of the following modified leaves: spines, tendrils, and bud scales?
- What are the functions of bulbs? Of succulent leaves?
- What are some of the specialized features of the leaves of insectivorous plants?

BiologyNow™ Assess your understanding of **modified leaves** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Discuss variation in leaf form, including simple versus compound leaves, leaf arrangement on the stem, and venation patterns.

- Leaves typically consist of a broad, flat **blade** and a stalklike **petiole.** Some leaves also have small, leaflike outgrowths from the base called **stipules.**
- Leaves may be simple (having a single blade) or compound (having a blade divided into two or more leaflets).
- Leaf arrangement on a stem may be alternate (one leaf at each **node**), opposite (two leaves at each node), or whorled (three or more leaves at each node).
- Leaves may have parallel or netted venation. Netted venation may be pinnately netted, with several major veins radiating from one point, or palmately netted, with veins branching along the entire length of the midvein.

2 Describe the major tissues of the leaf (epidermis, photosynthetic ground tissue, xylem, and phloem), and label them on a diagram of a leaf cross section.

- Upper and lower surfaces of the leaf blade are covered by an **epidermis.** A waxy **cuticle** coats the epidermis, enabling the plant to survive the dry conditions of a terrestrial existence.

SUMMARY WITH KEY TERMS *(continued)*

- **Stomata** are small pores in the epidermis that permit gas exchange needed for photosynthesis. Each pore is surrounded by two **guard cells** that are often associated with special epidermal cells called **subsidiary cells.** Subsidiary cells provide a reservoir of water and ions that move into and out of the guard cells as they change shape during stomatal opening and closing.
- **Mesophyll** consists of photosynthetic parenchyma cells. Mesophyll is divided into **palisade mesophyll,** which functions primarily for photosynthesis, and **spongy mesophyll,** which functions primarily for gas exchange.
- Leaf **veins** have **xylem** to conduct water and essential minerals to the leaf and **phloem** to conduct sugar produced by photosynthesis to the rest of the plant.

3 Compare leaf anatomy in dicots and monocots.

- Monocot leaves have parallel venation, whereas dicot leaves have netted venation.
- Some monocots (corn and other grasses) do not have mesophyll differentiated into distinct palisade and spongy layers.
- Some monocots (grasses, reeds, and sedges) have guard cells shaped like dumbbells, unlike the more common bean-shaped guard cells.

4 Relate leaf structure to its function of photosynthesis.

- Leaf structure is adapted for its primary function of **photosynthesis.** Most leaves have a broad, flattened blade that is quite efficient in collecting the sun's radiant energy.
- Stomata generally open during the day for gas exchange needed during photosynthesis and close at night to conserve water when photosynthesis is not occurring.
- The transparent epidermis allows light to penetrate into the middle of the leaf, where photosynthesis occurs.
- Air spaces in mesophyll tissue permit the rapid diffusion of carbon dioxide and water into, and oxygen out of, mesophyll cells.

5 Explain the role of blue light in the opening of stomata.

- **Blue light,** which is a component of sunlight, triggers the activation of **ATP synthase** located in the guard cell plasma membrane. Blue light also triggers the synthesis of malic acid and the **hydrolysis** of starch.

6 Outline the physiological changes that accompany stomatal opening and closing.

- ATP synthase pumps protons (H^+) out of the guard cells. The protons are produced when malic acid ionizes. As protons leave the guard cells, an **electrochemical gradient** (a charge and concentration difference) forms on the two sides of the guard cell plasma membrane.
- The electrochemical gradient drives the uptake of potassium ions through **voltage-activated potassium channels** into the guard cells. Chloride ions are also taken into the guard cells through ion channels. These osmotically active ions increase the solute concentration in the guard cell vacuoles.
- The resulting osmotic movement of water into the guard cells causes them to become turgid, forming a pore.
- As the day progresses, potassium ions slowly leave the guard cells, and starch is hydrolyzed to sucrose, which increases in concentration in the guard cells. Stomata close when water leaves the guard cells as a result of a decline in the concentration of sucrose, an osmotically active solute. The sucrose is converted to starch, which is osmotically inactive.
- Several environmental factors affect stomatal opening and closing, including light or darkness, CO_2 concentration, water stress, and the plant's circadian rhythm.

7 Discuss transpiration and its effects on plants.

- **Transpiration** is the loss of water vapor from aerial parts of plants. Transpiration occurs primarily through the stomata.
- The rate of transpiration is affected by environmental factors such as temperature, wind, and relative humidity.
- Transpiration appears to be both beneficial and harmful to the plant—that is, transpiration represents a tradeoff between the CO_2 requirement for photosynthesis and the need for water conservation.

8 Distinguish between transpiration and guttation.

- **Guttation,** the release of liquid water from leaves of some plants, occurs through special structures when transpiration is negligible and available soil moisture is high. In contrast, transpiration is the loss of water vapor and occurs primarily through the stomata.

9 Define leaf *abscission,* explain why it occurs, and describe the physiological and anatomical changes that precede it.

- Leaf **abscission** is the loss of leaves that often occurs as winter approaches in temperate climates or at the beginning of the dry period in tropical climates with wet and dry seasons.
- Abscission is a complex process involving physiological and anatomic changes that occur prior to leaf fall. An **abscission zone** develops where the petiole detaches from the stem. Sugars, amino acids, and many essential minerals are transported from the leaves to other plant parts. Chlorophyll breaks down, and **carotenoids** and **anthocyanins** become evident.

10 List at least four examples of modified leaves, and give the function of each.

- **Spines** are leaves adapted to deter herbivores.
- Some **tendrils** are leaves modified for grasping and holding onto other structures (to support weak stems).
- **Bud scales** are leaves modified to protect delicate meristematic tissue or dormant buds.
- **Bulbs** are short underground stems with fleshy leaves specialized for storage.
- Many plants adapted to arid conditions have succulent leaves for water storage.
- Insectivorous plants have leaves modified to trap insects.

POST-TEST

1. Plants with an alternate leaf arrangement have (a) blades divided into two or more leaflets (b) major veins that radiate out from one point (c) one leaf at each node (d) major veins branching off along the entire length of the midvein (e) two leaves at each node
2. The photosynthetic ground tissue in the middle of the leaf is called (a) cutin (b) mesophyll (c) the abscission zone (d) subsidiary cells (e) palisade and spongy stomata

POST-TEST *(continued)*

3. The primary function of the spongy mesophyll is (a) reduction of water loss from the leaf surface (b) changing the shape of the guard cells (c) support to prevent the leaf from collapsing under its own weight (d) diffusion of gases within the leaf (e) deterrence of herbivores
4. Gas exchange occurs through microscopic pores formed by two (a) subsidiary cells (b) abscission cells (c) mesophyll cells (d) guard cells (e) stipules
5. Most stomata are usually located in the _____ of the leaf. (a) upper epidermis (b) lower epidermis (c) cuticle (d) spongy mesophyll (e) palisade mesophyll
6. The thin, noncellular layer of wax secreted by the epidermis of leaves is the (a) stoma (b) subsidiary cell (c) trichome (d) bundle sheath (e) cuticle
7. The _____ encircles a vein. (a) palisade mesophyll (b) guard cell (c) bundle sheath (d) blade (e) cuticle
8. The _____ of a leaf vein transports water and dissolved nutrient minerals, whereas the _____ transports sugars produced by the leaf during photosynthesis. (a) xylem; phloem (b) xylem; bundle sheath (c) phloem; xylem (d) phloem; vein (e) vascular bundle; bundle sheath
9. Which of the following is *not* an adaptation of pine needles to conserve water? (a) less surface area exposed to the air than thin-bladed leaves (b) a relatively thick cuticle (c) sunken stomata (d) netted veins instead of parallel veins (e) both c and d are not adaptations of pine needles
10. Most of the water that a plant absorbs from the soil is lost by the process of (a) guttation (b) circadian rhythm (c) abscission (d) transpiration (e) photosynthesis
11. When transpiration is negligible, plants such as grasses exude excess water by (a) guttation (b) circadian rhythm (c) abscission (d) pumping H^+ out of and K^+ into guard cells (e) photosynthesis
12. At sunrise, the accumulation in the guard cells of the osmotically active substance, _____, causes an inflow of water and the opening of the pore. (a) protons (b) starch (c) ATP synthase (d) sucrose (e) potassium ions
13. Stomatal opening is most pronounced in response to _____ light. (a) green (b) yellow (c) blue (d) ultraviolet (e) infrared
14. The seasonal detachment of leaves is known as (a) forest decline (b) transpiration (c) abscission (d) guttation (e) dormancy
15. Anatomically, the abscission zone where a petiole detaches from a stem consists of (a) thin-walled parenchyma cells with few fibers (b) thick-walled cork parenchyma cells (c) clusters of fibers and collenchyma strands (d) hard and pointed stipules (e) epidermal cells with sunken stomata
16. Modified leaves that enable a stem to climb are called _____ whereas modified leaves that cover the winter buds of a dormant woody plant are called _____ (a) spines; bud scales (b) bud scales; tendrils (c) tendrils; bud scales (d) tendrils; spines (e) insectivorous leaves; spines
17. Leaves have a tradeoff between photosynthesis and transpiration that results from (a) numerous stomatal pores that provide both gas exchange for photosynthesis and openings through which water vapor escapes (b) secretion of a waxy layer, the cuticle, that reduces water loss (c) blue light triggering an influx of potassium ions (K^+) into the guard cells (d) abscission of leaves of deciduous plants as winter approaches in temperate climates (e) stomata being closed at night, although water continues to move into the roots by osmosis

CRITICAL THINKING

1. Suppose you are asked to observe a micrograph of a leaf cross section and distinguish between the upper and lower epidermis. How would you make this decision?
2. Given that (a) xylem is located toward the upper epidermis in leaf veins while phloem is toward the lower epidermis, and (b) the vascular tissue of a leaf is continuous with that of the stem, suggest one possible arrangement of vascular tissues in the stem that might account for the arrangement of vascular tissue in the leaf.
3. What might be some of the advantages of a plant having a few very large leaves? What might some disadvantages be? What might be some advantages of having many very small leaves? What disadvantages might this entail? How would your answer differ along a moisture gradient, from a humid environment to a desert?
4. Briefly explain why additional research on the molecular mechanism of stomatal closure might be of future use in agriculture.

Stems and Plant Transport

Michael Fairchild/Peter Arnold, Inc.

Baobab tree. Baobabs (*Adansonia digitata*), which are native to Africa, Madagascar, and Australia, store large volumes of water and starch in their massive trunks. Baobab trees are relatively short (growing to 18 m, or 60 ft), but their trunks can be as much as 9 m, or 30 ft, in diameter. Photographed in Namibia, with children around the tree as a size reference.

CHAPTER OUTLINE

- **External Stem Structure in Woody Twigs**
- **Stem Growth and Structure**
- **Transport in the Plant body**

A vegetative (not sexually reproductive) vascular plant has three parts: roots, leaves, and stems. As discussed in Chapter 31, roots serve to anchor the plant and absorb materials from the soil, whereas leaves are primarily for photosynthesis, converting radiant energy into the chemical energy of carbohydrate molecules. Stems, the focus of this chapter, link a plant's roots to its leaves and are usually located above ground, although many plants have underground stems. Stems exhibit varied forms, ranging from ropelike vines to massive tree trunks. They can be either herbaceous (consisting of soft, nonwoody tissues) or woody (with extensive hard tissues of wood and bark).

Stems perform three main functions in plants. First, stems of most species support leaves and reproductive structures. The upright position of most stems and the arrangement of the leaves on them allow each leaf to absorb light for use in photosynthesis. Reproductive structures (flowers and fruits) are located on stems in areas accessible to insects, birds, and air currents, which transfer pollen from flower to flower and help disperse seeds and fruits.

Second, stems provide internal transport. They conduct water and dissolved nutrient minerals from the roots, where these materials are absorbed from the soil, to leaves and other plant parts. Stems also conduct the sugar produced in leaves by photosynthesis to roots and other parts of the plant. Remember, however, that stems are not the only plant organs that conduct materials. The vascular system is continuous throughout all parts of a plant, and conduction occurs in roots, stems, leaves, and reproductive structures.

Third, stems produce new living tissue. They continue to grow throughout a plant's life, producing buds that develop into stems with new leaves and/or reproductive structures. In addition to the main functions of support, conduction, and production of new stem tissues, stems of some species are modified for asexual reproduction (see Chapter 35) or, if green, to manufacture sugar by photosynthesis. Also, some stems are specialized to store starch *(see photograph)*. ■

EXTERNAL STEM STRUCTURE IN WOODY TWIGS

Learning Objective

1 Describe the external features of a woody twig.

Although stems exhibit great variation in structure and growth, they all have **buds,** which are embryonic shoots. A **terminal bud** is the embryonic shoot located at the tip of a stem. The dormant (not actively growing) apical meristem of a terminal bud is covered and protected by an outer layer of **bud scales,** which are modified leaves (see Fig. 32-14c). **Axillary buds,** also called **lateral buds,** are located in the axils of a plant's leaves (see Fig. 32-1). An axil is the upper angle between a leaf and the stem to which it is attached. When terminal and axillary buds grow, they form branches that bear leaves and/or flowers. The area on a stem where each leaf is attached is called a **node,** and the region between two successive nodes is an **internode.**

A woody twig of a deciduous tree that has shed its leaves can be used to demonstrate certain structural features of the stem (Fig. 33-1). Bud scales cover the terminal bud and protect its delicate apical meristem during dormancy. When the bud resumes growth, the bud scales covering the terminal bud fall off, leaving **bud scale scars** on the stem where they were attached. Because temperate-zone woody plants form terminal buds at the end of each year's growing season, the number of sets of bud scale scars on a twig indicates its age. A **leaf scar** shows where each leaf was attached on the stem; the pattern of leaf scars can be used to determine leaf arrangement on a stem—alternate, opposite, or whorled (see Fig. 32-2b). The vascular (conducting) tissue that extends from the stem out into the leaf forms **bundle scars** within a leaf scar. Axillary buds may be found above the leaf scars. Also, the bark of a woody twig has **lenticels,** sites of loosely arranged cells that allow oxygen to diffuse into the interior of the woody stem. Lenticels look like tiny specks on the bark of a twig.

Review

- What is the difference between terminal and axillary buds?
- What is the function of bud scales? Of lenticels?
- How can you tell the age of a woody twig?

BiologyNow™ Assess your understanding of **external stem structure in woody plants** by taking the pretest on your BiologyNow CD-ROM.

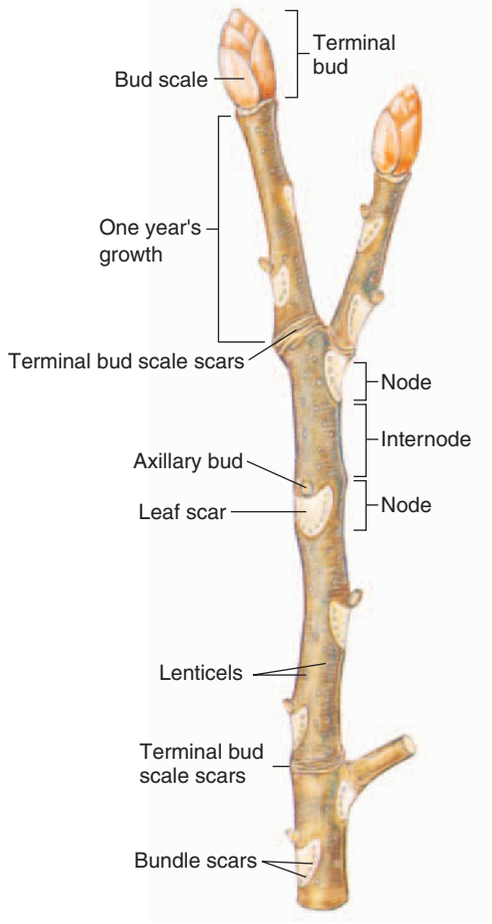

FIGURE **33-1** **External structure of a woody twig in its winter condition.**

The age of a woody twig can be determined by the number of sets of bud scale scars (do not count side branches). How old is this twig?

STEM GROWTH AND STRUCTURE

Learning Objectives

2 Label cross sections of herbaceous dicot and monocot stems, and describe the functions of each tissue.

3 Name the two lateral meristems, and describe the tissues that arise from each.

4 Outline the transition from primary growth to secondary growth in a woody stem.

You may recall from Chapter 31 that plants have two different types of growth. **Primary growth** is an increase in the length of a plant and occurs at **apical meristems** located at the tips of roots and shoots and also within the buds of stems. **Secondary growth** is an increase in the girth (thickness) of a plant owing to the activity of **lateral meristems** located within stems and roots. The new tissues formed by the lateral meristems are called *secondary tissues* to distinguish them from *primary tissues* produced by apical meristems.

All plants have primary growth; some plants have both primary and secondary growth. Stems with only primary growth are herbaceous, whereas those with both primary and secondary growth are woody.[1] A woody plant increases in length by primary growth at the tips of its stems and roots, while its older stems and roots farther back from the tips increase in girth by secondary growth. In other words, at the same time that second-

[1] Certain herbaceous stems, such as geranium and sunflower, also have a limited amount of secondary growth.

ary growth is adding wood and bark, thereby causing the stem to thicken, primary growth is increasing the length of the stem.

Herbaceous dicot and monocot stems differ in internal structure

Although considerable structural variation exists in stems, they all possess an outer protective covering (epidermis or periderm), one or more types of ground tissue, and vascular tissues (xylem and phloem). Let us first consider the structure of herbaceous dicot stems and then of monocot stems.

Vascular bundles of herbaceous dicot stems are arranged in a circle in cross section

A young sunflower stem is a representative herbaceous dicot stem that exhibits primary growth (Fig. 33-2). Its outer covering, the **epidermis,** provides protection in herbaceous stems, as it does in leaves and herbaceous roots (see Table 31-4 and Fig. 31-6). The **cuticle,** a waxy layer of *cutin,* covers the stem epidermis and reduces water loss from the stem surface. **Stomata** permit gas exchange. (Recall from Chapter 32 that a cuticle and stomata are also associated with the leaf epidermis.)

Inside the epidermis is the **cortex,** a cylinder of ground tissue that may contain parenchyma, collenchyma, and sclerenchyma cells (see Table 31-2 and Fig. 31-4). As might be expected from the various types of cells that it contains, the cortex in herbaceous dicot stems can have several functions, such as photosynthesis, storage, and support. If a stem is green, photosynthesis occurs in chloroplasts of cortical parenchyma cells. Parenchyma in the cortex also stores starch (in amyloplasts) and crystals (in vacuoles). Collenchyma and sclerenchyma in the cortex confer strength and structural support for the stem.

The vascular tissues provide conduction and support. In herbaceous dicot stems, the vascular tissues are located in bundles that, when viewed in cross section, are arranged in a circle. However, viewed lengthwise, these bundles extend as long strands throughout the length of a stem and are continuous with vascular tissues of both roots and leaves.

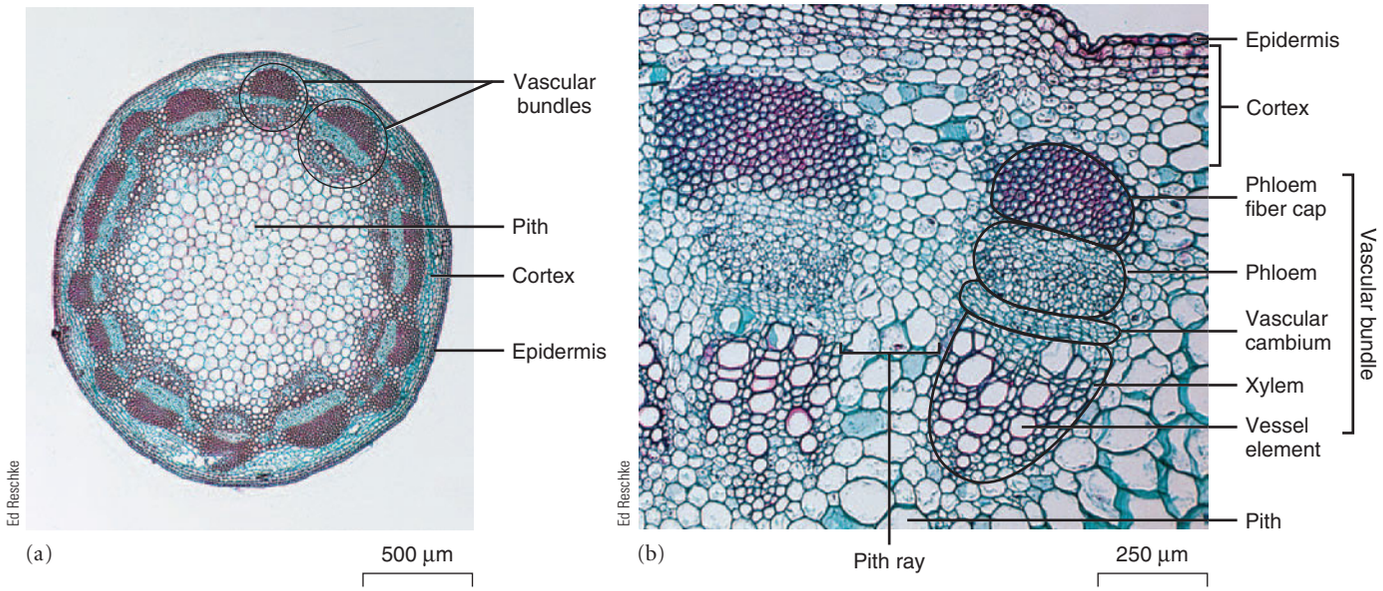
Each vascular bundle contains both **xylem,** which transports water and dissolved nutrient minerals from roots to leaves, and **phloem,** which transports dissolved sugar (see Table 31-3 and Fig. 31-5). Xylem is located on the inner side of the vascular bundle, and phloem is found toward the outside. Sandwiched between xylem and phloem in some herbaceous stems is a single layer of cells called the *vascular cambium,* a lateral meristem responsible for secondary growth (discussed later).

Because most stems support the aerial plant body, they are much stronger than roots. The thick walls of tracheids and vessel elements in xylem help support the plant. Fibers also occur in both xylem and phloem, although they are usually more extensive in phloem. These fibers add considerable strength to the herbaceous stem. In sunflowers and certain other herbaceous dicot stems, phloem contains a cluster of fibers toward the outside of the vascular bundle, called a **phloem fiber cap,** that helps strengthen the stem. The phloem fiber cap is not present in all herbaceous dicot stems.

The **pith** is a ground tissue at the center of the herbaceous dicot stem that consists of large, thin-walled parenchyma cells

FIGURE **33-2** **LMs of a herbaceous dicot stem.**

(a) Cross section of a sunflower (*Helianthus annuus*) stem. Note the vascular bundles arranged in a circle around a central core of pith. **(b)** Closeup of two vascular bundles. In each bundle, xylem is located toward the stem's interior, and phloem toward the exterior. Each vascular bundle is "capped" by a batch of fibers for additional support.



that function primarily in storage. Because of the arrangement of the vascular tissues in bundles, there is no distinct separation of cortex and pith between the vascular bundles. The areas of parenchyma between the vascular bundles are often referred to as **pith rays.**

Vascular bundles are scattered throughout monocot stems

An epidermis with its waxy cuticle covers monocot stems such as the herbaceous stem of corn. As in herbaceous dicot stems, the vascular tissues run in strands throughout the length of a stem. In cross section the vascular bundles contain xylem toward the inside and phloem toward the outside. In contrast with herbaceous dicots, however, vascular bundles of monocots are not arranged in a circle but instead are scattered throughout the stem (Fig. 33-3). Each vascular bundle is enclosed in a bundle sheath of supporting sclerenchyma cells. The monocot stem does not have distinct areas of cortex and pith. The ground tissue in which the vascular tissues are embedded performs the same functions as cortex and pith in herbaceous dicot stems.

Monocot stems do not possess lateral meristems (vascular cambium and cork cambium) that give rise to secondary growth. Monocots have primary growth only and do not produce wood and bark. Although some treelike monocots such as palms attain considerable size, they do so by a modified form of primary growth in which parenchyma cells divide and enlarge. Stems of some monocots such as bamboo and palm contain a great deal of sclerenchyma tissue, which makes them hard and woodlike in appearance.

Woody plants have stems with secondary growth

Woody plants undergo secondary growth, an increase in the girth of stems and roots. Secondary growth occurs as a result of the activity of two lateral meristems: vascular cambium and cork cambium. Among flowering plants, only woody dicots (such as apple, hickory, and maple) have secondary growth. Cone-bearing gymnosperms (such as pine, juniper, and spruce) also have secondary growth.

Cells in the **vascular cambium** divide and produce two conducting and supporting tissues: secondary xylem (wood) to replace primary xylem, and secondary phloem (inner bark) to replace primary phloem. Primary xylem and primary phloem are not able to transport materials indefinitely and so are replaced in plants that have extended life spans.

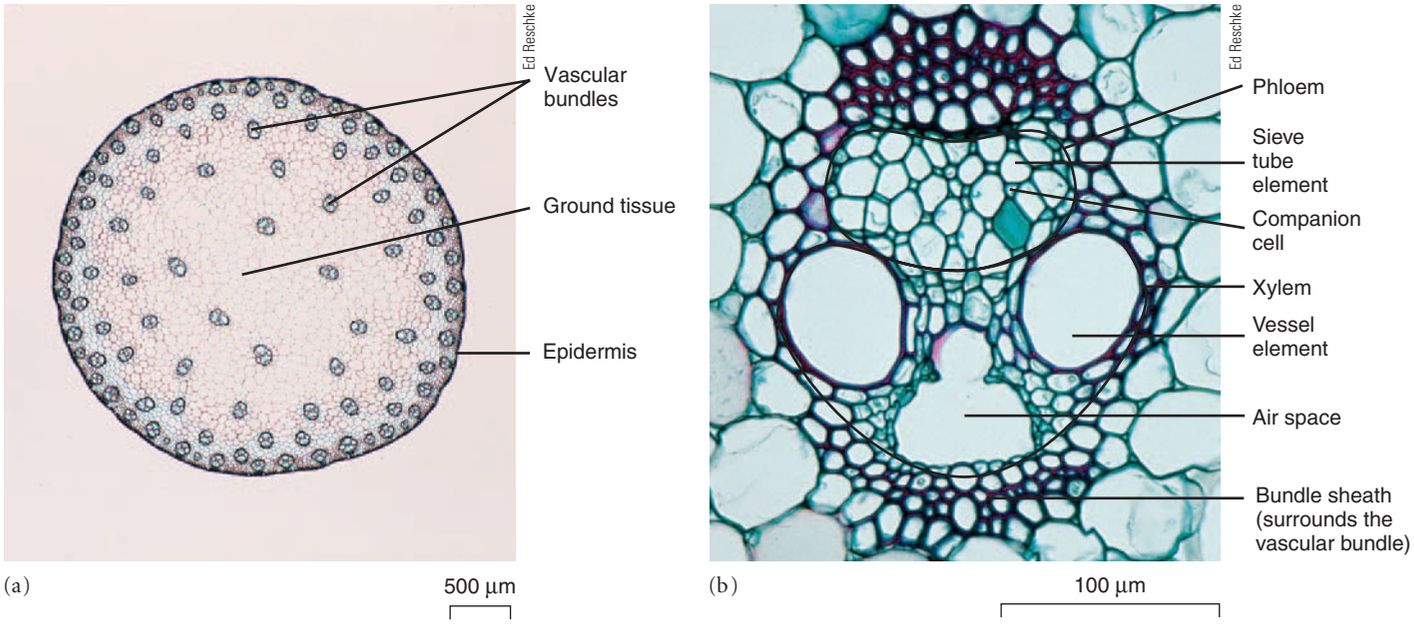
Cells of the outer lateral meristem, called **cork cambium,** divide and produce cork cells and cork parenchyma. Cork cambium and the tissues it produces are collectively referred to as **periderm** (outer bark), which functions as a replacement for the epidermis (see the last LM in Table 31-4).

Vascular cambium gives rise to secondary xylem and secondary phloem

Primary tissues in woody dicot stems are organized like those in herbaceous dicot stems, with the vascular cambium a thin layer of cells sandwiched between xylem and phloem in the vascular bundles. Once secondary growth begins, the internal structure of a stem changes considerably (Fig. 33-4). Although vas-

FIGURE **33-3** **LMs of a monocot stem.**

(a) Cross section of a corn (*Zea mays*) stem shows vascular bundles scattered throughout ground tissue. **(b)** Closeup of a vascular bundle. The air space is the site where the first xylem elements were formed and later disintegrated. The entire bundle is enclosed in a bundle sheath of sclerenchyma for additional support.



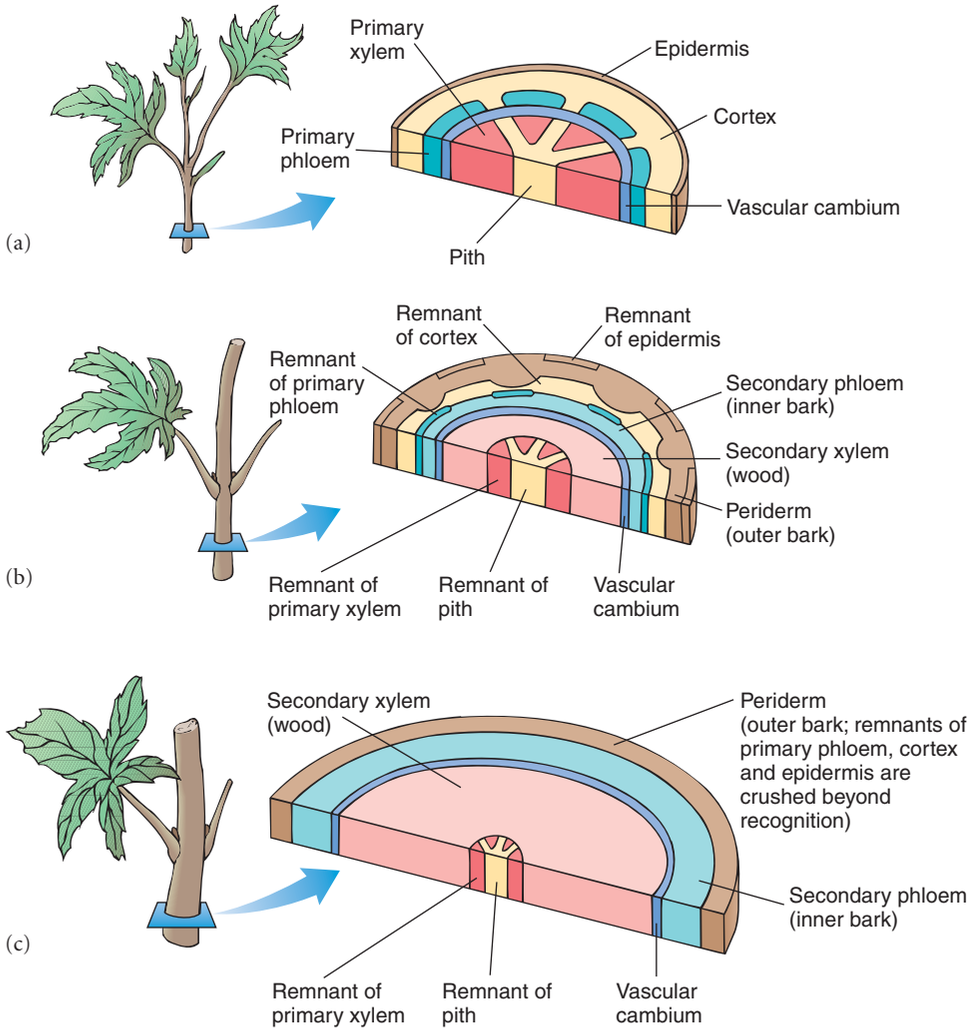


FIGURE **33-4**

Development of secondary growth.

Vascular cambium and the tissues it produces are shown in cross section; cork cambium is not depicted. **(a)** At the onset of secondary growth, vascular cambium arises in the parenchyma between the vascular bundles (that is, in the pith rays), forming a cylinder of meristematic tissue (blue circle in cross section). **(b)** Vascular cambium begins to divide, forming secondary xylem on the inside and secondary phloem on the outside. **(c)** A young woody stem. Vascular cambium produces significantly more secondary xylem than secondary phloem. (The figures change in scale owing to space limitations; pith and primary xylem are actually the same size in all three diagrams, but the change in scale makes those tissues appear to shrink from part a to part b to part c.)

cular cambium is not initially a continuous cylinder of cells (because the vascular bundles are separated by pith rays), it becomes continuous when production of secondary tissues begins. This continuity develops because certain parenchyma cells in each pith ray retain the ability to divide. These cells connect to vascular cambium cells in each vascular bundle, forming a complete ring of vascular cambium.

Cells in the vascular cambium divide and produce daughter cells in two directions. The cells formed from the dividing vascular cambium are located either *inside* the ring of vascular cambium (to become secondary xylem, or wood), or *outside* it (to become secondary phloem, or inner bark) (Fig. 33-5). When a cell in the vascular cambium divides tangentially (inward or outward), one daughter cell remains meristematic; that is, it remains part of the vascular cambium. The other cell may divide again several times, but eventually it stops dividing and develops into mature secondary tissue. Thus vascular cambium is a thin layer of cells sandwiched between the wood and inner bark, the two tissues it produces (Fig. 33-6).

As the stem increases in circumference, the number of cells in the vascular cambium also increases. This occurs by an occasional radial division of a vascular cambium cell, at right angles to its normal direction of division. In this case, both daughter cells remain meristematic.

What happens to the original primary tissues of a stem once secondary growth develops? As a stem increases in thickness, the orientation of the original primary tissues changes. For example, secondary xylem and secondary phloem are laid down between the primary xylem and primary phloem within each vascular bundle. Therefore, as vascular cambium forms secondary tissues, the primary xylem and primary phloem in each vascular bundle become separated from one another (Fig. 33-7). The primary tissues located outside the cylinder of secondary growth (that is, primary phloem, cortex, and epidermis) are subjected to the mechanical pressures produced by secondary growth and are gradually crushed or torn apart and sloughed off.

Secondary tissues replace the primary tissues in function. Secondary xylem conducts water and dissolved nutrient minerals from roots to leaves in the woody plant. It contains the same types of cells found in primary xylem: water-conducting tracheids and vessel elements, in addition to xylem parenchyma cells and fibers. The arrangement of the different cell types in secondary xylem produces the distinctive wood characteristics of each species.

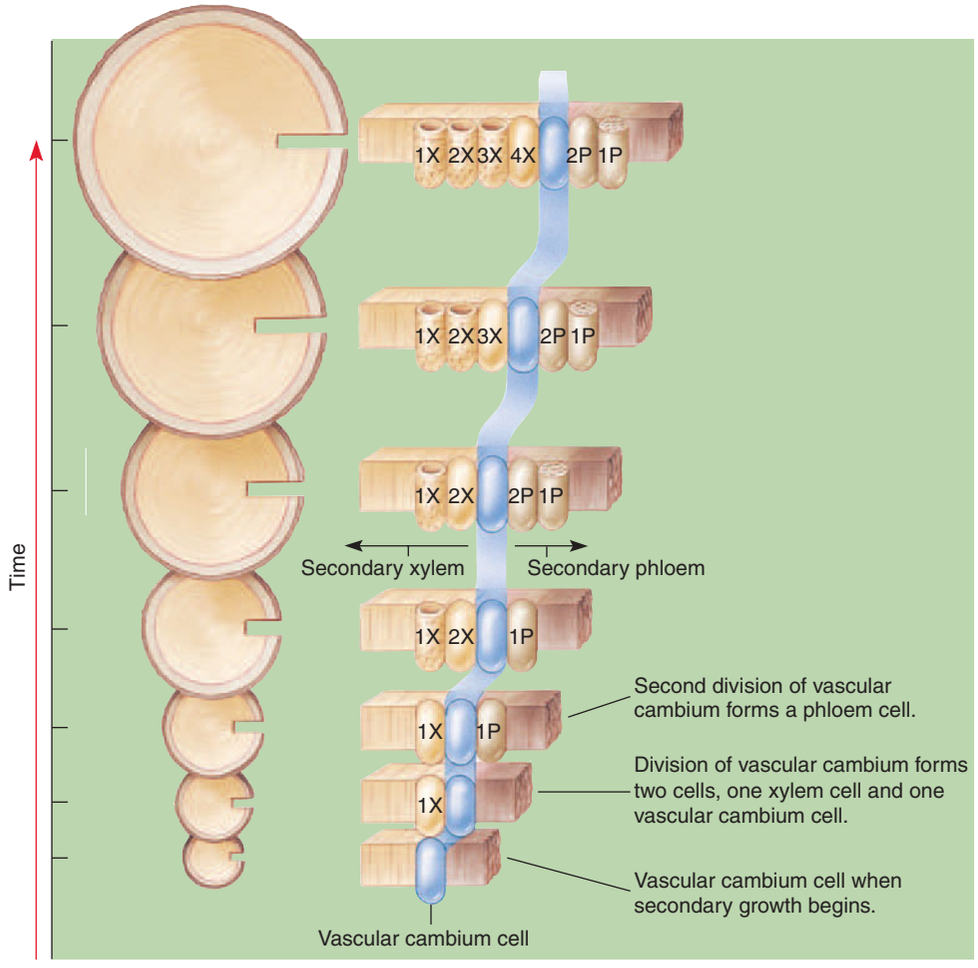

FIGURE **33-5**

Development of secondary xylem and secondary phloem.

To study the figure, which shows a radial view of a dividing vascular cambium cell, start at the bottom and move up. Note that vascular cambium *(the blue cell)* divides in two directions, forming secondary xylem (X) to the inside and secondary phloem (P) to the outside. These cells, which are numbered in the order in which they are produced, differentiate to form the mature cell types associated with xylem and phloem. As secondary xylem accumulates, vascular cambium "moves" outward, and the woody stem increases in diameter.

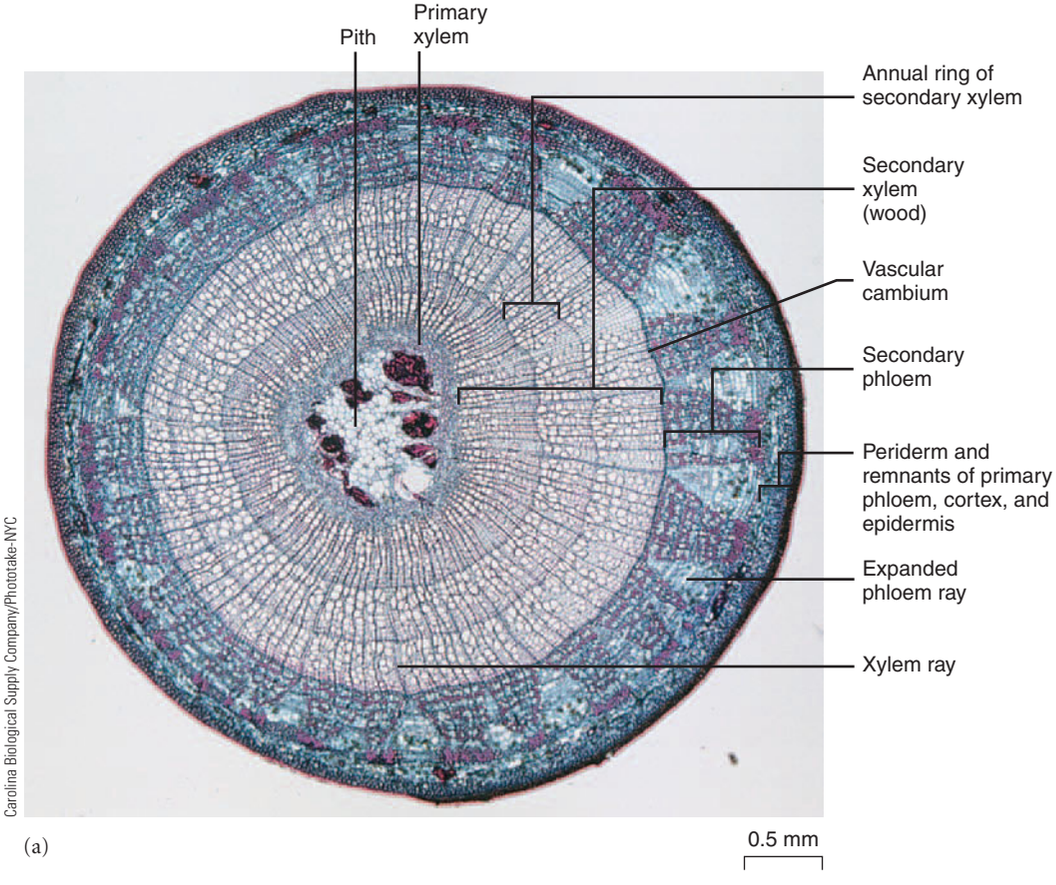

FIGURE **33-6**

Three-year-old stem in cross section.

(a) LM of entire cross section of basswood (*Tilia americana*) stem. **(b)** Sketch of a pie-shaped segment of the cross section (on the facing page). It may be easier to study the parts labeled on the sketch and then locate them on the micrograph. Note the location of the vascular cambium between the secondary xylem (wood) and secondary phloem (inner bark). The primary phloem is not labeled, because it is crushed beyond recognition.

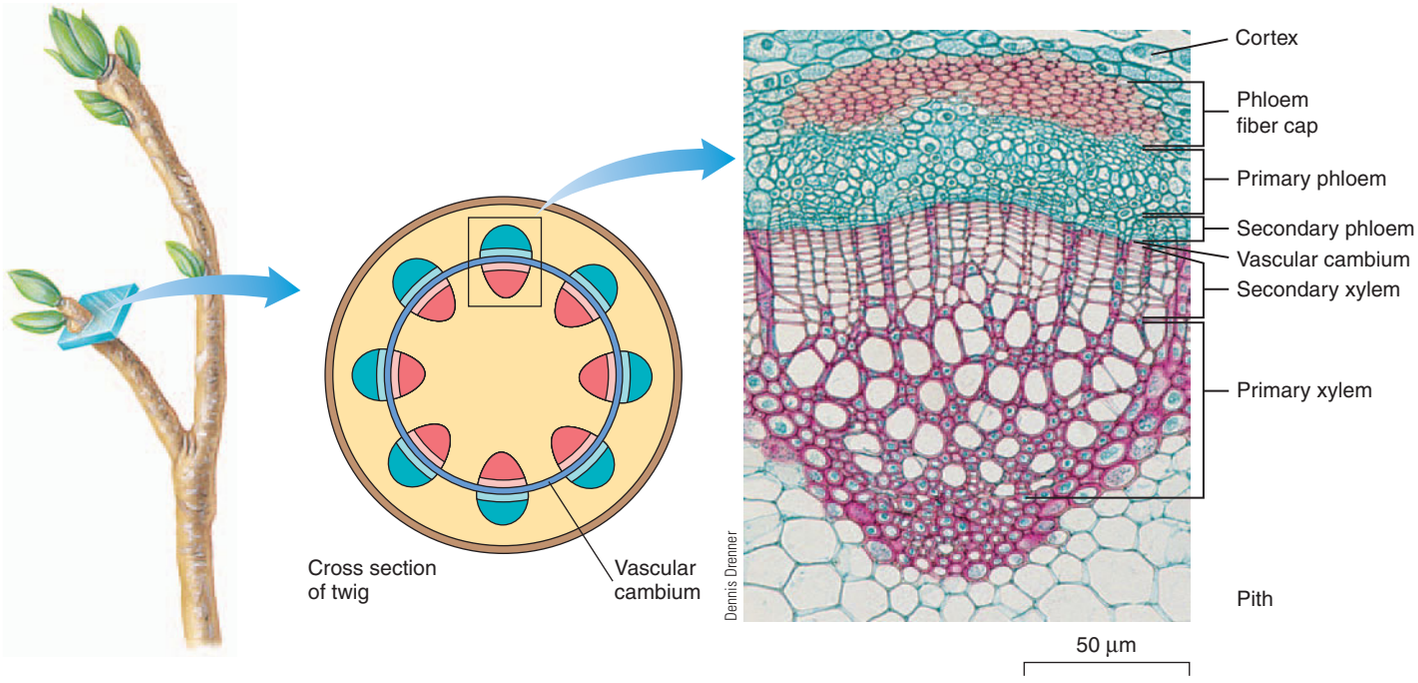

FIGURE 33-7 **LM of part of a young *Magnolia* stem in cross section.**

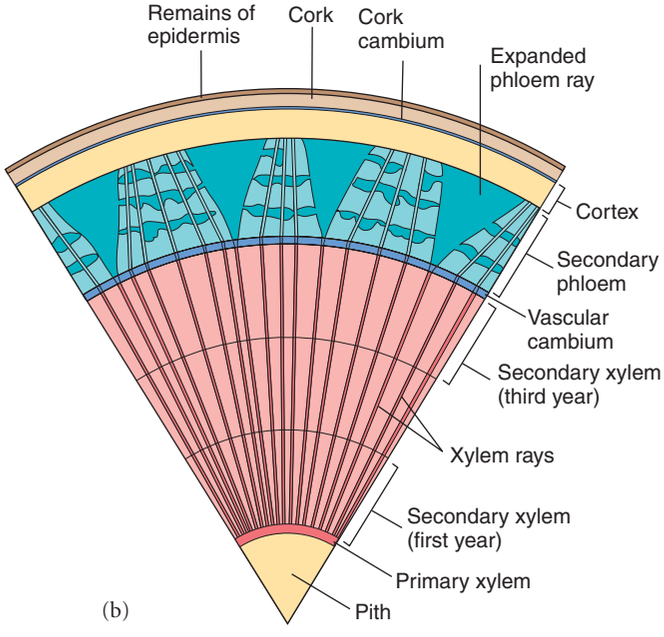
Note that secondary growth is splitting the vascular bundle apart.

Secondary phloem conducts dissolved sugar from its place of manufacture (leaves) to a place of use and storage (such as roots). The same types of cells found in primary phloem (sieve tube elements, companion cells, phloem parenchyma cells, and fibers) are also found in secondary phloem, although secondary phloem usually has more fibers than primary phloem.

Secondary xylem and secondary phloem transport water, minerals, and sugar vertically throughout the woody plant body. However, materials must also move horizontally (laterally). Lateral movement occurs through **rays,** which are chains of parenchyma cells that radiate out from the center of the woody stem or root (see Fig. 33-6). The vascular cambium forms rays, which are often continuous from the secondary xylem to the secondary phloem. Water and dissolved nutrient minerals are transported laterally through rays, from the secondary xylem to the secondary phloem. Likewise, rays form pathways for the lateral transport of dissolved sugar, from the secondary phloem to the secondary xylem, and of waste products to the center, or heart, of the tree (discussed later).



Cork cambium produces periderm

Cork cambium, which usually arises from parenchyma cells in the outer cortex, produces **periderm,** the functional replacement for the epidermis. Cork cambium is either a continuous cylinder of dividing cells (similar to vascular cambium) or a series of overlapping arcs of meristematic cells that form from parenchyma cells in successively deeper layers of the cortex and, eventually, secondary phloem. Variation in cork cambia and their rates of division explain why the outer bark of some tree species is fissured (as in bur oak), rough and shaggy (shagbark hickory), scaly (Norway pine), or smooth and peeling (paper birch).

As is true of vascular cambium, cork cambium divides to form new tissues in two directions—to its inside and its outside. Cork cells, formed to the outside of cork cambium, are dead at maturity and have walls that contain layers of *suberin* and waxes, making them waterproof. These cork cells protect the woody stem against mechanical injury, mild fires, attacks by insects and fungi, temperature extremes, and water loss. To its inside, cork cambium sometimes forms cork parenchyma cells that store water and starch granules. Cork parenchyma is only one to several cells thick, much thinner than the cork cell layer.

Cork cells are impermeable to water and gases, yet the living internal cells of the woody stem require oxygen and must

be able to exchange gases with the surrounding atmosphere. As a stem thickens from secondary growth, the epidermis, including stomata that exchange gases for the herbaceous stem, dies. Stomata are replaced by lenticels, which permit gas exchange through the periderm (Fig. 33-8).

Common terms associated with wood are based on plant structure

If you have ever examined different types of lumber, you may have noticed that some trees have wood with two different colors (Fig. 33-9). The functional secondary xylem, that is, the part that conducts water and dissolved nutrient minerals, is the *sapwood,* a thin layer of younger, lighter-colored wood that is closest to the bark. *Heartwood,* the older wood in the center of the tree, is typically a brownish red. A microscopic examination of heartwood reveals that its vessels and tracheids are plugged with pigments, tannins, gums, resins, and other materials. Therefore, heartwood no longer functions in conduction but instead functions as a storage site for waste products. Heartwood is denser than sapwood and therefore provides structural support for trees. Some evidence suggests heartwood is also more resistant to decay.

Almost everyone has heard of hardwood and softwood. Botanically speaking, *hardwood* is the wood of flowering plants and *softwood* is the wood of conifers (cone-bearing gymnosperms). The wood of pine and other conifers typically lacks fibers (with their thick secondary cell walls) and vessel elements; the conducting cells in gymnosperms are tracheids. These cell differences generally make conifer wood softer than the wood of flowering plants, although there is a substantial variation from one species to another. The balsa tree, for example, is a flowering plant whose extremely light, soft wood is used to fashion airplane models.

Woody plants that grow in temperate climates where there is a growing period (during spring and summer) and a dormant period (during winter) exhibit *annual rings,* concentric circles found in cross sections of wood. To determine the age of a woody stem in the temperate zone, simply count the annual rings. In the tropics, environmental conditions, particularly seasonal or year-round precipitation patterns, determine the presence or absence of rings, so rings are not a reliable method of determining the ages of most tropical trees.

Examination of annual rings with a magnifying lens reveals no actual "ring," or line, separating one year's growth from the next. The appearance of a ring in cross section is due to differences in cell size and cell wall thickness between secondary xylem formed at the end of the preceding year's growth and that formed at the beginning of the following year's growth. In the

FIGURE 33-9 **Heartwood and sapwood.**

The wood of older trees consists of a dense, central heartwood and an outer layer of sapwood. The sapwood is the functioning xylem that conducts water and dissolved nutrient minerals. The annual rings in the heartwood are very conspicuous.

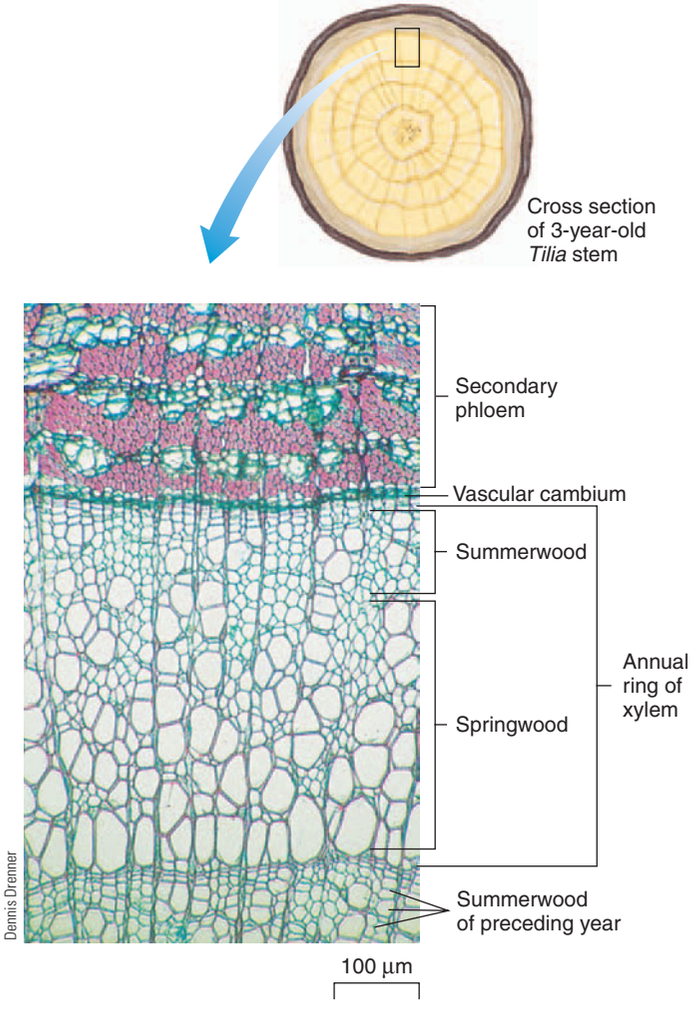
Carlyn Iverson

spring, when water is plentiful, wood formed by vascular cambium has large-diameter conducting cells (tracheids and vessel elements) and few fibers and is appropriately called *springwood* or *early wood*. As summer progresses and water becomes less plentiful, the wood formed, known as *summerwood* or *late wood*, has narrower conducting cells and many fibers. It is this difference in cell size between the summerwood of one year and the springwood of the following year that gives the appearance of rings (Fig. 33-10). A great deal of information about climate in past times can be learned from the study of annual rings of ancient trees (see *Focus On: Tree Ring Analysis and Climate Change*).

As a woody stem increases in girth over the years, the branches that it bears grow along with it as long as they are alive. If a branch dies, it no longer continues to grow with the stem. In time, as the stem increases in girth, it surrounds the base of the dead branch. The basal portion of an embedded dead branch is called a *knot*. It is possible for a knot to contain bark as well as wood. The presence of knots in wood reduces its commercial value, except for ornamental purposes.

FIGURE **33-10** **LM of a portion of a basswood (*Tilia americana*) stem cross section.**

One annual ring, or growth increment, is shown. Note the differences in cell size between the vessel elements of springwood and summerwood. The pink cells in the secondary phloem are fibers.



Review

- How does the arrangement of vascular tissue in a stem cross section differ in dicots and monocots?
- What is the difference between vascular cambium and cork cambium? What tissues arise from vascular cambium? From cork cambium?
- What happens to the primary tissues of a stem when secondary growth occurs?
- How do growth rings form in woody stems?
- When a strip of bark is peeled off a tree branch, what tissues are usually removed?

TRANSPORT IN THE PLANT BODY

Learning Objectives

5 Describe the pathway of water movement in plants.
6 Define *water potential*.
7 Explain the roles of tension-cohesion and root pressure as mechanisms responsible for the rise of water and dissolved nutrient minerals in xylem.
8 Describe the pathway of sugar translocation in plants.
9 Discuss the pressure-flow hypothesis of sugar translocation in phloem.

Now that we have discussed stem structure and primary and secondary growth, we examine internal transport in the vascular system of the plant. Roots obtain water and dissolved nutrient minerals from the soil. Once inside roots, these materials are transported upward to stems, leaves, flowers, fruits, and seeds. Furthermore, sugar molecules manufactured in leaves by photosynthesis are transported dissolved in water throughout the plant, including into the subterranean roots. Water and dissolved nutrient minerals are transported from roots to other parts of the plant in xylem, whereas dissolved sugar is **translocated** in phloem.

Xylem transport and phloem translocation do not resemble the movement of materials in animals, because in plants nothing *circulates* in a system of vessels. Water and minerals, transported in xylem, travel in one direction only (upward), whereas translocation of dissolved sugar may occur upward or downward in separate phloem cells. In addition, xylem transport and phloem translocation differ from internal circulation in animals because movement in both xylem and phloem is driven largely by natural physical processes rather than by a pumping organ, or heart.

How, exactly, do materials travel in the continuous system of the plant's vascular tissues? We first examine water and its movement through the plant, and later we discuss the translocation of dissolved sugar.

Focus On Tree Ring Analysis and Climate Change

In temperate climates, counting the number of annual rings determines the age of a tree. The size of each ring varies depending on local weather conditions, including precipitation and temperature. Sometimes the variation in tree rings can be attributed to a single environmental factor, and similar patterns appear in the rings of different tree species over a large geographic area. For example, trees in the U.S. Southwest have similar ring patterns, caused by variations in the amount of annual precipitation. Years with adequate precipitation produce wider rings of growth, whereas years of drought produce much narrower rings.

It is possible to study ring sequences that go back several thousand years. First, a *master chronology,* a complete sample of rings dating back as far as possible, is developed (see figure). To obtain a sample of rings, a small core of wood is bored out of the trunk of an old living tree. The oldest rings (those toward the center of the tree) are matched with the youngest rings (those toward the outside) of an older tree or even an old piece of wood from a house. A master chronology of the area is obtained by using successively older and older sections of wood, even those found in prehistoric dwellings, and by overlapping their matching ring sequences. The longest master chronology is of bristlecone pines in the western United States; it goes back almost 9000 years.

Dendrochronology, the study of both visible and microscopic details of tree rings, has been used extensively in several fields. Tree ring analysis has been extremely useful in dating prehistoric sites of Native Americans in the Southwest. For example, the Cliff Palace in the Mesa Verde National Park dates back to the year 1073. Tree ring analysis indicates that an extended drought forced the original inhabitants to abandon their homes. Tree ring analysis is also useful in other disciplines, including ecology (to study changes in a forest community over time), environmental science (to study the effects of air pollution on tree growth), and geology (to date earthquakes and volcanic eruptions).

Climatologists are increasingly using tree ring data to study past climate patterns. Annual ring widths of certain tree species that grow at high elevations are sensitive to yearly temperature variations; the rings of these trees are wider in warm years and narrower in cool years. Studying tree rings across long time sequences helps researchers determine the natural pattern of global temperature fluctuations. This information is particularly important because of concerns about the human influence on global climate. Scientists generally agree Earth has warmed in recent decades, and there is little doubt that human production of "greenhouse gases" such as carbon dioxide has contributed to this warming (see Chapter 55).

Researchers are not sure how much of the recent warming is the result of human influence, as opposed to natural climate variability. Tree ring analysis may help answer this vital question. Scientists in nine European countries are cooperating in a massive tree ring analysis to construct an annual history of temperatures across northern Europe and Asia since the end of the last Ice Age, about 10,000 years ago. Local diving clubs are obtaining samples of well-preserved logs that are thousands of years old from river and lake sediments. Scientists will use these and other samples, including living trees, to piece together a 10,000-year master chronology. When that is accomplished (sometime before the year 2010), it should be possible to determine conclusively if today's climate patterns are distinctly different from the natural climate patterns of the past.

Water and minerals are transported in xylem

Water initially moves horizontally into roots from the soil, passing through several tissues until it reaches xylem. Once the water moves into the tracheids and vessel elements of root xylem, it travels upward through a continuous network of these hollow, dead cells from root to stem to leaf. Dissolved nutrient minerals are carried along passively in the water. The plant does not expend any energy of its own to transport water, which moves as a result of natural physical processes. The transport of xylem sap is the most rapid of any movement of materials in plants (Table 33-1).

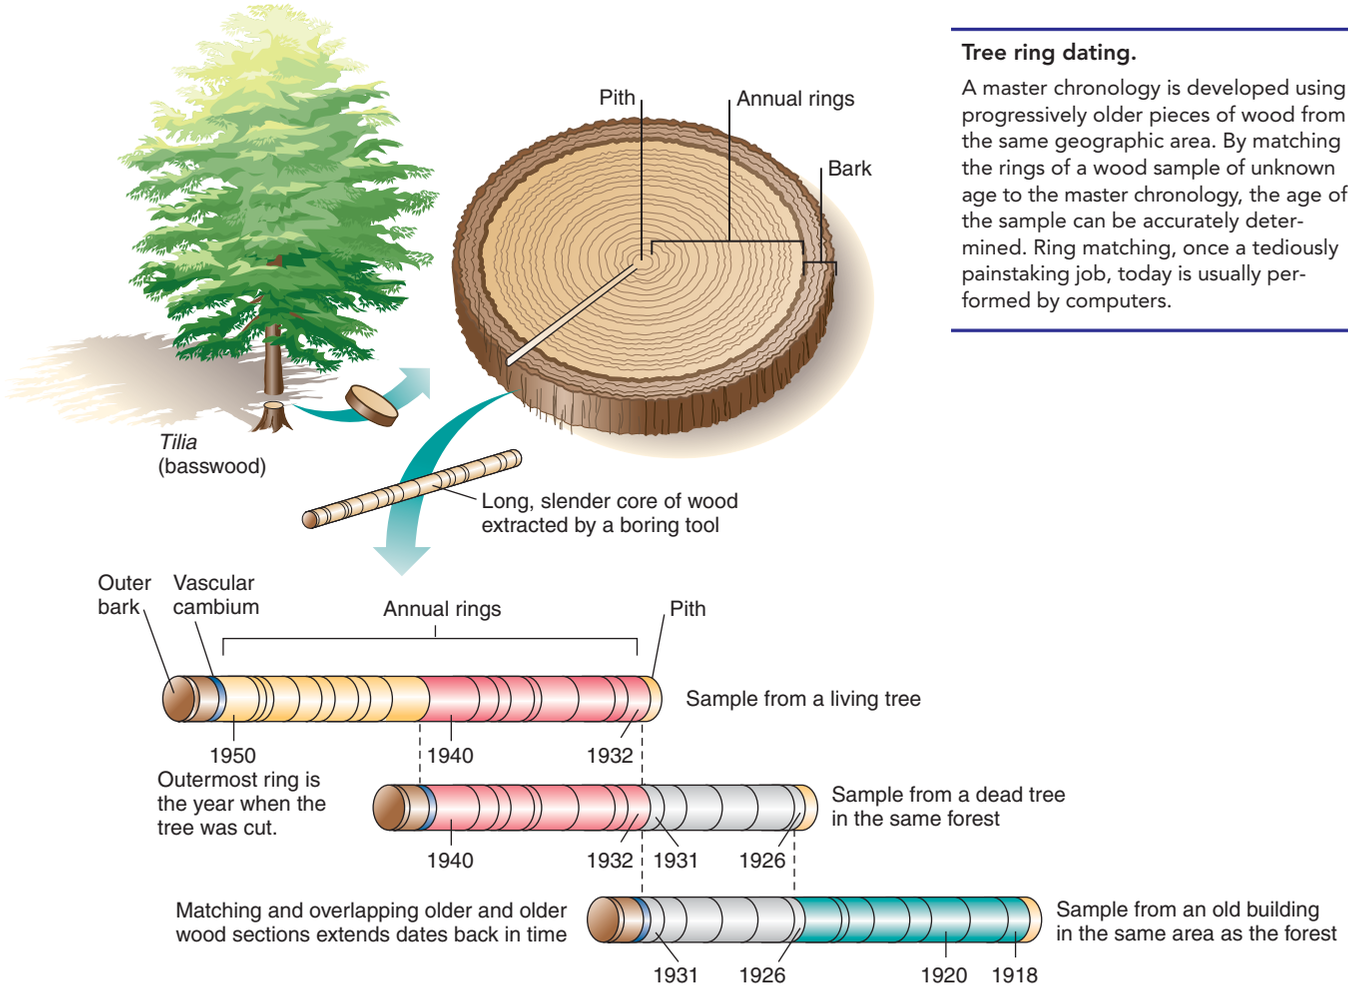
How does water move to the tops of plants? It is either pushed up from the bottom of the plant or pulled up to the top of the plant. Although plants use both mechanisms, current evidence indicates most water is transported through xylem by being *pulled* to the top of the plant.

TABLE **33-1** Xylem and Phloem Transport Rates in Selected Plants

Plant	Maximum Rate in Xylem (cm\min)	Maximum Rate in Phloem (cm\min)
Conifer	2	0.8
Woody dicot	73	2
Herbaceous dicot/monocot	100	2.8–11
Herbaceous vine	250	1.2

Note: Xylem and phloem rates are from different plants within each general group and should be used for comparative purposes only.

Source: Adapted form J.D. Mauseth, *Botany: An Introduction to Plant Biology,* 2nd ed., Philadelphia, Saunders College Publishing, 1995.



Tree ring dating.

A master chronology is developed using progressively older pieces of wood from the same geographic area. By matching the rings of a wood sample of unknown age to the master chronology, the age of the sample can be accurately determined. Ring matching, once a tediously painstaking job, today is usually performed by computers.

Water movement can be explained by a difference in water potential

To understand how water moves, it is helpful to introduce **water potential,** which is defined as the **free energy** (see Chapter 6) of water. Water potential is important in plant physiology because it is a measure of a cell's ability to absorb water by **osmosis** (see Chapter 5). Water potential also provides a measure of water's tendency to evaporate from cells.

The water potential of pure water is conventionally set at 0 megapascals (MPa), because it cannot be measured directly. (A megapascal is a unit of pressure equal to about 10 atmospheres, or 145.1 pounds per square inch.) However, botanists can measure differences in the free energy of water molecules in different situations. When solutes dissolve in water, the free energy of water decreases. Solutes induce **hydration,** in which water molecules surround ions and polar molecules, keeping them in solution by preventing them from coming together (see Fig. 2-10). The association of water molecules with hydrated molecules and ions reduces the motion of water molecules, decreasing their free energy. Thus *dissolved solutes lower the water potential to a negative number. Water moves from a region of higher (less negative) water potential to a region of lower (more negative) water potential.*

The water potential of the soil varies, depending on how much water it contains. When a soil is extremely dry, its water potential is very low (very negative). When a soil is moister, its water potential is higher, although it is still a negative number because dissolved nutrient minerals are present in dilute concentrations.

The water potential in root cells is also negative owing to the presence of dissolved solutes. Roots contain more dissolved materials than does soil water, unless the soil is extremely dry. This means that *under normal conditions the water potential of the root is more negative than the water potential of the soil.* Thus water moves by osmosis from the soil into the root.

The tension-cohesion model pulls water up a stem

According to the **tension-cohesion model,** also known as the **transpiration-cohesion model,** water is pulled up the plant as a result of a *tension* produced at the top of the plant (Fig. 33-11). This tension, which resembles that produced when drinking a liquid through a straw, is caused by the evaporative pull of transpiration. Recall from Chapter 32 that **transpiration** is the evaporation of water vapor from plants. Most water loss from transpiration takes place through stomata, the numerous microscopic pores present on leaf and stem surfaces. The tension extends from leaves, where most transpiration occurs, down the stems and into the roots. It draws water up stem xylem to leaf cells that have lost water as a result of transpiration, and pulls water from root xylem into stem xylem. As water is pulled upward, additional water from the soil is drawn into the roots. Thus the pathway of water movement is as follows:

Soil ⟶ root tissues (epidermis, cortex, and so forth) ⟶ root xylem ⟶ stem xylem ⟶ leaf xylem ⟶ leaf mesophyll ⟶ atmosphere

This upward pulling of water is only possible as long as there is an unbroken column of water in xylem throughout the plant. Water forms an unbroken column in xylem because of the *cohesiveness* of water molecules. Recall from Chapter 2 that water molecules are **cohesive,** that is, strongly attracted to one another, because of **hydrogen bonding.** In addition, the **adhesion** of water to the walls of xylem cells, also the result of hydrogen bonding, is an important factor in maintaining an unbroken column of water. Thus the cohesive and adhesive properties of water enable it to form a continuous column that can be pulled up through the xylem.

The movement of water in xylem by the tension-cohesion mechanism can be explained in terms of water potential. The atmosphere has an extremely negative water potential. For example, air with a relative humidity of 50% has a water potential of −100 MPa; even moist air at a relative humidity of 90% has a negative water potential of −13 MPa. Thus *there is a water potential gradient from the least negative (the soil) up through the plant to the most negative (the atmosphere).* This gradient literally pulls the water from the soil up through the plant.

Is the tension-cohesion model powerful enough to explain the rise of water in the tallest plants? Plant biologists have calculated that the tension produced by transpiration is strong enough

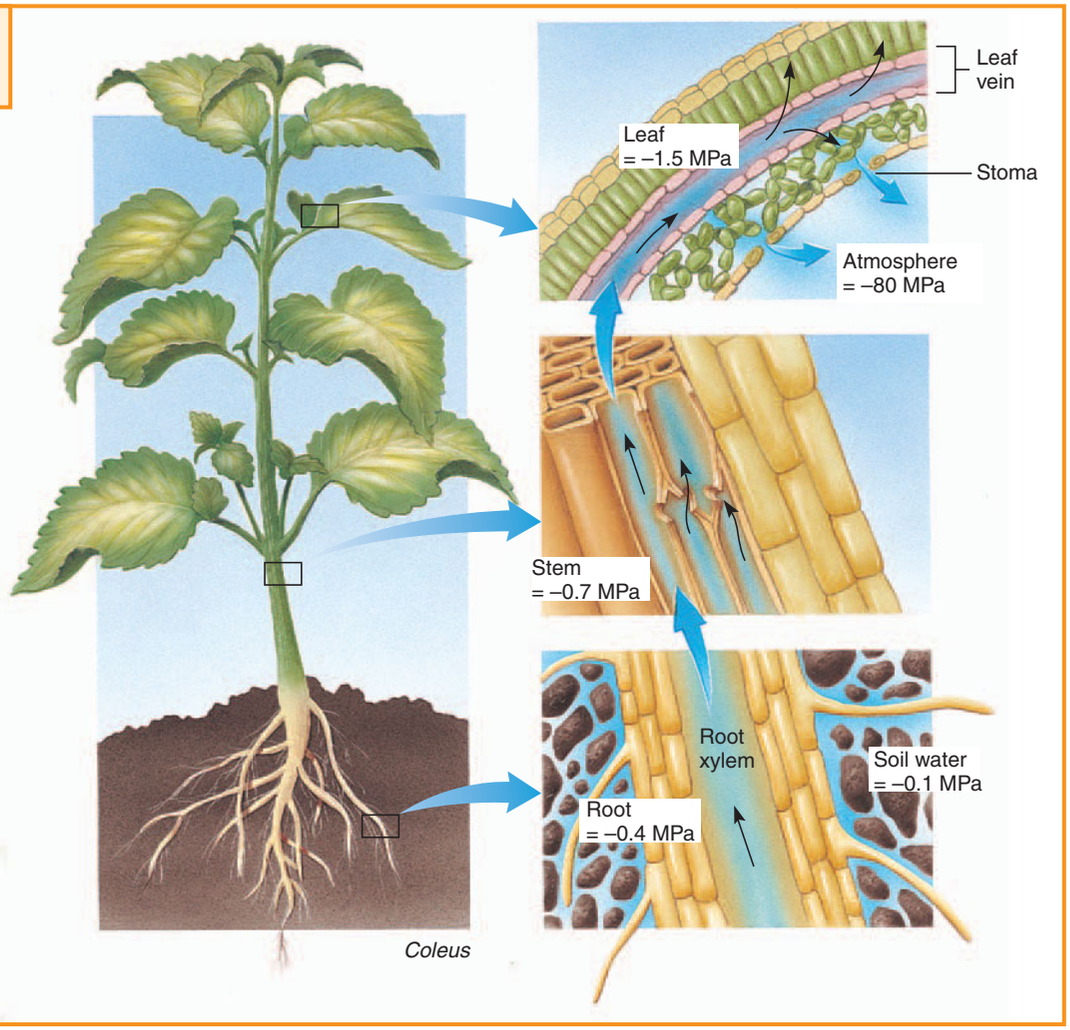
KEY CONCEPT: Transpiration is the driving force of the tension-cohesion model.

ACTIVE FIGURE **33-11**

The tension-cohesion model.

(Top) This model hypothesizes that water vapor transpires from the surfaces of leaf mesophyll cells to the drier atmosphere through stomata. This produces a tension that pulls water out of leaf xylem toward the mesophyll cells. *(Middle)* The cohesion of the water molecules, caused by hydrogen bonding, allows unbroken columns of water to be pulled up the narrow vessels and tracheids of stem xylem. *(Bottom)* This in turn pulls water up root xylem, forming a continuous column of water from root xylem to stem xylem to leaf xylem. As water moves upward in the root, it produces a pull that causes soil water to diffuse into the root.

Biology Now™ Learn more about **the cohesion model** by clicking on this figure on your BiologyNow CD-ROM.



to pull water upward 150 m (500 ft) in tubes the diameter of xylem vessels. Because the tallest trees are about 117 m (375 ft), the tension-cohesion model easily accounts for the transport of water. Currently, most botanists consider the tension-cohesion model to be the dominant mechanism of xylem transport in most plants.

Although the tension-cohesion model was first proposed toward the end of the 19th century, conclusive experimental evidence to support this mechanism was first obtained in 1995 by two research groups working independently. Both groups demonstrated that large negative pressures exist in xylem and that the water potential gradients in root, stem, and leaf xylem are adequate to explain the observed movement of water.

Root pressure pushes water from the root up a stem

In the less important mechanism for water transport, known as **root pressure,** water that moves into roots from the soil is *pushed* up through xylem toward the top of the plant. Root pressure occurs because nutrient mineral ions that are actively absorbed from the soil are pumped into the xylem, decreasing its water potential. Water then moves into xylem cells from surrounding root cells. In turn, water moves into roots by osmosis because of the difference in water potential between the soil and root cells. The accumulation of water in root tissues produces a positive pressure (as high as +0.2 MPa) that forces the water up through the xylem.

Guttation, a phenomenon in which liquid water is forced out through special openings in the leaves (see Chapter 32), results from root pressure. However, root pressure is not strong enough to explain the rise of water to the tops of coastal redwoods and other tall trees. Root pressure exerts an influence in smaller plants, particularly in the spring when the soil is quite wet, but it clearly does not cause water to rise 100 m (330 ft) or more in the tallest plants. Furthermore, root pressure does not occur to any appreciable extent in summer (when water is often not plentiful in soil), yet the movement of water is greatest during hot summer days.

Sugar in solution is translocated in phloem

The sugar produced during photosynthesis is converted into sucrose (common table sugar), a disaccharide composed of one molecule of glucose and one of fructose (see Fig. 3-8b), before being loaded into phloem and translocated to the rest of the plant. Sucrose is the predominant photosynthetic product carried in phloem. Phloem sap also contains much smaller amounts of other materials, such as amino acids, organic acids, proteins, hormones, certain minerals, and sometimes disease-causing plant viruses. Translocation of phloem sap is not as rapid as xylem transport (see Table 33-1).

Fluid within phloem tissue moves both upward and downward. Sucrose is translocated in individual sieve tubes from a *source,* an area of excess sugar supply (usually a leaf), to a *sink,* an area of storage (as insoluble starch) or of sugar use such as roots, apical meristems, fruits, and seeds.

The pressure-flow hypothesis explains translocation in phloem

Current experimental evidence supports the translocation of dissolved sugar in phloem by the **pressure-flow hypothesis,** which was first proposed in 1930 by the German scientist Ernst Münch. The pressure-flow hypothesis states that solutes (such as dissolved sugars) move in phloem by means of a pressure gradient—that is, a difference in pressure. The pressure gradient exists between the source, where the sugar is loaded into phloem, and the sink, where the sugar is removed from phloem.

At the source, the dissolved sucrose is moved from a leaf's mesophyll cells, where it was manufactured, into the companion cell, which loads it into the sieve tube elements of phloem. This loading occurs by active transport, a process that requires adenosine triphosphate (ATP) (Fig. 33-12). The ATP supplies energy to pump protons out of the sieve tube elements, producing a proton gradient that drives the uptake of sugar through specific channels by the **cotransport** of protons back into the sieve tube elements (an example of a linked cotransport system, discussed in Chapter 5). The sugar therefore accumulates in the sieve tube element. The increase in dissolved sugars in the sieve tube element at the source—a concentration that is two to three times greater than in surrounding cells—decreases (makes more negative) the water potential of that cell. As a result, water moves by osmosis from the xylem cells into the sieve tubes, increasing the **turgor pressure** (hydrostatic pressure) inside them. Thus, phloem loading at the source is as follows:

> Proton pump moves H^+ out of sieve tube element ⟶ sugar is actively transported into sieve tube element ⟶ water diffuses from xylem into sieve tube element ⟶ turgor pressure increases within sieve tube

At its destination (the sink), sugar is unloaded by various mechanisms, both active and passive, from the sieve tube elements. With the loss of sugar, the water potential in the sieve tube elements at the sink increases (becomes less negative). Therefore, water moves out of the sieve tubes by osmosis and into surrounding cells where the water potential is more negative. Most of this water diffuses back to the xylem to be transported upward. This water movement decreases the turgor pressure inside the sieve tubes at the sink. Thus phloem unloading at the sink proceeds as follows:

> Sugar is transported out of sieve tube element ⟶ water diffuses out of sieve tube element and into xylem ⟶ turgor pressure decreases within sieve tube

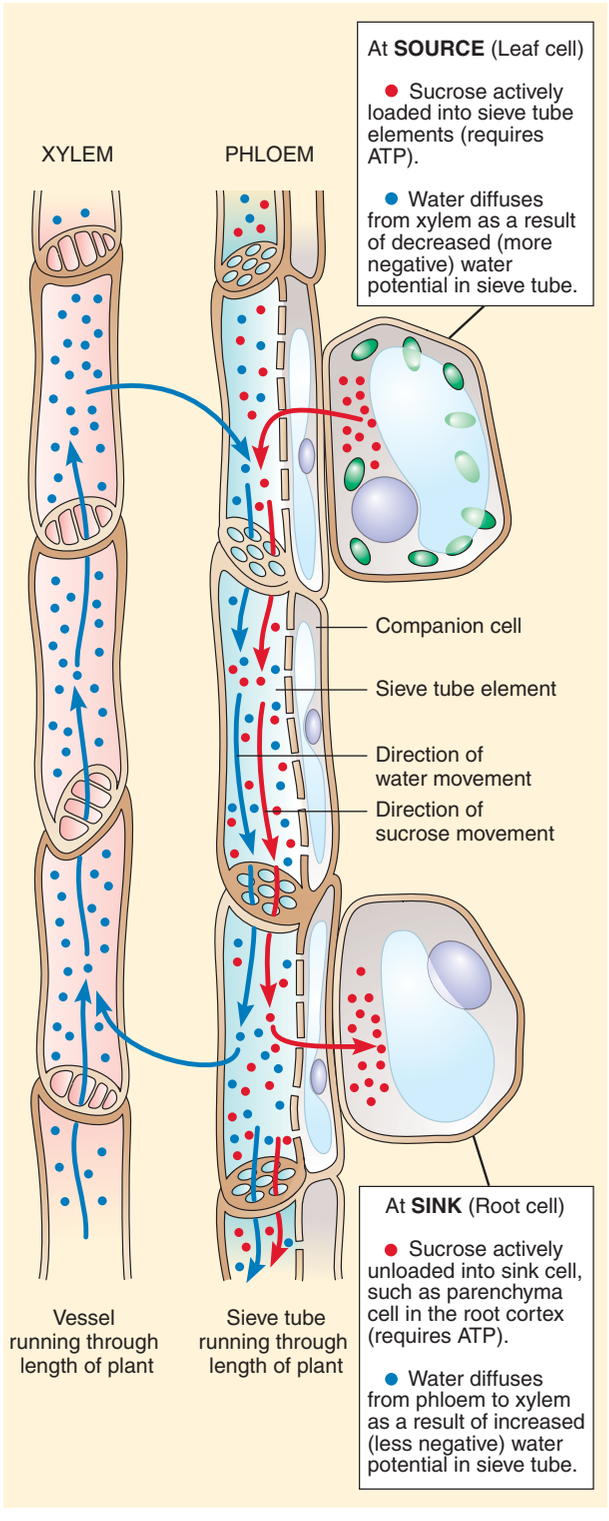
The pressure-flow hypothesis explains the movement of dissolved sugar in phloem by means of a pressure gradient. The difference in sugar concentrations between the source and the sink causes translocation in phloem, as water and dissolved sugar flow along the pressure gradient. This pressure gradient

ACTIVE FIGURE **33-12** **The pressure-flow hypothesis.**

Sugar is actively loaded into the sieve tube element at the source. As a result, water diffuses from the xylem into the sieve tube element. At the sink, the sugar is actively or passively unloaded, and water diffuses from the sieve tube element into the xylem. The pressure gradient within the sieve tube, from source to sink, causes translocation from the area of higher turgor pressure (the source) to the area of lower turgor pressure (the sink).

BiologyNow™ Learn more about **how sugar travels** by clicking on this figure on your BiologyNow CD-ROM.

KEY CONCEPT: In phloem, solutes move from sources to sinks.



pushes the sugar solution through phloem much as water is forced through a hose.

The actual translocation of dissolved sugar in phloem does not require metabolic energy. However, the loading of sugar at the source and the active unloading of sugar at the sink require energy derived from ATP to move the sugar across cell membranes by active transport.

PROCESS OF SCIENCE

Although the pressure-flow hypothesis adequately explains current data on phloem translocation, much remains to be learned about this complex process. Phloem translocation is difficult to study in plants. Because phloem cells are under pressure, cutting into phloem to observe it releases the pressure and causes the contents of the sieve tube elements (the phloem sap) to exude and mix with the contents of other severed cells that are also unavoidably cut. In the 1950s botanists developed a unique research tool to avoid contaminating the phloem sap: aphids, which are small insects that insert their mouthparts into phloem sieve tubes for feeding (Fig. 33-13). The pressure in the punctured phloem drives the sugar solution through the aphid's mouthpart and into its digestive system. When the aphid's mouthpart is severed from its body by a laser beam, the sugar solution continues to flow through the mouthpart at a rate proportional to the pressure in phloem. This rate can be measured, and the effects on phloem transport of different environmental conditions—varying light intensities, darkness, and mineral deficiencies, for example—can be ascertained.

The identity and proportions of translocated substances can also be determined using severed aphid mouthparts. This technique has verified that in most plant species the sugar sucrose is the primary carbohydrate transported in phloem; however, some species transport other sugars, such as raffinose, or sugar alcohols, such as sorbitol.

Review

- How does the direction of transport differ in xylem and phloem?
- What is water potential? How is the movement of water related to water potential?
- How does the tension-cohesion model explain the rise of water in the tallest trees?
- How does the pressure-flow hypothesis explain sugar movement in phloem? In your answer, make sure you include the activities at source and sink.

BiologyNow™ Assess your understanding of **transport in the plant body,** by taking the pretest on your BiologyNow CD-ROM.

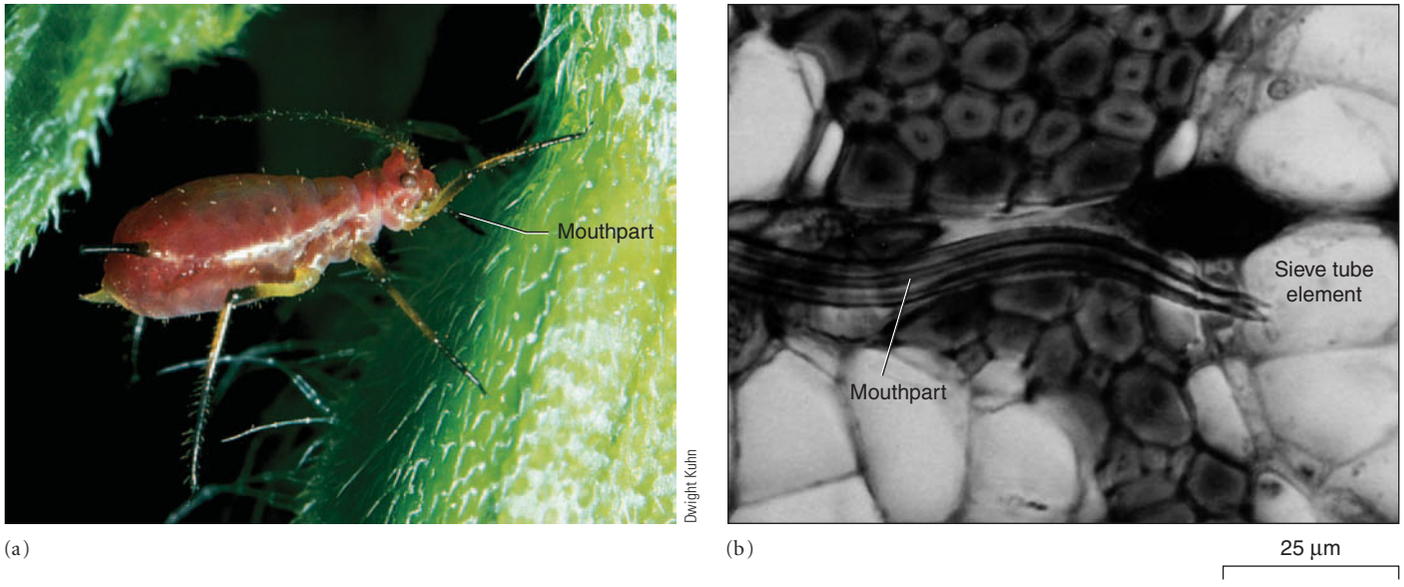


FIGURE **33-13** **Aphids are used to study translocation in phloem.**

SUMMARY WITH KEY TERMS

1 Describe the external features of a woody twig.

- Woody twigs demonstrate the external structure of stems. **Buds** are undeveloped embryonic shoots. A **terminal bud** is located at the tip of a stem, whereas **axillary buds** (**lateral buds**) are located in leaf axils. A dormant bud is covered and protected by **bud scales.** When the bud resumes growth, bud scales covering the bud fall off, leaving **bud scale scars.**
- The area on a stem where each leaf is attached is called a **node,** and the region of a stem between two successive nodes is an **internode.** A **leaf scar** shows where each leaf was attached to the stem. **Bundle scars** are the areas within a leaf scar where the vascular tissue extended from the stem to the leaf.
- **Lenticels** are sites of loosely arranged cells that allow oxygen to diffuse into the interior of a woody stem.

2 Label cross sections of herbaceous dicot and monocot stems, and describe the functions of each tissue.

- Herbaceous stems possess an epidermis, vascular tissue, and either ground tissue or cortex and pith. The **epidermis** is a protective layer covered by a water-conserving **cuticle. Stomata** permit gas exchange. **Xylem** conducts water and dissolved nutrient minerals, and **phloem** conducts dissolved sugar. The **cortex, pith,** and **ground tissue** function primarily for storage.
- Although all herbaceous stems have the same basic tissues, their arrangement varies considerably. Herbaceous dicot stems have the vascular bundles arranged in a circle (in cross section) and have a distinct cortex and pith. Monocot stems have vascular bundles scattered in ground tissue.

3 Name the two lateral meristems, and describe the tissues that arise from each.

- **Vascular cambium** is the lateral meristem that produces secondary xylem (wood) and secondary phloem (inner bark).
- **Cork cambium** produces **periderm,** which consists of cork parenchyma and cork cells. Cork cells are the functional replacement for epidermis in a woody stem. Cork parenchyma functions primarily for storage in a woody stem.

4 Outline the transition from primary growth to secondary growth in a woody stem.

- **Secondary growth** (the production of the secondary tissues, wood and bark) occurs in some flowering plants (woody dicots) and in all cone-bearing gymnosperms.
- During secondary growth, the vascular cambium, which develops between the primary xylem and the primary phloem, divides in two directions to form secondary xylem (to the inside) and secondary phloem (to the outside). The primary xylem and primary phloem in the original vascular bundles become separated as secondary growth proceeds.

5 Describe the pathway of water movement in plants.

- Water and dissolved nutrient minerals move from the soil into root tissues (epidermis, cortex, and so forth). Once in root xylem, water and dissolved minerals move upward, from root xylem to stem xylem to leaf xylem. Much of the water entering the leaf exits leaf veins and passes into the atmosphere.

6 Define *water potential.*

- **Water potential** is a measure of the **free energy** of water. Pure water has a water potential of 0 megapascals, whereas water with dissolved solutes has a negative water potential.

SUMMARY WITH KEY TERMS *(continued)*

- Water moves from an area of higher (less negative) water potential to an area of lower (more negative) water potential.

7 Explain the roles of tension-cohesion and root pressure as mechanisms responsible for the rise of water and dissolved nutrient minerals in xylem.

- The **tension-cohesion model** explains the rise of water in even the largest plants. The evaporative pull of **transpiration** causes tension at the top of the plant. This tension is the result of a water potential gradient that ranges from the slightly negative water potentials in the soil and roots to the very negative water potentials in the atmosphere. As a result of the **cohesive** and **adhesive** properties of water, the column of water pulled up through the plant remains unbroken.
- **Root pressure,** caused by the movement of water into roots from the soil as a result of the active absorption of nutrient mineral ions from the soil, helps explain the rise of water in smaller plants, particularly when the soil is wet. Root pressure pushes water up through xylem.

8 Describe the pathway of sugar translocation in plants.

- Dissolved sugar is **translocated** upward or downward in phloem, from a source (an area of excess sugar, usually a leaf) to a sink (an area of storage or of sugar use, such as roots, apical meristems, fruits, and seeds). Sucrose is the predominant sugar translocated in phloem.

9 Discuss the pressure-flow hypothesis of sugar translocation in phloem.

- The movement of materials in phloem is explained by the **pressure-flow hypothesis.**
- Companion cells actively load sugar into the sieve tubes at the source; ATP is required for this process. The ATP supplies energy to pump protons out of the sieve tube elements. The proton gradient drives the uptake of sugar by the cotransport of protons back into the sieve tube elements. Sugar therefore accumulates in the sieve tube element, causing the movement of water into the sieve tubes by **osmosis.**
- Companion cells actively (requiring ATP) and passively (not requiring ATP) unload sugar from the sieve tubes at the sink. As a result, water leaves the sieve tubes by osmosis, decreasing the **turgor pressure** (hydrostatic pressure) inside the sieve tubes.
- The flow of materials between source and sink is driven by the turgor pressure gradient produced by water entering phloem at the source and water leaving phloem at the sink.

POST-TEST

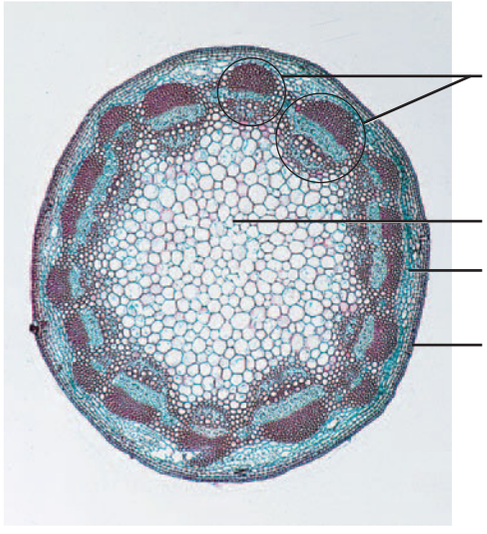
1. The three main functions of stems are (a) support, conduction, and photosynthesis (b) support, anchorage in soil, and production of new living tissues (c) conduction, production of new living tissues, and sexual reproduction (d) conduction, asexual reproduction, and sexual reproduction (e) support, conduction, and production of new living tissues
2. All stems have undeveloped embryonic shoots called (a) lenticels (b) buds (c) vines (d) phloem fiber caps (e) periderm
3. Axillary buds are located (a) at the tips of stems (b) in unusual places, such as on roots (c) in the region between two successive nodes (d) in the upper angle between a leaf and the stem to which it is attached (e) within the loosely arranged cells of lenticels
4. The tissue in monocot stems in which the vascular tissues are embedded is (a) cork cambium (b) cortex (c) ground tissue (d) pith (e) phloem
5. The protective outer layer of cells covering herbaceous stems is the (a) periderm (b) cork cambium (c) lateral meristem (d) epidermis (e) bud scale
6. Ground tissue in monocot stems performs the same functions as _____ and _____ in herbaceous dicot stems (a) phloem; xylem (b) cork cambium; vascular cambium (c) epidermis; periderm (d) primary xylem; secondary xylem (e) cortex; pith
7. Which of the following statements is *false?* (a) Primary growth is an increase in the length of a plant (b) Primary growth occurs at both apical and lateral meristems (c) All plants have primary growth (d) Herbaceous stems have primary growth, whereas woody stems have both primary and secondary growth (e) Buds are embryonic shoots that contain apical meristems
8. The two lateral meristems responsible for secondary growth are (a) phloem and xylem (b) cork cambium and vascular cambium (c) epidermis and periderm (d) primary xylem and secondary xylem (e) cortex and pith
9. Cork cambium and the tissues it produces are collectively called (a) periderm (b) lenticels (c) cortex (d) epidermis (e) wood
10. Horizontal movement of materials in woody plants occurs in (a) bud scales (b) cortex (c) rays (d) lenticels (e) pith rays
11. The older wood in the center of a tree trunk is commonly called (a) hardwood (b) softwood (c) sapwood (d) heartwood (e) cork
12. Each annual ring in a section of wood represents one year's growth of (a) primary xylem (b) secondary xylem (c) primary xylem or secondary xylem in alternate years (d) primary phloem (e) secondary phloem
13. Water potential is (a) the formation of a proton gradient across a cell membrane (b) the transport of a watery solution of sugar in phloem (c) the transport of water in both xylem and phloem (d) the removal of sucrose at the sink, causing water to move out of the sieve tubes (e) the free energy of water in a particular situation
14. Which of the following is a mechanism of water movement in xylem that does *not* generate sufficient force to explain the rise of water to the tops of the tallest trees? (a) pressure-flow hypothesis (b) tension-cohesion (c) root pressure (d) active transport of potassium ions into guard cells (e) transpiration
15. Which of the following is a mechanism of water movement in xylem that combines the evaporative pull of transpiration with the cohesive and adhesive properties of water? (a) pressure-flow (b) tension-cohesion (c) root pressure (d) active transport of potassium ions into guard cells (e) guttation
16. Which of the following is a mechanism of phloem transport in which dissolved sugar is moved by means of a pressure gradient

POST-TEST *(continued)*

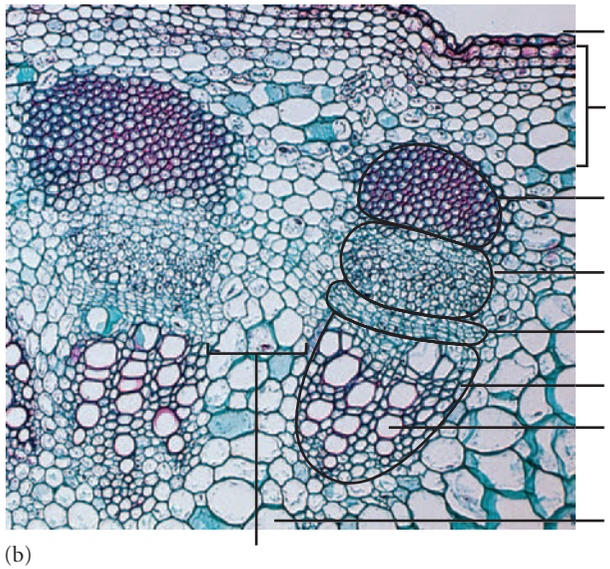
that exists between the source and the sink? (a) pressure-flow (b) tension-cohesion (c) root pressure (d) active transport of potassium ions into guard cells (e) guttation

17. How does increasing solute concentration affect water potential? (a) water potential becomes more positive (b) water potential becomes more negative (c) water potential becomes more positive under certain conditions and more negative under other conditions (d) water potential is not affected by solute concentration (e) water potential is always zero when solutes are dissolved in water

18. Label the various tissues, give at least one function for each tissue, and identify the stem as a herbaceous dicot, monocot, or woody plant. Use Figure 33-2 to check your answers.



(a)



(b)

CRITICAL THINKING

1. When secondary growth is initiated, certain cells become meristematic and begin to divide. Could a mature tracheid ever do this? A sieve tube element? Why or why not?
2. Why does the wood of many tropical trees lack annual rings? Why does the wood of other tropical trees possess annual rings?
3. Why is hardwood more desirable than softwood for making furniture? Explain your answer, based on the structural differences between hardwood and softwood.
4. Why should you cut off a few inches from the stem ends of cut flowers before placing them in water? Base your answer on what you have learned about the tension-cohesion model.

Roots and Mineral Nutrition

R. Calentine/Visuals Unlimited

Storage roots. Carrots (*Daucus carota*) are biennials that live for two years. During the first year's growth, food is stored in the fleshy root system; during the second year, the shoot elongates and produces flowers. Carrots and other root crops are important sources of human food.

CHAPTER OUTLINE

- **Root Structure and Function**
- **Root Associations with Other Organisms**
- **The Soil Environment**

In Chapters 32 and 33 we discussed the aerial vegetative structures of a plant: the leaves and stems. In this chapter we turn to the third major vegetative organ: the roots. Branching underground root systems are often more extensive than a plant's aerial parts. The roots of a corn plant, for example, may grow to a depth of 2.5 m (about 8 ft) and spread outward 1.2 m (4 ft) from the stem. Desert-dwelling tamarisk (*Tamarix*) trees reportedly have roots that grow to a depth of 50 m (163 ft) to tap underground water. The total root length, not counting root hairs, of a four-month-old rye (*Secale cereale*) plant was found to exceed 500 km (310 mi)! The extent of a plant's root depth and spread varies considerably among different species and even among different individuals in the same species. Soil conditions, discussed in this chapter, greatly affect the extent of root growth.

Because roots are usually underground and out of sight, people do not always appreciate the important functions they perform. First, as anyone who has ever pulled weeds can attest, roots anchor a plant securely in the soil. A plant needs a solid foundation from which to grow. Firm anchorage is essential to a plant's survival so that the stem remains upright, enabling leaves to absorb sunlight effectively.

Second, roots absorb water and dissolved nutrient minerals such as nitrates, phosphates, and sulfates, which are necessary for synthesizing important organic molecules. These dissolved nutrient minerals are then transported throughout the plant in the xylem.

Storage is the third main function performed by many roots. Carrots (see photograph), sweet potatoes, cassava, and other root crops are important sources of human food. Surplus sugars produced in the leaves by photosynthesis are transported in the phloem to the roots for storage (usually as starch or sucrose) until needed. Carrot roots have extensive phloem for this purpose. Although roots use some photosynthetic products for their own respiratory needs, most are stored and later transported out of the roots for use by the plant. Both *taproots* (carrots, beets,

radishes, and turnips) and *fibrous roots* (sweet potatoes) may be modified for storage. Plants with storage taproots are often **biennials** (see Chapter 31) that, as part of the strategy to survive winter, store their food reserves in the root during the first year's growth and use these reserves to reproduce during the second year's growth. Other plants, particularly those living in arid regions, possess storage roots adapted to store water.

In certain species, roots are modified for functions other than anchorage, absorption, conduction, and storage. Roots specialized to perform uncommon functions are discussed later in this chapter. ■

ROOT STRUCTURE AND FUNCTION

Learning Objectives

1. Distinguish between taproot and fibrous root systems.
2. Label cross sections of a primary dicot root and a monocot root, and describe the functions of each tissue.
3. Trace the pathway of water and nutrient mineral ions from the soil through the various root tissues, and distinguish between the symplast and apoplast.
4. Discuss the structure of roots with secondary growth.
5. Describe at least four roots that are modified to perform uncommon functions.

Two types of root systems, a taproot system and a fibrous root system, occur in plants (Fig. 34-1). A **taproot** system consists of one main root that formed from the seedling's enlarging **radicle,** or embryonic root. Many lateral roots of various sizes branch out of a taproot. Taproots are characteristic of many dicots and gymnosperms. A dandelion is a good example of a common herbaceous plant with a taproot system. A few trees, such as hickory, retain their taproots, which become quite massive as the plants age. Most trees, however, have taproots when young and later develop large, shallow lateral roots from which other roots branch off and grow downward.

A **fibrous root** system has several to many roots of similar size developing from the end of the stem, with lateral roots of various sizes branching off these roots. Fibrous root systems form in plants that have a short-lived embryonic root. The roots first originate from the base of the embryonic root and later from stem tissue. The main roots of a fibrous root system do not arise from pre-existing roots, but rather from the stem; such roots are called **adventitious roots.** Adventitious organs occur in an unusual location, such as roots that develop on a stem, or buds that develop on roots. Onions, crabgrass, and other monocots have fibrous root systems.

Taproot and fibrous root systems are adapted to obtain water in different sections of the soil. Taproot systems often extend down into the soil to obtain water located deep underground, whereas fibrous root systems, which are located relatively close to the soil surface, are adapted to obtain rainwater from a larger area as it drains into the soil.

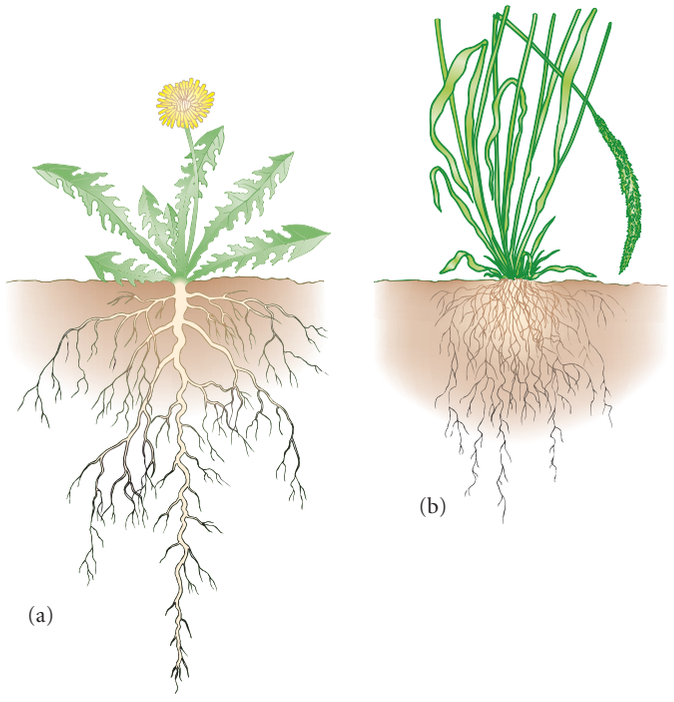

FIGURE **34-1** **Root systems.**
(a) A taproot system develops from the embryonic root in the seed. **(b)** The roots of a fibrous root system are adventitious and develop from stem tissue.

Roots have root caps and root hairs

Because of the need to adapt to the soil environment instead of the atmospheric environment, roots have several structures, such as root caps and root hairs, that shoots lack. Although stems and leaves have various types of hairs, they are distinct from root hairs in structure and function.

Each root tip is covered by a **root cap,** a protective, thimble-like layer many cells thick that covers the delicate root **apical meristem** (Fig. 34-2a; also see Fig. 31-7). As the root grows, pushing its way through the soil, cells of the root cap are sloughed off by the frictional resistance of the soil particles and replaced by new cells formed by the root apical meristem. The root cap cells secrete lubricating polysaccharides that reduce friction as the root passes through the soil. The root cap also appears to be involved in orienting the root so that it grows downward (see discussion of gravitropism in Chapter 36). When a root cap is removed, the root apical meristem grows a new cap. However, until the root cap has regenerated the root grows randomly rather than in the direction of gravity.

Root hairs are short-lived tubular extensions of epidermal cells located just behind the growing root tip. Root hairs continually form in the area of cell maturation closest to the root tip to replace those that are dying off at the more mature end of the root hair zone (Fig. 34-2b; also see Fig. 31-7). Each root hair is short (typically less than 1 cm, or 0.4 in, in length), but they are quite numerous. Root hairs greatly increase the absorptive

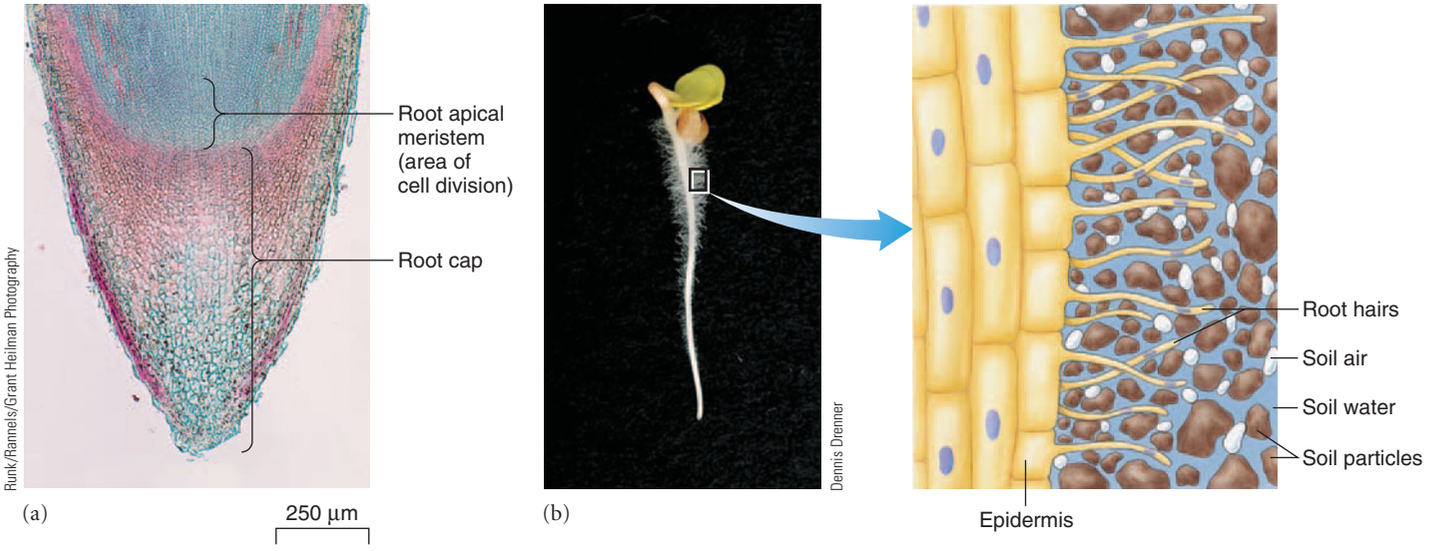

FIGURE **34-2** **Structures unique to roots.**

(a) LM of an oak (*Quercus* sp.) root tip showing its root cap. The root apical meristem is protected by the root cap. **(b)** Root hairs on a radish seedling. Each delicate hair is an extension of a single cell of the root epidermis. Root hairs increase the surface area of the root in contact with the soil. The seedling is approximately 5 cm (2 in) long.

capacity of roots by increasing their surface area in contact with moist soil. Soil particles are coated with a microscopically thin layer of water in which nutrient minerals are dissolved. The root hairs establish an intimate contact with soil particles, which allows absorption of much of the water and nutrient minerals.

Unlike stems, roots lack nodes and internodes and do not usually produce leaves or buds. Although herbaceous roots have certain primary tissues (such as epidermis, xylem, phloem, cortex, and pith) found in herbaceous stems, these tissues are arranged quite differently.

The arrangement of vascular tissues distinguishes the roots of herbaceous dicots and monocots

Although considerable variation exists in herbaceous dicot and monocot roots, they all have an outer protective covering (epidermis), a cortex for storage of starch and other organic molecules, and vascular tissues for conduction. Let us first consider the structure of herbaceous dicot roots.

In most herbaceous dicot roots, the central core of vascular tissue lacks pith

The buttercup root is a representative dicot root with primary growth (Fig. 34-3). Like other parts of this herbaceous dicot, a single layer of protective tissue, the **epidermis,** covers its roots. The root hairs are a modification of the root epidermis that enables it to absorb more water from the soil. The root epidermis does not secrete a thick, waxy cuticle in the region of root hairs, because this layer would impede the absorption of water from the soil. Both the lack of a cuticle and the presence of root hairs increase absorption. (*How* water moves from the soil into the root was explained in Chapter 33.)

Most of the water that enters the root moves along the cell walls rather than entering the cells. One of the major components of cell walls is cellulose, which absorbs water like a sponge. An example of the absorptive properties of cellulose is found in cotton balls, which are almost pure cellulose.

The **cortex,** which is primarily composed of loosely packed **parenchyma** cells, comprises the bulk of a herbaceous dicot root. Roots usually lack supporting **collenchyma** cells, probably because the soil supports the root, although roots may develop some **sclerenchyma** (another supporting tissue; see Chapter 31) as they age. The primary function of the root cortex is storage. A microscopic examination of the parenchyma cells that form the cortex often reveals numerous amyloplasts (see Fig. 34-3b and Fig. 3-9a), which store starch. Starch, an insoluble carbohydrate composed of glucose subunits, is the most common form of stored energy in plants. When used at a later time, these reserves provide energy for such activities as growth following winter or cell replacement following an injury.

The large intercellular (between-cell) spaces, a common feature of the root cortex, provide a pathway for water uptake and allow for aeration of the root. The oxygen that root cells need for aerobic respiration diffuses from air spaces in the soil into the intercellular spaces of the cortex and from there into the cells of the root.

The inner layer of the cortex, the **endodermis,** regulates the movement of nutrient minerals that enter the xylem in the root's center. Structurally, the endodermis differs from the rest of the cortex. Endodermal cells fit snugly against each other, and each has a special bandlike region, called a **Casparian strip** (Fig. 34-4),

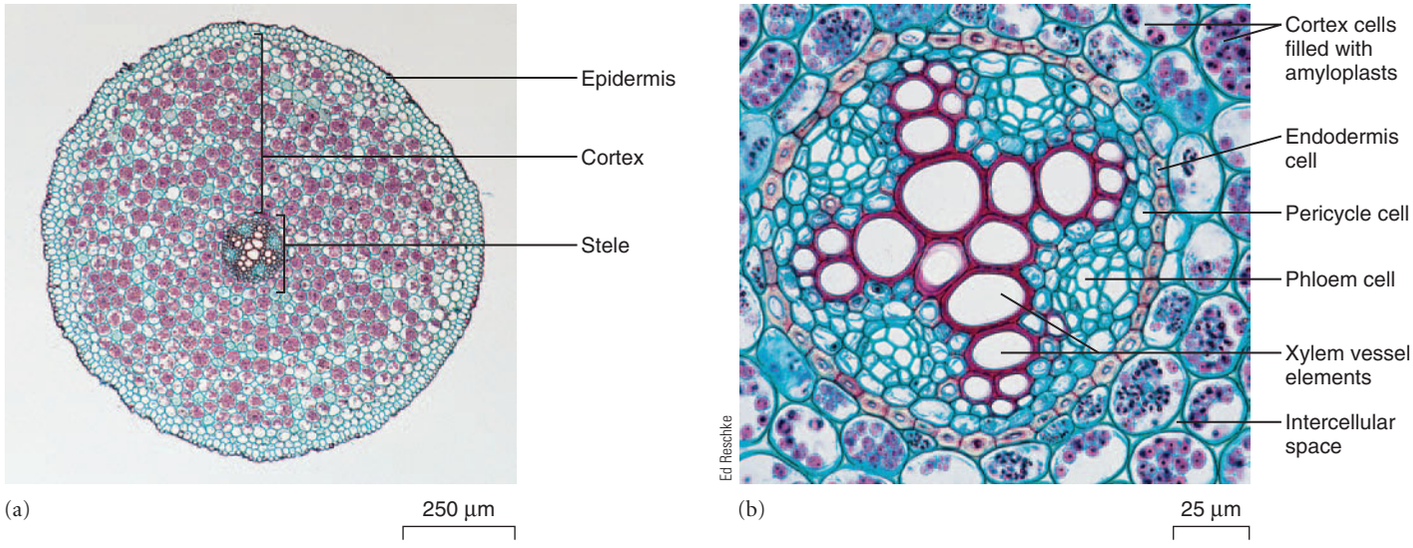

FIGURE 34-3 LMs of cross sections of a herbaceous dicot root.

Shown is a buttercup (*Ranunculus*) root. **(a)** Cortex comprises the bulk of herbaceous dicot roots. Note the X-shaped xylem in the center of the root. **(b)** Closeup of the root's stele. Surrounding the solid core of vascular tissues is a single layer of pericycle, which is meristematic in growing roots.

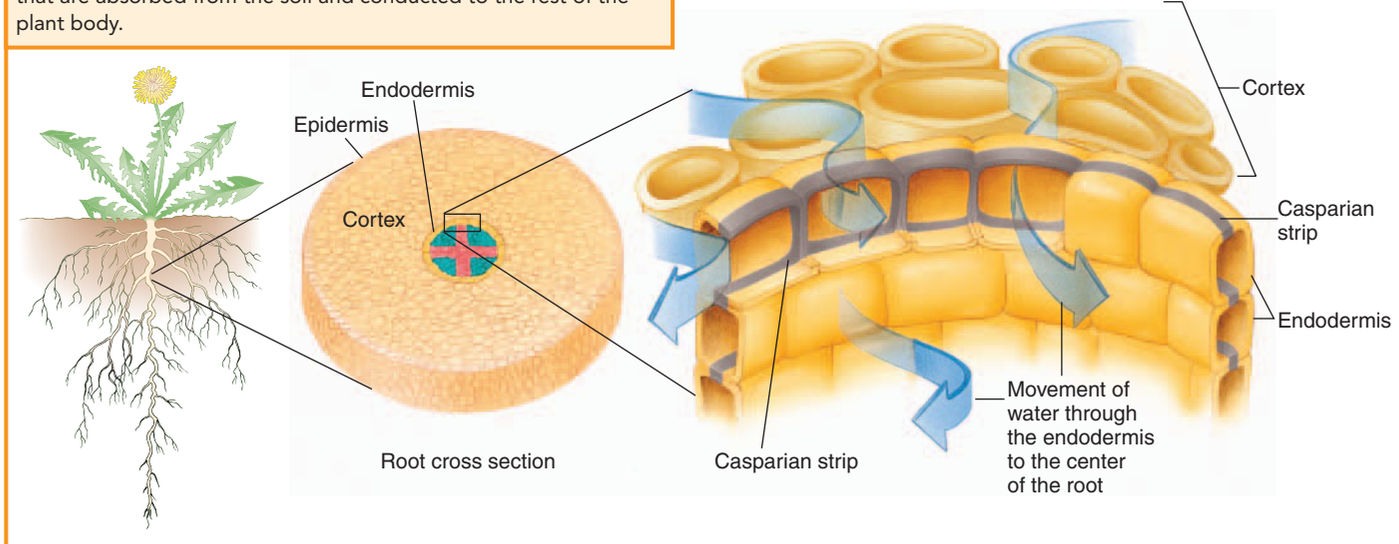
on its radial (side) and transverse (upper and lower) walls. If you compare the endodermis to a cylinder constructed of bricks, endodermal cells correspond to the bricks, and the Casparian strips correspond to the mortar between them. Casparian strips contain *suberin,* a fatty material that is waterproof. (Recall from Chapter 33 that suberin is also the waterproof material in cork cell walls.)

The water and dissolved nutrient minerals that enter the root cortex from the epidermis move in solution along two pathways: the symplast and apoplast. The **symplast** is the con-

FIGURE 34-4 Endodermis and nutrient mineral uptake.

Note the Casparian strip around the radial and transverse walls that prevents water and dissolved nutrient minerals from passing into the stele along endodermal cell walls. To reach the vascular tissues, water and dissolved nutrient minerals must pass through the plasma membranes of endodermal cells.

KEY CONCEPT: The endodermis regulates the kinds of minerals that are absorbed from the soil and conducted to the rest of the plant body.



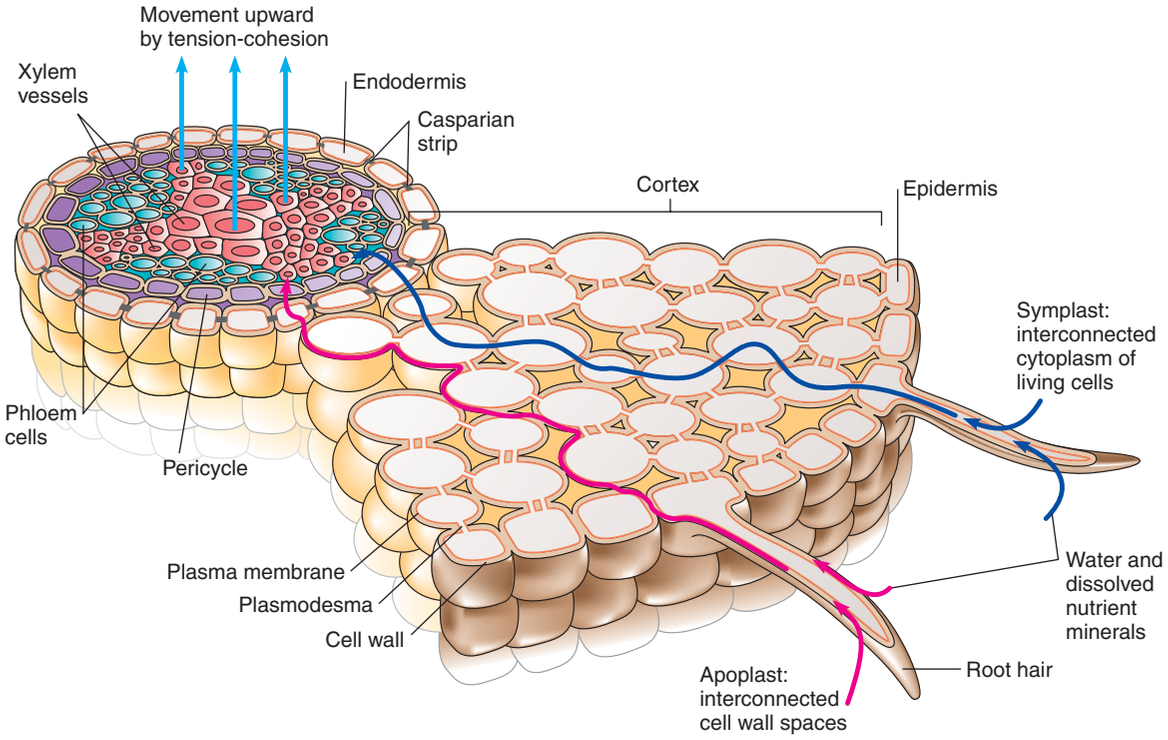


FIGURE **34-5** **Pathways of water and dissolved nutrient minerals in the root.**

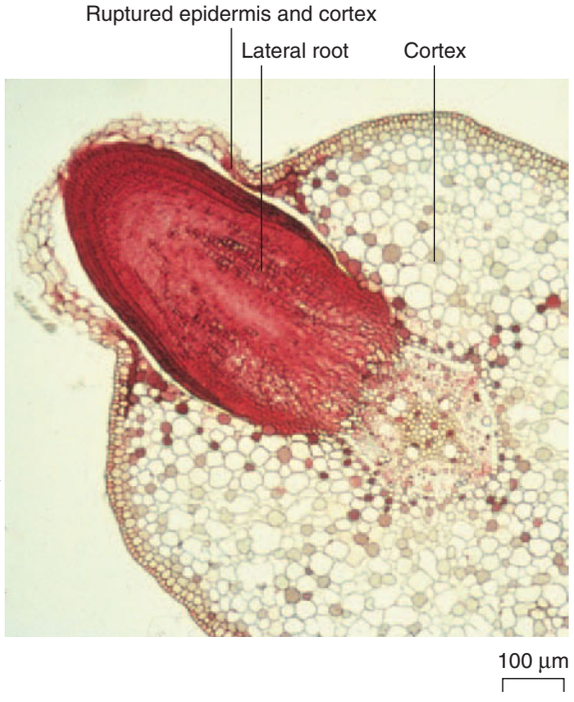
Water and dissolved nutrient minerals travel from cell to cell along the interconnected porous cell walls (the apoplast) or from one cell's cytoplasm to another through plasmodesmata (the symplast). On reaching the endodermis, water and nutrient minerals can only continue to move into the root's center if they pass through a plasma membrane and enter the cytoplasm of an endodermal cell. The Casparian strip blocks the passage of water and nutrient minerals along the cell walls between adjoining endodermal cells.

tinuum of living cytoplasm, which is connected from one cell to the next by cytoplasmic bridges called **plasmodesmata** (Fig. 34-5 and Fig. 5-25). Some dissolved mineral ions move from the epidermis through the cortex via the symplast. The **apoplast** consists of the interconnected porous cell walls of a plant, along which water and nutrient mineral ions move freely. The water and mineral ions can diffuse across the cortex without ever entering a living cell.

Until the endodermis is reached, most of the water and dissolved nutrient minerals have traveled along the apoplast and therefore have not passed through a plasma membrane or entered the cytoplasm of a root cell. However, the waterproof Casparian strip on the radial and transverse walls of the endodermal cells prevents water and nutrient minerals from continuing to move passively along the cell walls. For substances to pass further into the root interior, they must move from the cell walls into the cytoplasm of the endodermal cells. Water enters by osmosis, whereas nutrient minerals enter the endodermal cells by passing through carrier proteins in their plasma membranes. Even though dissolved nutrient minerals pass through the epidermis and cortex to reach the endodermis, it is the endodermis that is responsible for controlling the movement of nutrient minerals from the soil into the vascular tissue of the root (and from there to the rest of the plant body).

Dissolved nutrient mineral ions are actively transported through carrier proteins in the plasma membranes of endodermal cells (see Chapter 5). In **carrier-mediated active transport,** the nutrient mineral ions move *against* their concentration gradient—that is, from an area of *low* concentration of that mineral in the soil solution to an area of *high* concentration in the plant's cells. One of many reasons why root cells require sugar and oxygen for aerobic respiration is that this active transport requires the expenditure of cellular energy, usually in the form of ATP. From the endodermis, water and nutrient mineral ions enter the root xylem (botanists do not know precisely how this is done) and are conducted to the rest of the plant.

At the center of a dicot primary root is the **stele** or **vascular cylinder,** a central cylinder of vascular tissues (see Fig. 34-3a). The outermost layer of the stele is the **pericycle,** which is just inside the endodermis. The pericycle consists of a single layer of parenchyma cells that gives rise to multicellular lateral roots, also called *branch roots* (Fig. 34-6). Lateral roots originate when cells in a portion of the pericycle start dividing. As it grows, the lateral root pushes through several layers of root tissue (endodermis, cortex, and epidermis) before entering the soil. Each lateral root has all the structures and features—root cap, root hairs, epidermis, cortex, endodermis, pericycle, xylem, and phloem—of the larger root from which it emerges. In addition to pro-



James Mauseth, University of Texas

FIGURE **34-6** **LM of a lateral root.**
Lateral roots originate at the pericycle.

ducing lateral roots, the pericycle is involved in forming the lateral meristems that produce secondary growth in woody roots (discussed later in the chapter).

Xylem, the centermost tissue of the stele, often has two, three, four, or more extensions, or "xylem arms" (see Fig. 34-3b). **Phloem** is located in patches between the xylem arms. The xylem and phloem of the root have the same functions and kinds of cells as in the rest of the plant: Water and dissolved nutrient minerals are conducted in **tracheids** and **vessel elements** of xylem, and dissolved sugar (sucrose) is conducted in **sieve tube elements** of phloem.

After passing through the endodermal cells, water enters the root xylem, often at one of the xylem arms. Up to this point the pathway of water has been horizontal from the soil into the center of the root:

Root hair/epidermis ⟶ cortex ⟶ endodermis ⟶ pericycle ⟶ root xylem

Once water enters the xylem, it is transported upward through root xylem into stem xylem and from there to the rest of the plant.

One direction of phloem conduction is from the leaves, where sugar is made by photosynthesis, to the root, where sugar is used for the growth and maintenance of root tissues or stored, usually as starch. Another direction of phloem conduction is from the root, where sugar is stored as starch, to other parts of the plant, where sugar is used for growth and maintenance of tissues. The *vascular cambium,* which gives rise to secondary tissues in woody plants, is sandwiched between the xylem and phloem. Because it has an inner core of vascular tissue, the primary dicot root lacks **pith,** a ground tissue found in the centers of many stems and roots.

Xylem does not form the central tissue in some monocot roots

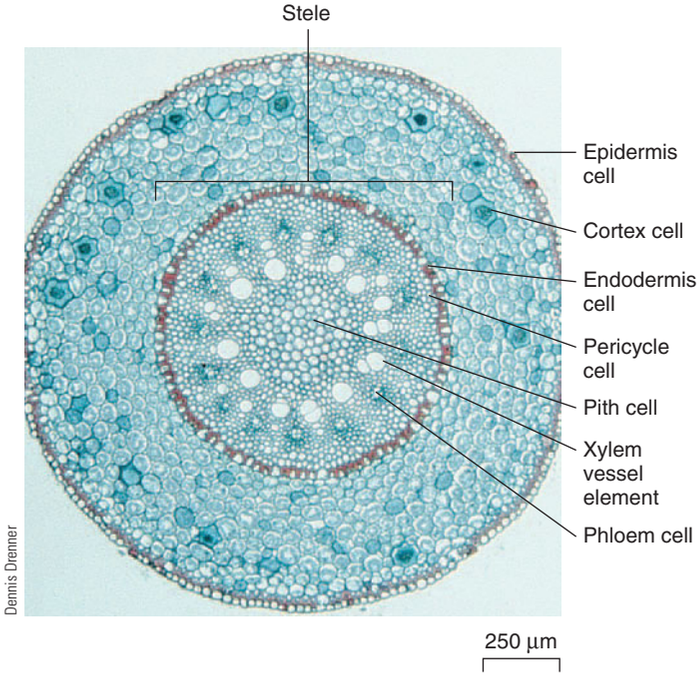
Monocot roots vary considerably in internal structure, compared with dicot roots. Starting at the outside of some monocot roots, there is epidermis, then cortex, endodermis, and pericycle (Fig. 34-7). Unlike the xylem in herbaceous dicot roots, the xylem in a monocot root does not form a solid cylinder in the center. Instead, the phloem and xylem are in separate alternating bundles arranged around the central pith, which consists of parenchyma cells.

Because virtually no monocots have secondary growth, no vascular cambium exists in monocot roots. Despite their lack of secondary growth, long-lived monocots, such as palms, may have thickened roots produced by a modified form of primary growth in which parenchyma cells in the cortex divide and enlarge.

Woody plants have roots with secondary growth

Plants that produce stems with secondary growth also produce roots with secondary growth. Recall from Chapter 33 that these plants—gymnosperms and woody dicots—have primary growth

FIGURE **34-7** **LM of a cross section of a monocot root.**
Shown is a greenbriar (*Smilax*) root. As in herbaceous dicot roots, the cortex of a monocot root is extensive.



Dennis Drenner

at apical meristems and secondary growth at lateral meristems. The production of secondary tissues occurs some distance back from the root tips and results from the activity of the same two lateral meristems found in woody stems: the vascular cambium and the cork cambium. Major roots of trees are often massive and have both wood and bark. In temperate climates, the wood of both roots and stems exhibits annual rings in cross section.

Before secondary growth starts in a root, the **vascular cambium** is sandwiched between the primary xylem and the primary phloem (Fig. 34-8a). At the onset of secondary growth, the vascular cambium extends out to the pericycle, which develops into vascular cambium opposite the xylem arms. As a result, the pericycle links the separate sections of vascular cambium so that the vascular cambium becomes a continuous, noncircular loop of cells in cross section (Fig. 34-8b). As the vascular cambium divides to produce secondary tissues, it eventually forms a cylinder of vascular cambium that continues to divide, producing secondary xylem (wood) to the inside and secondary phloem (inner bark) to the outside (Fig. 34-8c,d). The root increases in girth (thickness), and the vascular cambium continues to move outward.

The epidermis, cortex, endodermis, and primary phloem are gradually torn apart as the root increases in girth. The root epidermis is replaced by **periderm,** composed of cork cells and cork parenchyma, both produced by the **cork cambium** (the last figure in Table 31-4 shows a LM of periderm). The cork cambium in the root initially arises from regions in the pericycle.

Some roots are specialized for unusual functions

Adventitious roots often arise from the nodes of stems. Many aerial adventitious roots are adapted for functions other than anchorage, absorption, conduction, or storage. **Prop roots** are adventitious roots that develop from branches or a vertical stem and that grow downward into the soil to help support the plant in an upright position (Fig. 34-9a). Prop roots are more common in monocots than in dicots. Corn and sorghum, both monocots, are herbaceous plants that produce prop roots. Many tropical and subtropical dicot trees, such as red mangrove, and banyan also produce prop roots.

The roots of many tropical rainforest trees are shallow and concentrated near the surface in a mat only a few centimeters (an inch or so) thick. The root mat catches and absorbs almost all nutrient minerals released from leaves by decomposition. Swollen bases or braces called **buttress roots** hold the trees upright and aid in the extensive distribution of the shallow roots (Fig. 34-9b).

In swampy or tidal environments where the soil is flooded or waterlogged, some roots grow upward until they are above the high-tide level. Even though roots live in the soil, they still require oxygen for aerobic respiration. Flooded soils are depleted of oxygen, so these aerial "breathing" roots, known as **pneumatophores,** may assist in getting oxygen to the submerged roots (Fig. 34-9c). Pneumatophores, which also help anchor the plant, have a well-developed system of internal air spaces that is continuous with the submerged parts of the root, presumably allowing gas exchange. Black mangrove, white mangrove, and bald cypress are examples of plants with pneumatophores.

Climbing plants and **epiphytes,** which are plants that grow attached to other plants, have aerial roots that anchor the plant

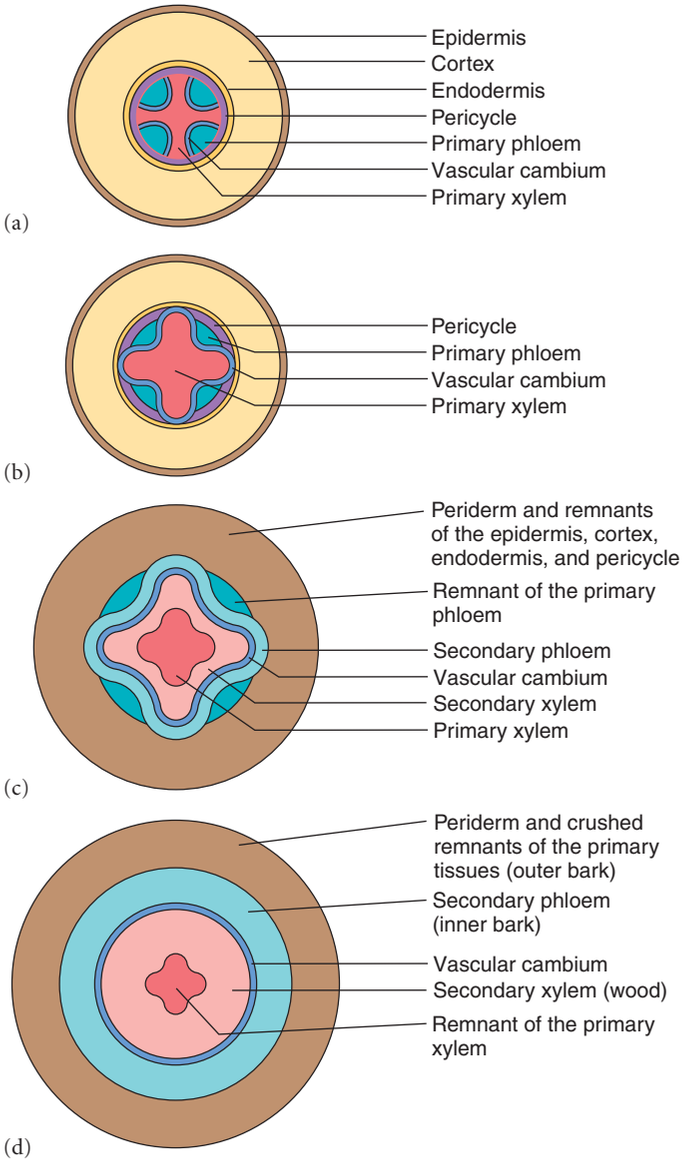


FIGURE **34-8** **Development of secondary vascular tissues in a primary root.**

(a) The tissues in a primary root. **(b)** At the onset of secondary growth, the vascular cambium extends out to the pericycle, forming a continuous, noncircular loop. **(c)** The vascular cambium produces secondary xylem to its inside and secondary phloem to its outside. **(d)** Over time, the ring of vascular cambium gradually becomes circular. As the vascular cambium continues to divide, the epidermis, cortex, and primary phloem located in the outer bark are torn apart. (The figures are not drawn to scale because of space limitations; the primary xylem is actually the same size in all four diagrams, but differences in scale make the xylem appear different sizes.)

FIGURE **34-9** **Specialized roots.**

(a) Prop roots are adventitious roots that arise near the base of the stem and provide additional support. *Pandanus* has an elaborate set of aerial prop roots. Photographed in Kauai, Hawaii. **(c)** White mangrove (*Laguncularia racemosa*) produces pneumatophores, shown protruding from the wet mud in the foreground. Pneumatophores may provide oxygen for roots buried in anaerobic (oxygen-deficient) soil. Photographed in Isla del Carmen, Mexico. **(e)** Plants that produce corms or bulbs often have contractile roots. During successive seasons, contractile roots pull the corm or bulb deeper into the soil.

to the bark, branch, or other surface on which they grow. Some epiphytes have aerial roots specialized for functions other than anchorage. Certain epiphytic orchids, for example, have photosynthetic roots (Fig. 34-9d). Epiphytic roots may absorb moisture as well. Some parasitic epiphytes such as mistletoe have modified roots that penetrate the host plant tissues and absorb water. Another plant that starts its life as an epiphyte is the strangler fig, which produces long roots that eventually reach the ground and anchor the plant (now a tree rather than an epiphyte) in the soil. The tree on which the strangler fig originally grew is often killed as the strangler fig grows around it, competing with it for light and other resources and crushing its secondary phloem.

Plants that produce corms or bulbs (underground stems or buds specialized for asexual reproduction; see Chapter 35) often have wiry **contractile roots** in addition to their "normal" roots. The contractile roots grow into the soil and then contract (the cortical cells shorten or totally collapse), thus pulling the corm or bulb deeper into the soil (Fig. 34-9e). Contractile roots are necessary for corms because each succeeding year's growth is *on top of* the preceding year's growth. As a result, corms tend to move upward in the soil over time. Without contractile roots they would eventually be exposed at the soil's surface. Contractile roots are more common in monocots, but certain dicots and ferns also possess them.

Review

ROOT ASSOCIATIONS WITH OTHER ORGANISMS

Learning Objective

6 List and describe two mutualistic relationships between roots and other organisms.

The roots of most plant species form **mutualistic**—that is, mutually beneficial—relationships with certain soil fungi (see Chapters 25 and 52). These subterranean associations, known as **mycorrhizae,** permit the transfer of materials (such as sugars) from roots to the fungus. At the same time, essential nutrient minerals such as phosphorus move from fungus to the roots of the host plant. The threadlike body of the fungal partner extends into the soil, extracting nutrient minerals well beyond the reach of the plant's roots. In some mycorrhizae, the fungal mycelium encircles the root like a sheath; in others, the fungus penetrates root cells (Fig. 34-10). The relationship is mutually beneficial because when mycorrhizae are not present, neither the fungus nor the plant grows as well (see Fig. 25-15). Recent evidence indicates that the hyphal network of mycorrhizae simultaneously interconnects different plant species in the community and that carbon compounds may flow from one plant to another through their mutual fungal partner.

Certain nitrogen-fixing bacteria, collectively called *rhizobia,* form associations with the roots of leguminous plants—clover, peas, and soybeans, for example. **Nodules** (swellings) that house millions of the rhizobia develop on the roots (see Fig. 53-8). As with mycorrhizae, the association between nitrogen-fixing bacteria and the roots of plants is mutually beneficial. Bacteria receive photosynthetic products from plants while helping them meet their nitrogen requirements by producing ammonia (NH_3) from atmospheric nitrogen.

For several decades, biologists have studied the molecular basis of associations between plants and rhizobia. The initial contact between the two partners in this association involves **cell signaling,** that is, communication between cells. Some signal molecules produced by the bacteria are nodulation factors that cause the roots of leguminous plants to produce nodules.

Roots also form associations with organisms other than fungi and bacteria. As roots of certain trees grow through the soil, they sometimes encounter roots of other trees of the same or different species. When this occurs, they may grow together by secondary growth to form a natural **graft.** Because their vascular tissues are connected in the graft, dissolved sugars and other materials such as hormones pass between the two trees; disease organisms can also be transmitted in this way. Root grafts have been observed in more than 160 tree species.

Review

- How are mycorrhizae and root nodules similar? How are they different?
- What are root grafts?

THE SOIL ENVIRONMENT

Learning Objectives

7 Describe the roles of weathering, organisms, climate, and topography in soil formation.

8 List the four components of soil, and give the ecological significance of each.

9 Describe how roots absorb positively charged nutrient mineral ions by the process of cation exchange.

10 Distinguish between macronutrients and micronutrients.

11 Explain the impacts of mineral depletion and soil erosion on plant growth.

We now examine the soil environment in which most roots live. Soil is a relatively thin layer of Earth's crust that has been modified by the natural actions of weather, wind, water, and organisms. It is easy to take soil for granted. We walk on and over it throughout our lives but rarely stop to think about how impor-

FIGURE **34-10** **Mycorrhizae.**

Mycorrhizae enhance plant growth by providing soil nutrients to the roots. **(a)** LM of ectomycorrhizae, fungal associations that form a sheath around the root. The fungal hyphae penetrate the root between cortical cells but do not enter the cells. **(b)** LM of endomycorrhizae, fungal associations in which the fungal hyphae penetrate root cells of the cortex and form branched haustoria (absorbing organs) within the cells to aid in delivering and receiving nutrients. Roots of most vascular plant species are colonized by endomycorrhizae.

tant it is to our survival. Vast numbers and kinds of organisms colonize soil and depend on it for shelter and food. Most plants anchor themselves in soil, and from it they receive water and essential nutrient minerals. Most elements essential for plant growth are obtained directly from the soil. Most plants cannot survive on their own without soil, and because we depend on plants for our food, humans could not exist without soil either.

Most soils are formed from rock (called *parent material*) that is gradually broken down, or fragmented, into smaller and smaller particles by biological, chemical, and physical **weathering processes.** Two important factors that work together in the weathering of rock are climate and organisms. When plant roots and other organisms living in the soil respire, they produce carbon dioxide (CO_2), which diffuses into the soil and reacts with soil water to form carbonic acid (H_2CO_3). Soil organisms such as lichens[1] also produce other kinds of acids. These acids etch tiny cracks, or fissures, in the rock surface; water then seeps into these cracks. If the parent material is located in a temperate climate, the alternate freezing and thawing of the water during winter cause the cracks to enlarge, breaking off small pieces of rock. Small plants can then become established and send their roots into the larger cracks, fracturing the rock further.

Topography, a region's surface features, such as the presence or absence of mountains and valleys, is also involved in soil formation. Steep slopes often have little or no soil on them, because the soil and rock are continually transported down the slopes by gravity. Runoff from precipitation tends to amplify erosion on steep slopes. Moderate slopes, in contrast, may encourage the formation of deep soils.

The disintegration of solid rock into finer and finer mineral particles and the accumulation of organic material (discussed in the next section) in the soil take an extremely long time, sometimes thousands of years. Soil forms constantly as the weathering of parent material beneath already formed soil continues to add new soil.

Soil is composed of inorganic minerals, organic matter, air, and water

Four distinct components comprise soil—inorganic mineral particles (which make up about 45% of a typical soil), organic matter (about 5%), water (about 25%), and air (about 25%). The plants, animals, fungi, and microorganisms that inhabit soil interact with it, and nutrient minerals are continually cycled from the soil to organisms, which use them in their biological processes. When the organisms die, bacteria and other soil organisms decompose the remains, returning the nutrient minerals to the soil.

The inorganic mineral particles, which come from weathered rock, provide anchorage and essential nutrient minerals for plants, as well as pore space for water and air. Because different rocks consist of different minerals, soils vary in mineral

[1] A lichen is a dual organism composed of a fungus and a phototroph (photosynthetic organism). See Chapter 25 for further discussion of lichens.

composition and chemical properties. Rocks rich in aluminum form acidic soils, for example, whereas rocks that contain silicates of magnesium and iron form soils that may be deficient in calcium, nitrogen, and phosphorus. Also, soils formed from the same kind of parent material may not develop in the same way, because other factors, such as weather, topography, and organisms, differ.

The texture, or structural characteristic, of a soil is determined by the percentages (by weight) of the different-sized inorganic mineral particles—sand, silt, and clay—in it. The size assignments for sand, silt, and clay give soil scientists a way to classify soil texture. Particles larger than 2 mm in diameter, called gravel or stones, are not considered soil particles, because they do not have any direct value to plants. The largest soil particles, are called *sand* (0.02 to 2 mm in diameter), the medium-sized particles are called *silt* (0.002 to 0.02 mm in diameter), and the smallest particles are called *clay* (less than 0.002 mm in diameter). Sand particles are large enough to be seen easily with the eye, and silt particles (about the size of flour particles) are barely visible. Most individual clay particles are too small to be seen with an ordinary light microscope; they can be seen only under an electron microscope.

A soil's texture affects many of that soil's properties, in turn influencing plant growth. The clay component of a soil is particularly important in determining many of its characteristics because clay particles have the greatest surface area of all soil particles. If the surface areas of about 450 g (1 lb) of clay particles were laid out side by side, they would occupy 1 hectare (2.5 acres).

Each clay particle has predominantly negative electrical charges on its outer surface that attract and reversibly bind **cations,** which are positively charged mineral ions such as potassium (K^+) and magnesium (Mg^{2+}). Because many cations are essential for plant growth, cation absorption to soil particles is an important aspect of soil fertility. Roots secrete protons (hydrogen ions, H^+), which are exchanged for other positively charged mineral ions absorbed to the surface of soil particles in a process known as **cation exchange.** These "freed" ions and the water that forms a film around the soil particles are absorbed by the plant's roots (Fig. 34-11).

In contrast, **anions,** which are negatively charged mineral ions, are repelled by the negative surface charges of clay particles and tend to remain in solution. Anions such as nitrate (NO_3^-) are often washed out of the root zone by water moving through the soil.

Soil always contains a mixture of different-sized particles, but the proportions vary from one soil to another. A *loam*, which is an ideal agricultural soil, has an optimum combination of different soil particle sizes: It contains approximately 40% each of sand and silt and about 20% of clay. Generally, the larger particles provide structural support, aeration, and permeability to the soil, whereas the smaller particles bind together into aggregates, or clumps, and hold nutrient minerals and water. Soils with larger proportions of sand are not as desirable for most plants, because they do not hold water and nutrient mineral ions well. Plants grown in such soils are more susceptible to drought and nutrient mineral deficiencies. Soils with larger proportions of clay are also not desirable for most plants because they provide poor drainage and often do not provide enough oxygen. Clay soils used in agriculture tend to get compacted, which reduces the number of soil spaces that can be filled by water and air.

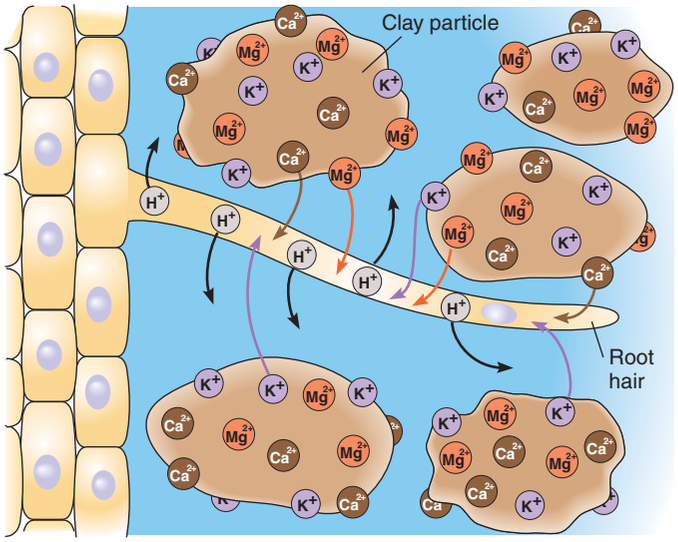

FIGURE **34-11** **Cation exchange.**
Negatively charged clay particles bind to positively charged nutrient mineral cations, holding them in the soil. Roots pump out protons (H^+), which are exchanged for the cations, facilitating their absorption.

A soil's organic matter consists of the wastes and remains of soil organisms

The organic matter in soil is composed of litter (dead leaves and branches on the soil's surface); droppings (animal dung); and the dead remains of plants, animals, and microorganisms in various stages of decomposition. Organic matter is decomposed by microorganisms, particularly bacteria and fungi, that inhabit the soil. During decomposition, essential nutrient mineral ions are released into the soil, where they may be bound by soil particles or absorbed by plant roots. Organic matter increases the soil's water-holding capacity by acting much like a sponge. For this reason gardeners often add organic matter to soils, especially sandy soils, which are naturally low in organic matter.

The partly decayed organic portion of the soil is referred to as **humus**. Humus, which is not a single chemical compound but a mix of many organic compounds, binds nutrient mineral ions and holds water. On average, humus persists in agricultural soil for about 20 years. Certain components of humus may persist in the soil for hundreds of years. Although humus is somewhat resistant to decay, a succession of microorganisms gradually reduces it to carbon dioxide, water, and nutrient minerals.

About 50% of soil volume is composed of pore spaces

Soil has numerous pore spaces of different sizes around and among the soil particles. Pore spaces occupy roughly 50% of a

soil's volume and are filled with varying proportions of air and water. Both soil air and soil water are necessary to produce a moist but aerated soil that sustains plants and other soil-dwelling organisms. Water is usually held in the smaller pores, whereas air is found in the larger pores. After a prolonged rain, almost all the pore spaces may be filled with water, but water drains rapidly from the larger pore spaces, drawing air from the atmosphere into those spaces.

Soil air contains the same gases as atmospheric air, although they are usually present in different proportions. As a result of respiration by soil organisms, there is less oxygen and more carbon dioxide in soil air than in atmospheric air. (Recall from Chapter 7 that aerobic respiration uses oxygen and produces carbon dioxide.) Among the important gases in soil are oxygen (O_2), required by soil organisms for aerobic respiration; nitrogen (N_2), used by nitrogen-fixing bacteria; and carbon dioxide (CO_2), involved in soil weathering.

Soil water originates as precipitation, which drains downward, or as groundwater (water stored in porous underground rock), which rises upward from the water table (the uppermost level of groundwater). Soil water contains low concentrations of dissolved nutrient minerals that enter the roots of plants when they absorb water. Water not bound to soil particles or absorbed by roots percolates (moves down) through soil, carrying dissolved nutrient minerals with it. The removal of dissolved materials from soil by percolating water is called **leaching.** The deposition of leached material in the lower layers of soil is known as **illuviation.** Iron and aluminum compounds, humus, and clay are some illuvial materials that can gather in the subsurface portion of the soil. Some substances completely leach out of the soil because they are so soluble that they migrate down into the groundwater. It is also possible for water that is moving *upward* through the soil to carry dissolved materials with it.

The organisms living in the soil form a complex ecosystem

A single teaspoon of fertile agricultural soil may contain millions of microorganisms such as bacteria, fungi, algae, protozoa, and microscopic nematodes and other worms. Many other organisms also colonize the soil ecosystem, including plant roots, earthworms, insects, moles, snakes, and groundhogs (Fig. 34-12). Most numerous in soil are bacteria, which number in the hundreds of millions per gram of soil. Scientists have identified about 170,000 species of soil organisms, but thousands remain to be identified. Little is known about the roles of soil organisms, in part because it is hard to study their activities under natural conditions.

Worms are some of the most important organisms living in soil. Earthworms, probably one of the most familiar soil inhabitants, ingest soil and obtain energy and raw materials by digesting humus. *Castings,* bits of soil that have passed through the gut of an earthworm, are deposited on or near the soil surface. In this way, nutrient minerals from deeper layers are brought to upper layers. Earthworm tunnels serve to aerate the soil, and the worms' waste products and corpses add organic material to the soil.

Ants live in the soil in enormous numbers, constructing tunnels and chambers that help aerate it. Members of soil-dwelling ant colonies forage on the surface for bits of food, which they carry back to their nests. Not all this food is eaten, however, and its eventual decomposition helps increase the organic matter in the soil. Many ants are also indispensable in plant reproduction because they bury seeds in the soil.

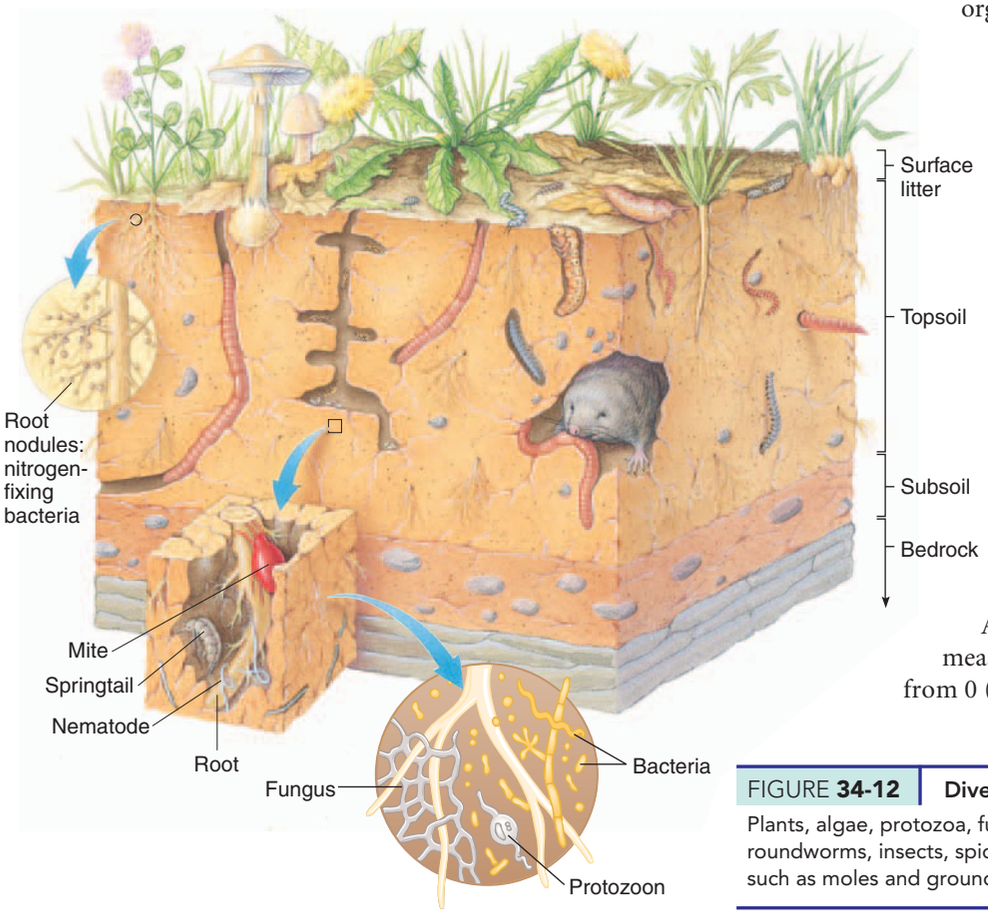

FIGURE **34-12** **Diversity of life in fertile soil.**
Plants, algae, protozoa, fungi, bacteria, earthworms, flatworms, roundworms, insects, spiders and mites, and burrowing animals such as moles and groundhogs live in soil.

Soil pH affects soil characteristics and plant growth

As discussed in Chapter 2, acidity is measured using the pH scale, which extends from 0 (extremely acidic) through 7 (neutral)

to 14 (extremely alkaline). The pH of most soils ranges from 4 to 8, but some soils are outside this range. The soil of the Pygmy Forest in Mendocino County, California, is extremely acidic (pH 2.8–3.9). At the other extreme, certain soils in Death Valley, California, have a pH of 10.5.

Plants are affected by soil pH, partly because the solubility of certain nutrient minerals varies with differences in pH. Soluble nutrient minerals can be absorbed by the plant, whereas insoluble forms cannot. At a low pH, for example, aluminum and manganese in soil water are more soluble and are sometimes absorbed by the roots in toxic concentrations. At a higher pH, certain nutrient mineral salts essential for plant growth, such as calcium phosphate, become less soluble and thus less available to plants.

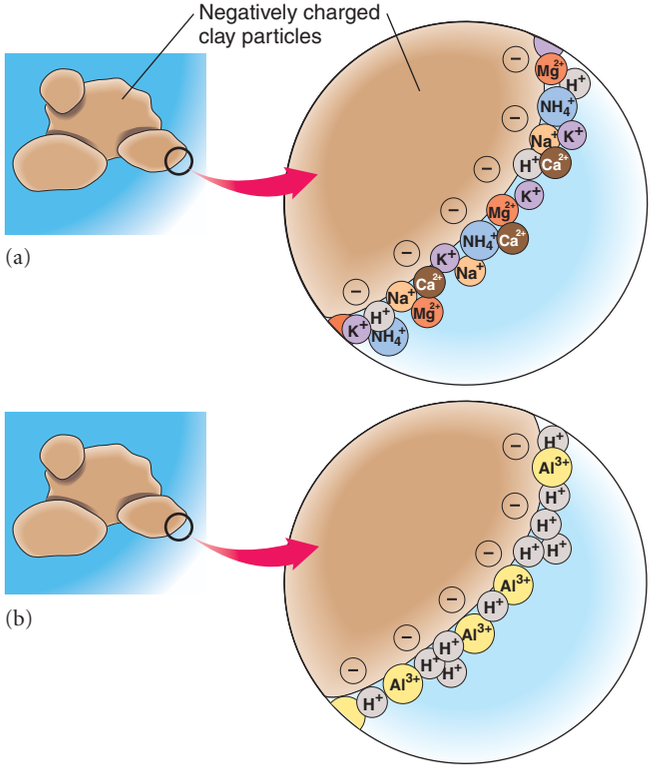
Soil pH also affects the leaching of nutrient minerals. An acidic soil has less ability to bind positively charged ions to it because the soil particles also bind the abundant protons (Fig. 34-13). As a result, certain nutrient mineral ions essential for plant growth, such as potassium (K^+), are leached more readily from acidic soil. The optimum soil pH for most plant growth is 6.0 to 7.0, because most essential nutrient minerals are available to plants in that pH range.

Soil pH affects plants, and plants and other organisms in turn influence soil pH. The decomposition of humus and the cellular respiration of soil organisms and roots decrease the pH of the soil.

Acid precipitation, a type of air pollution in which sulfuric and nitric acids produced by human activities fall to the ground as acid rain, sleet, snow, or fog, can seriously decrease soil pH. Acid precipitation is one of several factors implicated in **forest decline,** the gradual deterioration, and often death, of trees that has been observed in many European and North American forests. Forest decline may be partly the result of soil changes caused by acid precipitation. In central European forests that have experienced forest decline, for example, a strong correlation exists between forest damage and soil chemistry altered by acid precipitation.

FIGURE **34-13** **How acid alters soil chemistry.**

(a) In normal soil, positively charged nutrient mineral ions are attracted to the negatively charged soil particles. **(b)** In acidified soil, protons displace the cations. Aluminum ions released from inorganic mineral particles when the soil becomes acidified also adhere to soil particles.



Soil provides most of the minerals found in plants

More than 90 naturally occurring elements exist on Earth, and more than 60 of these, including elements as common as carbon and as rare as gold, have been found in plant tissues. Not all these elements are essential for plant growth, however.

Nineteen elements have been found essential for most, if not all, plants (Table 34-1). Ten of these are required in fairly large quantities (greater than 0.05% dry weight) and are therefore known as **macronutrients.** These include carbon, hydrogen, oxygen, nitrogen, potassium, calcium, magnesium, phosphorus, sulfur, and silicon. The remaining nine **micronutrients** are needed in trace amounts (less than 0.05% dry weight) for normal plant growth and development. These include chlorine, iron, boron, manganese, sodium, zinc, copper, nickel, and molybdenum.

Four of the 19 elements—carbon, oxygen, hydrogen, and nitrogen—come directly or indirectly from soil water or from gases in the atmosphere. Carbon is obtained from carbon dioxide in the atmosphere during photosynthesis. Oxygen is obtained from atmospheric oxygen (O_2) and water (H_2O). Water also supplies hydrogen to the plant. Plants absorb their nitrogen from the soil as ions of nitrogen salts, but the nitrogen in nitrogen salts ultimately comes from atmospheric nitrogen. The remaining 15 essential elements are obtained from the soil as dissolved nutrient mineral ions. Their ultimate source is the parent material from which the soil was formed.

Let us examine the main functions of essential elements. Carbon, hydrogen, and oxygen are found as part of the structure of all biologically important molecules, including lipids, carbohydrates, nucleic acids, and proteins. Nitrogen is part of proteins, nucleic acids, and chlorophyll.

Potassium, which plants use in fairly substantial amounts, is not found in a specific organic compound in plant cells. Instead, it remains as free K^+ and plays a key physiological role in maintaining the turgidity of cells because it is osmotically active. The presence of K^+ in cytoplasm causes water to pass through the plasma membrane into the cell by osmosis. Potassium is also involved in the opening and closing of stomata (see Chapter 32).

Calcium plays a key structural role as a component of the middle lamella (the cementing layer between cell walls of adja-

TABLE 34-1 Functions of Elements Required by Most Plants

Element	Taken Up As	Major Functions
Macronutrients		
Carbon	CO_2	Component of carbohydrate, lipid, protein, and nucleic acid molecules
Hydrogen	H_2O	Component of carbohydrate, lipid, protein, and nucleic acid molecules
Oxygen	CO_2, H_2O	Component of carbohydrate, lipid, protein, and nucleic acid molecules
Nitrogen	NO_3^-, NH_4^+	Component of proteins, nucleic acids, chlorophyll, certain coenzymes
Potassium	K^+	Osmotic and ionic balance; opening and closing of stomata; enzyme activator (for 40+ enzymes)
Calcium	Ca^{2+}	In cell walls; involved in membrane permeability; enzyme activator; second messenger
Magnesium	Mg^{2+}	In chlorophyll; enzyme activator in carbohydrate metabolism
Phosphorus	HPO_4^{2-}, $H_2PO_4^-$	In nucleic acids, phospholipids, ATP (energy transfer compound)
Sulphur	SO_4^{2-}	In certain amino acids and vitamins
Silicon	SiO_3^{2-}	In cell walls
Micronutrients		
Chlorine	Cl^-	Ionic balance; involved in photosynthesis
Iron	Fe^{2+}, Fe^{3+}	In enzymes and electron transport molecules involved in photosynthesis, respiration and nitrogen fixation
Boron	$H_2BO_3^-$	In cell walls; involved in nucleic acid metabolism and in cell growth
Manganese	Mn^{2+}	In enzymes involved in respiration and nitrogen metabolism; required for photosynthesis
Sodium	Na^+	Involved in photosynthesis; substitutes for potassium in osmotic and ionic balance
Zinc	Zn^{2+}	In enzymes involved in respiration and nitrogen metabolism
Copper	Cu^+, Cu^{2+}	In enzymes involved in photosynthesis
Nickel	Ni^{2+}	In enzymes (urease) involved in nitrogen metabolism
Molybdenum	MoO_4^{2-}	In enzymes involved in nitrogen metabolism

cent plant cells). Calcium ions (Ca^{2+}) are also important in a number of physiological roles in plants, such as altering membrane permeability and as **second messengers** in various cell signaling responses (see Chapter 5).

Magnesium is critical for plants because it is part of the chlorophyll molecule. Phosphorus is a component of nucleic acids, phospholipids (an essential part of cell membranes), and energy transfer molecules such as ATP. Sulfur is essential because it is found in certain amino acids and vitamins. Many plants accumulate silicon in their cell walls and intercellular spaces. Silicon enhances the growth and fertility of some species and may help reinforce cell walls.

Chlorine and sodium are micronutrients that help maintain turgor of cells. In addition to this osmotic role, chloride (Cl^-) and sodium (Na^+) ions are essential for photosynthesis. Six of the micronutrients (iron, manganese, zinc, copper, nickel, and molybdenum) are associated with various plant enzymes, often as **cofactors,** and are involved in certain enzymatic reactions. Boron, present in cell walls, is also involved in nucleic acid metabolism and in cell growth.

How do biologists determine whether an element is essential?

It is impossible to conduct mineral nutrition experiments by growing plants in soil, because soil is too complex and contains too many elements. Therefore, nutritional studies require special methods. One of the most useful techniques to test whether an element is essential is **hydroponics,** which is the growing of plants in aerated water to which nutrient mineral salts have been added. Hydroponics also has commercial applications in addition to its scientific use (Fig. 34-14).

If biologists suspect a particular element is essential for plant growth, they grow plants in a nutrient solution that contains all known essential elements *except* the one in question. If plants grown in the absence of that element can't develop normally or complete their life cycle, the element may be essential. Additional criteria are used to confirm whether an element is essential. For example, it must be demonstrated that the element has a direct effect on the plant's metabolism and that the element is essential for a wide variety of plants.

Soil can be damaged by human mismanagement

Soil is a valuable natural resource on which humans depend for food. Many human activities generate or aggravate soil problems, including nutrient mineral depletion, soil erosion, and accumulation of salt.

Nutrient mineral depletion may occur in soils that are farmed

In a natural ecosystem, the essential nutrient minerals removed from the soil by plants are returned when the plants or the ani-

Hank Morgan/Photo Researchers, Inc.

ACTIVE FIGURE **34-14** **Hydroponically grown lettuce.**

Lettuce is one of several hydroponic crops grown commercially. The white boards support the plants, which are not anchored in soil. A chemically defined liquid solution of nutrient minerals trickles over their roots, which also have access to atmospheric oxygen.

BiologyNow™ Diagnose a sick plant to **learn more about mineral nutrition** by clicking on this figure on your BiologyNow CD-ROM.

mals that eat them die and are decomposed. An agricultural system disrupts this pattern of nutrient cycling when the crops are harvested. Plant material containing nutrient minerals is removed from the nutrient cycle, and the harvested crops fail to decay and release their nutrients back to the soil. Over time, farmed soil inevitably loses its fertility, that is, its ability to produce abundant crops. Homeowners often mow their lawns and remove the clippings, similarly preventing decomposition and cycling of nutrient minerals that were in the grass blades.

The essential material (water, sunlight, or some essential element) that is in shortest supply usually limits plant growth. This phenomenon is sometimes called the concept of **limiting resources.** The three elements that are most often limiting resources for plants are nitrogen, phosphorus, and potassium. To sustain the productivity of agricultural soils, fertilizers are periodically added to depleted soils to replace the nutrient minerals that limit plant growth.

The two main types of fertilizers are organic and commercial inorganic. *Organic fertilizers* include such natural materials as cow manure, crop residues, bone meal, and compost. Green manure, a special type of organic fertilizer, is actually a crop that is planted and deliberately plowed into the soil to decompose instead of being harvested. Frequently the plants grown for green manure have nitrogen-fixing bacteria living in root nodules, thereby increasing the amount of nitrogen in the soil. Organic fertilizers are complex, and their exact compositions vary. The nutrient minerals in organic fertilizers become available to plants only as the organic material decomposes. For that reason, organic fertilizers are slow-acting and long-lasting.

Commercial inorganic fertilizers are manufactured from chemical compounds, and their exact compositions are known. Because they are soluble, they are immediately available to plants. Commercial inorganic fertilizers are available in the soil for only a short period (relative to organic fertilizers), because they quickly leach away, often into groundwater or surface runoff, polluting the water. Most commercial inorganic fertilizers contain the three elements (nitrogen, phosphorus, and potassium) that are usually the limiting resources in plant growth. The numbers on fertilizer bags (such as 10–20–20) tell the percentage concentrations of each of these three elements (N, P, and K).

Soil erosion is the loss of soil from the land

Water, wind, ice, and other agents cause **soil erosion,** the wearing away or removal of soil from the land. Water and wind are particularly effective in moving soil from one place to another. Rainfall loosens soil particles that can then be transported away by moving water (Fig. 34-15). Wind loosens soil and blows it away, particularly if the soil is barren and dry. Soil erosion is a natural process that can be greatly accelerated by human activities.

Soil erosion is a national and international problem that does not make the headlines very often. The U.S. Department of Agriculture estimates that approximately 4.2 billion metric tons (4.6 billion tons) of topsoil are lost each year from U.S. croplands and rangelands as a result of soil erosion. Approximately one fifth of U.S. cropland is vulnerable to soil erosion damage. Erosion causes a loss in soil fertility because essential nutrient minerals and organic matter that are a part of the soil are removed. As a result of these losses, the productivity of eroded agricultural soils declines, and more fertilizer must be used to replace the nutrients lost to erosion.

Humans often accelerate soil erosion through poor soil management practices. Agriculture is not the only culprit, because the removal of natural plant communities during surface mining, unsound logging practices (such as clearcutting large areas

FIGURE **34-15** **Soil erosion in an open field.**

Removal of plant cover exposes bare soil to erosion in heavy rains. Precipitation can cause gullies to enlarge rapidly, because they provide channels for the runoff of water.

USDA/Natural Resources Conservation Service

of forest), and the construction of roads and buildings also accelerate erosion.

Soil erosion has an impact on other natural resources. Sediment that enters streams, rivers, and lakes degrades water quality and fish habitats. Pesticides and fertilizer residues in sediment may add pollutants to the water. Also, when forests are removed within the watershed of a hydroelectric power facility, accelerated soil erosion fills the reservoir behind the dam with sediment much faster than usual. This process reduces electricity production at that facility.

Sufficient plant cover reduces the amount of soil erosion: Leaves and stems cushion the impact of rainfall, and roots help hold the soil in place. Although soil erosion is a natural process, abundant plant cover makes it negligible in many natural ecosystems.

Salt accumulates in soil that is improperly irrigated

Although irrigation improves the agricultural productivity of arid and semiarid lands, it sometimes causes salt to accumulate in the soil, a process called **salinization.** In a natural scenario, as a result of precipitation runoff rivers carry dissolved salts away. Irrigation water, however, normally soaks into the soil and does not run off the land into rivers, so when water evaporates, the salt remains behind and accumulates in the soil. Salty soil results in a decline in productivity and, in extreme cases, renders the soil completely unfit for crop production.

Most plants cannot obtain all the water they need from salty soil, because a water balance problem exists: Water moves by osmosis *out* of plant roots and into the salty soil. Obviously, most plants cannot survive under these conditions (see Fig. 5-13). Plant species that thrive in saline soils have special adaptations that enable them to tolerate the high amount of salt. Black mangroves, for example, excrete excess salt through their leaves.

Most crops, unless they have been genetically selected to tolerate high salt, are not productive in saline soil. Research on the molecular aspects of salt tolerance suggests that mutations in membrane transport proteins confer salt tolerance. A salt-tolerant variety of *Arabidopsis* was genetically engineered to overexpress a single gene that codes for a sodium transport protein in the vacuolar membrane. These plants are able to store large quantities of sodium in their vacuoles, thereby tolerating saline soils. Other salt-resistant plants exclude sodium from entering the cell through the plasma membrane.

Review

- What are the four components of soil, and how is each important to plants?
- What is cation exchange?
- How do weathering processes convert rock into soil?
- What are macronutrients and micronutrients?
- How are nutrient minerals lost from the soil?

BiologyNow™ Assess your understanding of **the soil environment** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Distinguish between taproot and fibrous root systems.

- A **taproot** system has one main root (formed from the radicle), from which many lateral roots extend.
- A **fibrous root** system has several to many **adventitious roots** of the same size developing from the end of the stem. Lateral roots branch from these adventitious roots.

2 Label cross sections of a primary dicot root and a monocot root, and describe the functions of each tissue.

- Primary roots have an epidermis, ground tissues (cortex and, in certain roots, pith), and vascular tissues (xylem and phloem). Each root tip is covered by a **root cap,** a protective layer that covers the delicate root **apical meristem** and may orient the root so that it grows downward.
- **Epidermis** protects the root. **Root hairs,** short-lived extensions of epidermal cells, increase the surface area of the root in contact with soil. Root hairs aid in absorption of water and dissolved nutrient minerals.
- **Cortex** consists of parenchyma cells that often store starch. **Endodermis,** the innermost layer of the cortex, regulates the movement of nutrient minerals into the root xylem. Cells of the endodermis have a **Casparian strip** around their radial and transverse walls that is impermeable to water and dissolved nutrient minerals. Nutrient minerals are actively transported through carrier proteins in the plasma membranes of endodermal cells. Pericycle, xylem, and phloem collectively make up the root's **stele,** or **vascular cylinder.**
- **Pericycle** gives rise to lateral roots and lateral meristems. **Xylem** conducts water and dissolved nutrient minerals; **phloem** conducts dissolved sugar.
- Xylem of a herbaceous dicot root forms a solid core in the center of the root. In contrast, the center of a monocot root often consists of **pith** surrounded by a ring of alternating bundles of xylem and phloem. Monocot roots lack a **vascular cambium** and therefore do not have secondary growth.

3 Trace the pathway of water and nutrient mineral ions from the soil through the various root tissues, and distinguish between the symplast and apoplast.

- As water and dissolved nutrient mineral ions move from the soil into the root, they pass through the following tissues: root hair/epidermis ⟶ cortex ⟶ endodermis ⟶ pericycle ⟶ root xylem.
- The water and dissolved nutrient minerals move through the epidermis and cortex along one of two pathways, the **apoplast** (along the interconnected porous cell walls) or the **symplast** (from one cell's cytoplasm to the next through **plasmodesmata**).

4 Discuss the structure of roots with secondary growth.

- Roots of gymnosperms and woody dicots develop secondary tissues (wood and bark). The production of secondary tissues is the result of the activity of two lateral meristems, the vascular cambium and cork cambium. The vascular cambium produces secondary xylem (wood) and secondary phloem (inner bark). The **cork cambium** produces **periderm** (outer bark).

SUMMARY WITH KEY TERMS *(continued)*

5 Describe at least four roots that are modified to perform uncommon functions.

- **Prop roots** develop from branches or from a vertical stem and grow downward into the soil to help support certain plants in an upright position. **Buttress roots** are swollen bases or braces that support certain tropical rainforest trees that have shallow root systems.
- **Pneumatophores** are aerial "breathing" roots that may assist in getting oxygen to submerged roots.
- Certain epiphytes have roots modified to photosynthesize, absorb moisture, or, if parasitic, penetrate host tissues.
- Corms and bulbs often have **contractile roots** that grow into the soil and then contract, thereby pulling the corm or bulb deeper into the soil.

6 List and describe two mutualistic relationships between roots and other organisms.

- **Mycorrhizae** are mutually beneficial associations between roots and soil fungi.
- Root **nodules** are swellings that develop on roots of leguminous plants and house millions of rhizobia (nitrogen-fixing bacteria).
- A root **graft** is a natural connection between the roots of trees belonging to the same or different species.

7 Describe the roles of weathering, organisms, climate, and topography in soil formation.

- Factors influencing soil formation include parent material (type of rock), climate, organisms, the passage of time, and topography. Most soils are formed from parent material that is broken into smaller and smaller particles by **weathering processes.** Climate and organisms work together in weathering rock.
- Soil organisms such as plants, algae, fungi, worms, insects, spiders, and bacteria are important not only in forming soil, but also in cycling nutrient minerals.
- Topography, a region's surface features, affects soil formation. Steep slopes have little or no soil on them, whereas moderate slopes often have deep soils.

8 List the four components of soil, and give the ecological significance of each.

- Soil is composed of inorganic minerals, organic matter, air, and water. Inorganic minerals provide anchorage and essential nutrient minerals for plants. Organic matter increases the soil's water-holding capacity. As it decomposes, organic matter releases essential nutrient minerals into the soil. Soil air provides oxygen for soil organisms to use during aerobic respiration. Soil water provides water and dissolved nutrient minerals to plants and other organisms.

9 Describe how roots absorb positively charged nutrient mineral ions by the process of cation exchange.

- In the soil, **cations,** positively charged nutrient mineral ions, are attracted and reversibly bound to clay particles, which have predominantly negative charges on their outer surfaces. In **cation exchange,** roots secrete protons (H^+), which are exchanged for other positively charged mineral ions, freeing them into the soil water to be absorbed by roots.

10 Distinguish between macronutrients and micronutrients.

- Plants require 19 essential elements for normal growth. Ten elements are **macronutrients:** carbon, hydrogen, oxygen, nitrogen, potassium, calcium, magnesium, phosphorus, sulfur, and silicon. Macronutrients are required in fairly large quantities.
- Nine elements are **micronutrients:** chlorine, iron, boron, manganese, sodium, zinc, copper, nickel, and molybdenum. Micronutrients are needed in trace amounts.

11 Explain the impacts of mineral depletion and soil erosion on plant growth.

- Mineral depletion may occur in soils that are farmed because the natural pattern of nutrient cycling is disrupted when crops are harvested (and not allowed to decompose into the soil).
- **Soil erosion** is the removal of soil from the land by the actions of agents such as water and wind. Erosion causes a loss in soil fertility, because essential nutrient minerals and organic matter that are a part of the soil are removed.

POST-TEST

1. One main root, formed from the enlarging embryonic root, with many smaller lateral roots coming out of it is a(an) (a) fibrous root system (b) adventitious root system (c) taproot system (d) contractile root system (e) prop root system
2. Roots produced at unusual places on the plant are (a) fibrous (b) adventitious (c) taproots (d) contractile (e) mycorrhizae
3. Root hairs (a) cover and protect the delicate root apical meristem (b) increase the absorptive capacity of roots (c) secrete a waxy cuticle (d) orient the root so it grows downward (e) store excess sugars produced in the leaves
4. Plants with corms often have _____ roots that pull the bulb deeper into the ground. (a) fibrous (b) adventitious (c) tap (d) contractile (e) prop
5. Certain plants adapted to flooded soil produce aerial "breathing" roots known as (a) fibrous roots (b) pneumatophores (c) mycorrhizae (d) contractile roots (e) prop roots
6. Unlike stems, roots produce (a) nodes and internodes (b) root caps and internodes (c) axillary buds and root hairs (d) terminal buds and axillary buds (e) root caps and root hairs
7. The waterproof region around the radial and transverse walls of endodermal cells is the (a) Casparian strip (b) pericycle (c) apoplast (d) symplast (e) pneumatophore
8. The apoplast is (a) a layer of cells that surrounds the vascular region in roots (b) the layer of cells just inside the endodermis (c) a system of interconnected plant cell walls through which water moves (d) the central cylinder of the root that comprises the vascular tissues (e) a continuum of cytoplasm of many cells, all connected by plasmodesmata
9. Plants obtain positively charged nutrient mineral ions from clay particles in the soil by cation exchange, in which (a) roots passively absorb the positively charged mineral ions they require (b) mineral ions flow freely along porous cell walls (c) roots se-

POST-TEST *(continued)*

crete protons, which free other positively charged mineral ions to be absorbed by roots (d) the Casparian strip effectively blocks the passage of water and nutrient mineral ions along the endodermal cell wall (e) a well-developed system of internal air spaces in the root allows both gas exchange and cation exchange

10. The cell layer from which lateral roots originate is the (a) epidermis (b) cortex (c) endodermis (d) pericycle (e) vascular cambium
11. The center of a herbaceous dicot root is composed of _____, whereas the center of a monocot root is composed of _____ (a) pith; cortex (b) xylem; phloem (c) phloem; xylem (d) xylem; pith (e) pith; xylem
12. Mutually beneficial associations between certain soil fungi and the roots of most plant species are called (a) mycorrhizae (b) pneumatophores (c) nodules (d) rhizobia (e) humus
13. Which of the following statements about soil is correct? (a) pore spaces are always filled with about 50% air and 50% water (b) a single teaspoon of fertile agricultural soil may contain up to several hundred living microorganisms (c) the texture of a soil is determined by the soil's pH (d) a soil's organic matter includes litter, droppings, and the dead remains of plants, animals, and microorganisms (e) soil formation is unaffected by a region's climate or topography
14. The technique of growing plants in aerated water containing dissolved nutrient mineral salts is known as (a) hydration (b) hydroponics (c) hydrophilic (d) hydrostatic (e) hydrolysis
15. Carbon, hydrogen, oxygen, nitrogen, potassium, calcium, magnesium, phosphorus, sulfur, and silicon are collectively known as (a) micronutrients (b) microvilli (c) micronuclei (d) macronuclei (e) macronutrients
16. In roots of woody plants (a) xylem does not form the central tissue of the root (b) the cortex comprises the bulk of the root (c) the vascular cambium gives rise to secondary xylem and secondary phloem (d) the pericycle gives rise to the apical meristem (e) secondary growth occurs despite the lack of a vascular cambium
17. Corn, sorghum, red mangrove, and banyon are plants that have (a) prop roots (b) buttress roots (c) pneumatophores (d) contractile roots (e) root nodules

CRITICAL THINKING

1. A mesquite root is found penetrating a mine shaft about 46 m (150 ft) below the surface of the soil. How could you determine *when* the root first grew into the shaft? (*Hint:* Mesquite is a woody plant.)
2. A barrel cactus that is 60 cm tall and 30 cm in diameter has roots more than 3 m long. However, all the plant's roots are found in the soil at a depth of 5 to 15 cm. What possible adaptive value does such a shallow root system confer on a desert plant?
3. How would you distinguish between a root hair and a small lateral root?
4. You are given a plant part that was found growing in the soil and are asked to determine whether it is a root or an underground stem. How would you identify the structure without a microscope? With a microscope?
5. How would you design an experiment to determine whether gold is essential for plant growth? What would you use for an experimental control?
6. Why does overwatering a plant often kill it?
7. Explain why, once secondary growth has occurred, that portion of the root is no longer involved in absorption. Where does absorption of water and dissolved nutrient minerals occur in plants that have roots with secondary growth?

Reproduction in Flowering Plants

Skip Moody/Dembinsky Photo Associates

Painted trillium. This plant, (*Trillium undulatum*), which grows to 50 cm (20 in), inhabits bogs and moist, acid woodlands in southern Canada and the northeastern United States, as well as the mountains south to Georgia.

CHAPTER OUTLINE

- The Flowering Plant Life Cycle
- Pollination
- Fertilization and Seed/Fruit Development
- Asexual Reproduction in Flowering Plants
- A Comparison of Sexual and Asexual Reproduction

In Chapter 31 you learned that flowering plants, which include at least 235,000 species, are the largest, most successful group of plants. One reason for the success of flowering plants, or **angiosperms,** is that they can reproduce both sexually and asexually. You may have admired flowers for their fragrances as well as their appealing colors and varied shapes (see photograph). The biological function of flowers, however, is sexual reproduction. Their colors, shapes, and fragrances are adaptations that increase the likelihood that pollen grains, which produce sperm cells, will be carried from plant to plant.

As in most organisms, sexual reproduction in plants includes meiosis and the fusion of reproductive cells—egg and sperm cells, collectively called **gametes.** The union of gametes, which is called *fertilization,* occurs within the flower's ovary. After fertilization, flowering plants produce seeds inside fruits.

The offspring of parents that reproduce sexually, show considerable genetic variation. They may resemble one of the parent plants, both of the parents, or neither of the parents. Sexual reproduction offers the advantage of new gene combinations, not found in either parent, that may make an individual plant better suited to its environment. These new gene combinations largely result from the **independent assortment** of chromosomes that occurs during meiosis before the production of both egg and sperm cells. (How this variation occurs, that is, the details of independent assortment and genetic recombination, is discussed in Chapters 9 and 10.)

Many flowering plants also reproduce asexually. Asexual reproduction doesn't usually involve the formation of flowers, seeds, and fruits. Instead, offspring generally form when a vegetative part of an existing plant expands, grows, and then becomes separated from the rest of the plant, often by the death of tissues. This part then forms a complete, independent plant.

Flowering plants have many methods of asexual reproduction, most of which involve modified vegetative organs such as stems, roots, and leaves. In particular, many modified stems, such as rhizomes, tubers, corms, and stolons, reproduce asexu-

ally. Because asexual reproduction requires only one parent, and no meiosis or fusion of gametes occurs, the offspring of asexual reproduction are virtually genetically identical to each other and to the parent plant from which they came.[1]

In this chapter we look at various aspects of both sexual and asexual reproduction in flowering plants, including floral adaptations that are important in pollination, seed and fruit structure and dispersal, and several kinds of asexual reproduction. We conclude with a discussion of the evolutionary advantages and disadvantages of sexual and asexual reproduction. ■

THE FLOWERING PLANT LIFE CYCLE

Learning Objectives

1. Label the parts of a flower on a diagram, and describe the functions of each part.
2. Identify where eggs and pollen grains are formed within the flower.

In Chapters 26 and 27 you learned that angiosperms and other plants have a cyclic **alternation of generations** in which they spend a portion of their life cycle in a multicellular haploid stage and a portion in a multicellular diploid stage. The haploid portion, called the **gametophyte generation,** gives rise to gametes by mitosis. When two gametes fuse during **fertilization,** the diploid portion of the life cycle, called the **sporophyte generation,** begins. The sporophyte generation produces haploid spores by meiosis. Each spore has the potential to give rise to a gametophyte plant, and the cycle continues.

In flowering plants the diploid sporophyte generation is larger and nutritionally independent. The haploid gametophyte generation, which is located in the flower, is microscopic and nutritionally dependent on the sporophyte. We revisit alternation of generations in flowering plants later in the chapter, after our discussion of the role of flowers as reproductive structures. It may be helpful for you to review Figure 27-12, which shows the main stages in the flowering plant life cycle.

Flowers are involved in sexual reproduction

How does a plant "know" it is time to start forming flowers? Correct timing is crucial to ensure reproductive success when a plant switches from vegetative to reproductive development. What happens, for example, if a plant flowers so late in the season that it does not have enough time to set seed before winter? A variety of environmental cues, such as temperature and day length, ensure proper timing, and different species are adapted to respond to distinctly different environmental cues. When environmental conditions induce flowering, *floral meristem identity genes* are activated, and the shoot apical meristem undergoes a transition from vegetative growth to reproductive growth—that is, to produce flowers. In Chapter 36 we say more about the initiation of flowering.

Flowers are reproductive shoots, usually consisting of four kinds of organs—sepals, petals, stamens, and carpels—arranged in whorls (circles) on the end of a flower stalk (Fig. 35-1; also see Fig. 27-10). In flowers with all four organs, the normal order of whorls from the flower's periphery to the center (or from the flower's base upward) is

Sepals ⟶ petals ⟶ stamens ⟶ carpels

The tip of the stalk enlarges to form a **receptacle** on which some or all of the flower parts are borne. All four floral parts are important in the reproductive process, but only the stamens (the "male" organs) and carpels (the "female" organs) participate directly in sexual reproduction—sepals and petals are sterile.

Sepals, which constitute the outermost and lowest whorl on a floral shoot, cover and protect the flower parts when the flower is a bud. Sepals are leaflike in shape and form and are often green. Some sepals, such as those in lily flowers, resemble petals. As the blossom opens from a bud, the sepals fold back to reveal the more conspicuous petals. The collective term for all the sepals of a flower is **calyx.**

The whorl just inside and above the sepals consists of **petals,** which are broad, flat, and thin (like sepals and leaves) but tremendously varied in shape and frequently brightly colored, attracting pollinators. As discussed later, petals play an important role in ensuring that sexual reproduction will occur. Sometimes petals fuse to form a tube or other floral shape. The collective term for all the petals of a flower is **corolla.**

Just inside and above the petals are the **stamens,** the male reproductive organs. Each stamen has a thin stalk, called a **filament,** at the top of which is an **anther,** a saclike structure in which **pollen grains** form. For sexual reproduction to occur, pollen grains must be transferred from the anther to the female reproductive structure (the carpel), usually of another flower of the same species. At first, each pollen grain consists of two cells surrounded by a tough outer wall. One cell, the **generative cell,** divides mitotically to form two nonflagellated male gametes, known as *sperm cells.* The other cell, the **tube cell,** produces a **pollen tube,** through which the sperm cells travel to reach the ovule.

In the center or top of most flowers are one or more **carpels,** the female reproductive organs. Carpels bear **ovules,** which are structures with the potential to develop into seeds. The carpels of a flower may be separate or fused together into a single structure. The female part of the flower, often called a **pistil,** may be a single carpel (a *simple pistil*) or a group of fused carpels (a *compound pistil*) (see Fig. 27-11). Each pistil has three sections: a **stigma,** on which the pollen grains land; a **style,** a necklike structure through which the pollen tube grows; and an **ovary,** a juglike structure that contains one or more ovules and can develop into a fruit.

[1] Although offspring of asexual reproduction are generally considered genetically uniform, somatic mutations can result in some variability among asexually derived offspring.

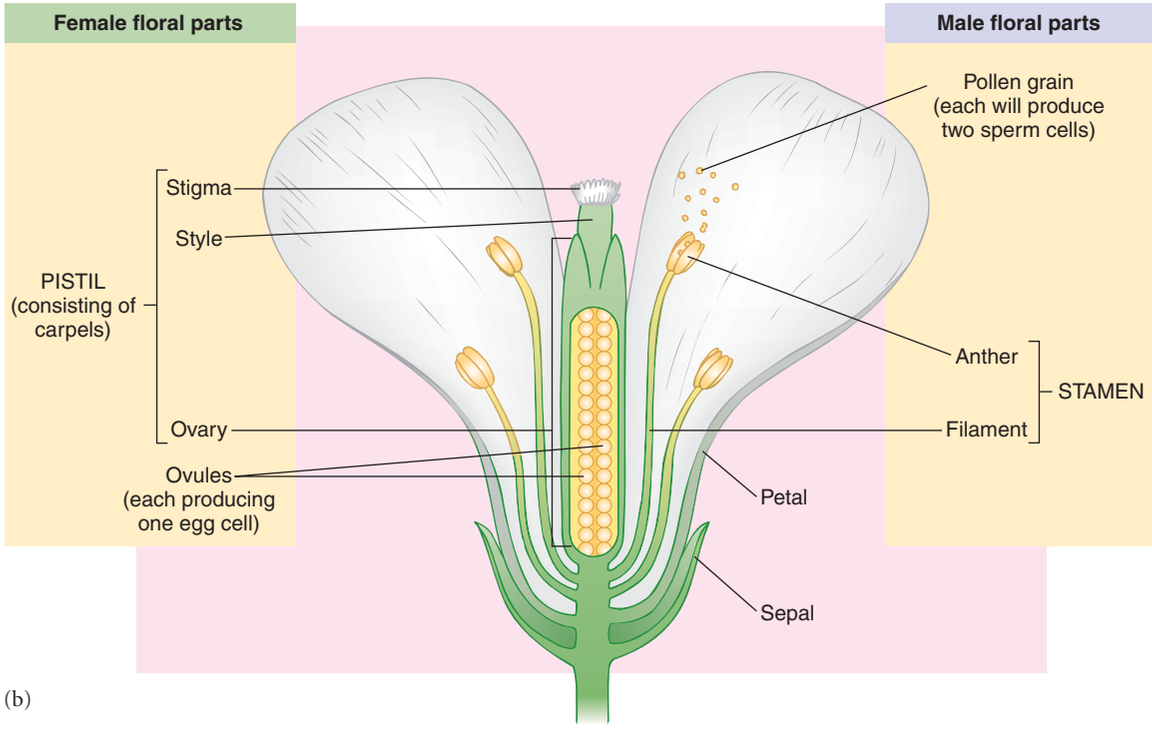
FIGURE **35-1** **Floral structure.**

(b) Cutaway view of an *Arabidopsis* flower. Each flower has four sepals (two are shown), four petals (two are shown), six stamens, and one pistil. Four of the stamens are long, and two are short (two long and two short are shown). Pollen grains develop within sacs in the anthers. In *Arabidopsis*, the compound pistil consists of two carpels that each contain numerous ovules.



(b)

Female gametophytes are produced in the ovary, male gametophytes in the anther

Before we proceed, it may be helpful to relate the stages in alternation of generations to floral structure. As discussed in Chapters 26 and 27, angiosperms and certain other plants are heterosporous and produce two kinds of spores: megaspores and microspores (Fig. 35-2).

Each young ovule within an ovary contains a diploid cell, the *megasporocyte*, which undergoes meiosis to produce four haploid **megaspores.** Three of these usually disintegrate, and the fourth, the functional megaspore, divides mitotically to produce a multicellular female gametophyte, also called an **embryo sac.** The embryo sac, which is embedded in the ovule, typically contains seven cells with eight haploid nuclei. Six of these cells, including the egg cell (the female gamete), contain a single nucleus each; a large central cell has two nuclei, called **polar nuclei.** The egg and both polar nuclei participate directly in fertilization.

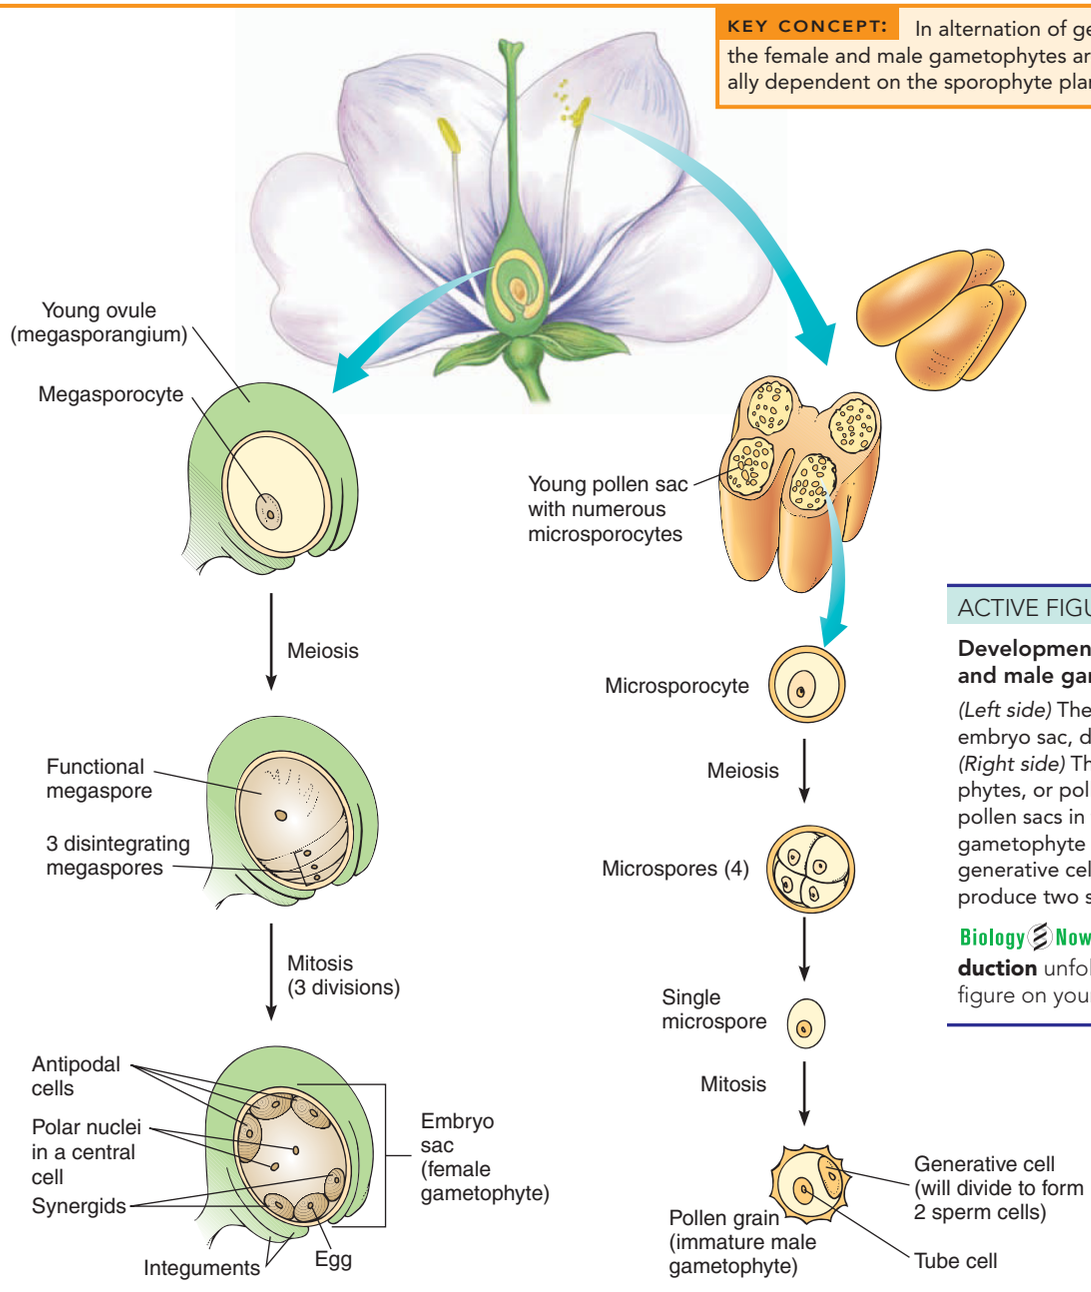
Pollen sacs within the anther contain numerous diploid cells called *microsporocytes*, each of which undergoes meiosis to produce four haploid cells called **microspores.** Each microspore divides mitotically to produce an immature male gametophyte, also called a pollen grain, that consists of two cells, the tube cell and the generative cell. The pollen grain becomes mature when its generative cell divides to form two nonmotile sperm cells.

Review

- How do petals differ from sepals? How are they similar?
- How do stamens differ from carpels? How are they similar?
- What are female gametophytes, and where are they formed?
- What are male gametophytes, and where are they formed?

BiologyNow™ Assess your understanding of **the flowering plant life cycle** by taking the pretest on your BiologyNow CD-ROM.

KEY CONCEPT: In alternation of generation in flowering plants, the female and male gametophytes are microscopic and nutritionally dependent on the sporophyte plant.



ACTIVE FIGURE **35-2**

Development of female and male gametophytes.

(Left side) The female gametophyte, or embryo sac, develops within the ovule. *(Right side)* The immature male gametophytes, or pollen grains, develop within pollen sacs in the anthers. Each male gametophyte becomes mature when its generative cell divides mitotically to produce two sperm cells.

BiologyNow™ Watch **plant reproduction** unfold by clicking on this figure on your BiologyNow CD-ROM.

POLLINATION

Learning Objectives

3 Compare the evolutionary adaptations that characterize flowers pollinated in different ways (by insects, birds, bats, and wind).

4 Define *coevolution*, and give examples of ways that plants and their animal pollinators have affected one another's evolution.

Before fertilization can occur, pollen grains must travel from the anther (where they form) to the stigma. The transfer of pollen grains from anther to stigma is known as **pollination.** Plants are *self-pollinated* if pollination occurs within the same flower or a different flower on the same individual plant. When pollen grains are transferred to a flower on another individual of the same species, we say the plant is *cross-pollinated.* Flowering plants accomplish pollination in a variety of ways. Beetles, bees, flies, butterflies, moths, wasps, and other insects pollinate many flowers. Other animals such as birds, bats, snails, and small nonflying mammals (rodents, primates, and marsupials) also pollinate plants. Wind is an agent of pollination for certain flowers, whereas a few aquatic flowers are pollinated by water.

Many plant species have mechanisms to prevent self-pollination

In plant sexual reproduction, the two gametes that unite to form a zygote may be from the same parent or from two different parents. The combination of gametes from two different parents increases the variation in offspring, and this variation

may confer a selective advantage. Some offspring, for example, may be able to survive environmental changes better than either parent can.

Plants have evolved a variety of mechanisms that prevent self-pollination and thus prevent **inbreeding,** which is the mating of genetically similar individuals. Inbreeding can increase the concentration of deleterious genes in the offspring. Some species have separate male and female individuals; the male plants have staminate flowers that lack carpels, and the female plants have pistillate flowers that lack stamens. Other species have flowers with both stamens and pistils, but the pollen is shed from a given flower either before or after the time that the stigma of that flower is receptive to pollen.

Many species have genes for **self-incompatibility,** a genetic condition in which the pollen is ineffective in fertilizing the same flower or other flowers on the same plant. In other words, an individual plant can identify and reject its own pollen. Genes for self-incompatibility usually inhibit the growth of the pollen tube in the stigma and style, thereby preventing sperm cell delivery to the ovules. Self-incompatibility, which is more common in wild species than in cultivated plants, ensures that reproduction occurs only if the pollen comes from a genetically different individual.

The molecular basis of self-incompatibility in *Arabidopsis* and related plants is an area of active scientific interest. It appears that self-incompatibility in these plants is the ancestral (normal) condition. Self-fertile individuals contain mutations in one or more of the genes involved in self-incompatibility.

Flowering plants and their animal pollinators have coevolved

Animal pollinators and the plants they pollinate have had such close, interdependent relationships over time that they have affected the evolution of certain physical and behavioral features in each other. The term **coevolution** describes such reciprocal adaptation, in which two species interact so closely that they become increasingly adapted to one another as they each undergo evolutionary change by *natural selection.* Let's examine some of the features of flowers and their pollinators that may be the products of coevolution.

Flowers pollinated by animals have various features to attract their pollinators, including showy petals (a visual attractant) and scent (an olfactory attractant). One reward for the animal pollinator is food. Some flowers produce nectar, a sugary solution, in special floral glands called *nectaries.* Pollinators use nectar as an energy-rich food. Pollen grains are also a protein-rich food for many animals. As they move from flower to flower searching for food, pollinators inadvertently carry along pollen grains on their body parts, helping the plants reproduce sexually.

Biologists estimate that insects pollinate about 70% of all flowering plant species. Bees are particularly important as pollinators of crop plants. Crops pollinated by bees provide about 30% of human food. Plants pollinated by insects often have blue or yellow petals. The insect eye does not see color the same way the human eye does. Most insects see well in the violet, blue, and yellow range of visible light but do not perceive red as a distinct color. So flowers pollinated by insects are not usually red. Insects can also see in the ultraviolet range, wavelengths that are invisible to the human eye. Insects see ultraviolet radiation as a color called *bee's purple.* Many flowers have dramatic uv markings that may or may not be visible to humans but that direct insects to the center of the flower where the pollen grains and nectar are (Fig. 35-3).

Insects have a well-developed sense of smell, and many insect-pollinated flowers have a strong scent that may be pleasant or foul to humans. The carrion plant, for example, is pollinated by flies and smells like the rotting flesh in which flies lay their eggs. As flies move from one reeking flower to another looking for a place to lay their eggs, they transfer pollen grains.

Birds such as hummingbirds are important pollinators (Fig. 35-4a). Flowers pollinated by birds are usually red, orange, or yellow, because birds see well in this range of visible light. Because birds do not have a strong sense of smell, bird-pollinated flowers usually lack a scent.

Bats, which feed at night and do not see well, are important pollinators, particularly in the tropics, where they are most abun-

FIGURE **35-4** **Animal pollinators.**

(a) A ruby-throated hummingbird (*Archilochus colubris*) obtains nectar from a trumpet vine flower (*Campis radicans*). The pollen grains on the bird's feathers are carried to the next plant. **(b)** A lesser long-nosed bat (*Leptonycteris curasoae*) obtains nectar from a cardon cactus flower (*Pachycereus*) and transfers pollen as it moves from flower to flower. Bats pollinate several hundred species of plants.

dant (Fig. 35-4b). Bat-pollinated flowers bloom at night and have dull white petals and a strong scent, usually of fermented fruit. Nectar-feeding bats are attracted to the flowers by the scent; they lap up the nectar with their long, extendible tongues. As they move from flower to flower, they transfer pollen grains. At least one bat-pollinated flower (the tropical vine *Mucana holtonii*) has evolved an unusual adaptation to encourage pollination by bats. When the pollen in a given flower is mature, a concave petal lifts up. The petal bounces the echo from the bat's echolocating calls back to the bat, helping it find the flower.

During the time when plants were coevolving specialized features such as petals, scent, and nectar to attract pollinators, animal pollinators also coevolved. Specialized body parts and behaviors adapted animals to aid pollination as they obtain nectar and pollen grains as a reward. For example, coevolution has selected for bumblebees' hairy bodies, which catch and hold the sticky pollen grains for transport from one flower to another.

Coevolution may also have led to the long, curved beaks of the 'i'iwi, one of the Hawaiian honeycreepers, that inserts its beak into tubular flowers to obtain nectar (see Figs. 1-11b and 19-15). The long, tubular corolla of the flowers that 'i'iwis visit probably also came about through coevolution. During the 20th century, some of the tubular flower species (such as lobelias) became rare, largely as a result of grazing by nonnative cows and feral goats, and about 25% of lobelia species have become extinct. The 'i'iwi now feeds largely on the flowers of the 'ohi'a tree, which lacks petals, and the 'i'iwi bill appears to be slowly adapting to this change in feeding preference. Comparison of the bills of 'i'iwi museum specimens collected in 1902 with the bills of live birds captured in the 1990s showed that 'i'iwi bills were about 3% shorter in the 1990s than in 1902.

Animal behavior has also coevolved, sometimes in bizarre and complex ways. The flowers of certain orchids (*Ophrys*) resemble female bees in coloring and shape. The unpollinated flowers also secrete a scent similar to that produced by female bees, and the males are irresistibly attracted to it. The resemblance between *Ophrys* flowers and female bees is so strong that male bees mount the flowers and try to copulate with them. During this pseudocopulation, a pollen sac usually attaches to the back of the bee. When the frustrated bee departs and tries to copulate with another orchid flower, it transfers pollen grains to that flower. Interestingly, once a flower has been pollinated, it emits a scent like that released by female bees that have already mated. Male bees have no interest in visiting flowers that have been pollinated (just like they lose interest in female bees that have already been inseminated).

Some flowering plants depend on wind to disperse pollen

Some flowering plants, such as grasses, ragweed, maples, and oaks, are pollinated by wind. Wind-pollinated plants produce many small, inconspicuous flowers (Fig. 35-5). They don't produce large, colorful petals, scent, or nectar. Some have large, feathery stigmas, presumably to trap wind-borne pollen grains. Because wind pollination is a hit-or-miss affair, the likelihood of a particular pollen grain landing on a stigma of the same species of flower is slim. Wind-pollinated plants produce large quantities of pollen grains, which increase the likelihood that some pollen grains will land on the appropriate stigma.

Review

- A flower has yellow petals, a pleasant scent, and sugary nectar. How is it probably pollinated?
- A flower has small, inconspicuous flowers without petals, a scent or nectar. How is it probably pollinated?
- What is coevolution?

BiologyNow™ Assess your understanding of **pollination** by taking the pretest on your BiologyNow CD-ROM.

FIGURE **35-5** **Wind pollination.**
Each cluster of male oak flowers (*Quercus*) dangles from a tree branch and sheds a shower of pollen when the wind blows. These flowers lack petals.

FERTILIZATION AND SEED/FRUIT DEVELOPMENT

Learning Objectives

5 Distinguish between pollination and fertilization.
6 Trace the stages of embryo development in flowering plants, and list and define the main parts of seeds.
7 Explain the relationships among the following: ovules, ovaries, seeds, and fruits.
8 Distinguish among simple, aggregate, multiple, and accessory fruits; give examples of each type; and cite several different methods of seed and fruit dispersal.

Once pollen grains have been transferred from anther to stigma, the tube cell, one of the two cells in the pollen grain, grows a thin pollen tube down through the style and into an ovule in the ovary. How does the pollen tube "know" where to grow? Scientists found that molecular signals from the embryo sac guide the growing pollen tube toward the ovule. Once a pollen tube penetrates the ovule, the attracting signals cease. As a result, only one pollen tube enters each embryo sac. The second cell within the pollen grain divides to form two male gametes (the sperm cells), which move down the pollen tube and enter the ovule (Fig. 35-6).

A unique double fertilization process occurs in flowering plants

The egg within the ovule unites with one of the sperm cells, forming a zygote (fertilized egg) that develops into an embryonic plant contained in the future seed. The two polar nuclei in the central cell of the ovule fuse with the second sperm cell to form the first cell of the triploid ($3n$) **endosperm,** the tissue with nutritive and hormonal functions that surrounds the developing embryonic plant in the seed. This process, in which two separate cell fusions occur, is called **double fertilization.** It is, with two exceptions, unique to flowering plants. (A type of double fertilization has been reported in two gymnosperm species, *Ephedra nevadensis* and *Gnetum gnemon.*)

After double fertilization, the ovule develops into a *seed,* and the surrounding ovary develops into a *fruit.* (We discuss double fertilization and the flowering plant life cycle in greater detail in Chapter 27.)

Embryonic development in seeds is orderly and predictable

Flowering plants package a young plant embryo, complete with stored nutrients, in a compact **seed,** which develops from the ovule after fertilization. The nutrients in seeds are not only used by *germinating* plant embryos but also eaten by animals, including humans (see *Focus On: Seed Banks*). Development of the embryo and endosperm following fertilization is possible because of the constant flow of nutrients into the developing seed from the parent plant.

Cell divisions of the fertilized egg to form a multicellular embryo proceed in several ways in flowering plants. We next describe dicot embryonic development; monocot embryonic development is similar in the early stages.

The two cells (basal cell and apical cell) that are formed as a result of the first division of the fertilized egg establish *polarity,* or direction, in the embryo. The large **basal cell** (located toward the outside of the ovule) typically develops into a **suspensor,** an embryonic tissue that anchors the developing embryo and aids in nutrient uptake from the endosperm. The **apical cell** (toward the inside of the ovule) develops into the plant embryo. Scientists are currently studying molecular differences between the apical cell and basal cell to determine the initial molecular signals that are involved in establishing polarity.

Initially, the apical cell divides to form a short cluster of cells, called a *proembryo* (Fig. 35-7 on page 677). As cell division continues, a small sphere of cells, often called a *globular embryo,* develops. Cells begin to develop into specialized tissues during this stage. When the dicot embryo starts to develop its two cotyledons (seed leaves), it has two lobes and resembles a heart; this is often called the *heart stage.* During the *torpedo stage,* the embryo continues to grow as the cotyledons elongate. As the embryo enlarges, it often curves back on itself and crushes the suspensor beyond recognition.

The mature seed contains an embryonic plant and storage materials

A mature seed contains an embryonic plant and food (stored in the cotyledons or endosperm), surrounded by a tough, protective **seed coat** derived from the **integuments,** which are

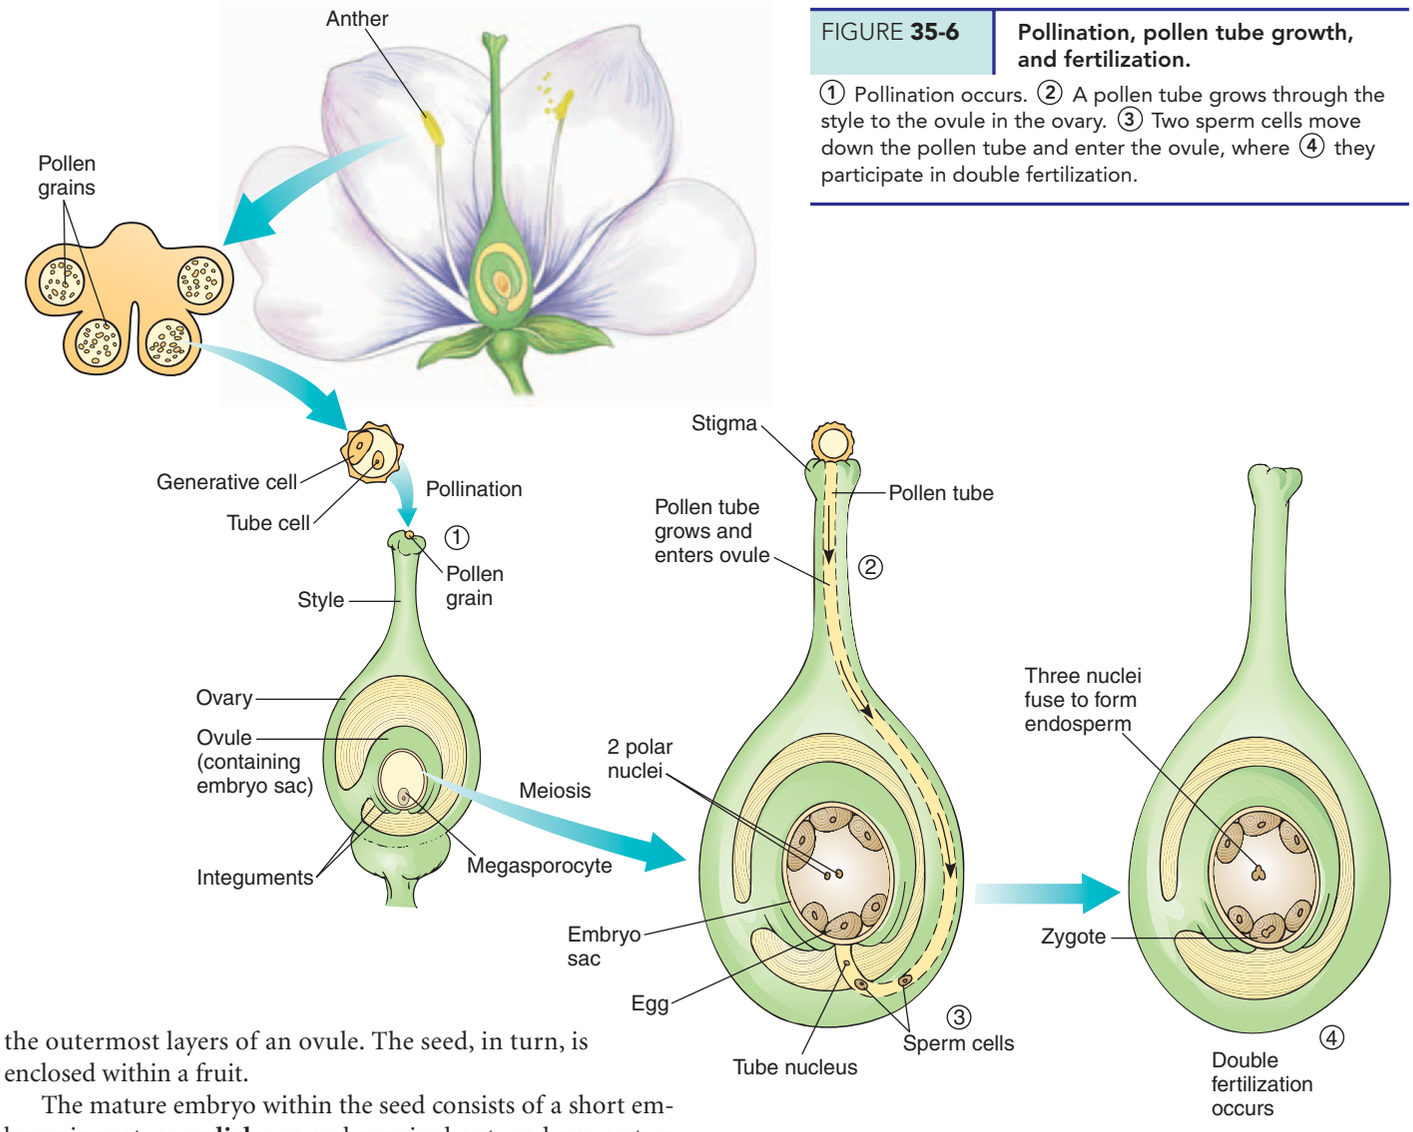

FIGURE 35-6 **Pollination, pollen tube growth, and fertilization.**

① Pollination occurs. ② A pollen tube grows through the style to the ovule in the ovary. ③ Two sperm cells move down the pollen tube and enter the ovule, where ④ they participate in double fertilization.

the outermost layers of an ovule. The seed, in turn, is enclosed within a fruit.

The mature embryo within the seed consists of a short embryonic root, or **radicle;** an embryonic shoot; and one or two seed leaves, or **cotyledons.** Monocots have a single cotyledon, whereas dicots have two (Fig. 35-8 on page 677). The short portion of the embryonic shoot connecting the radicle to one or two cotyledons is the **hypocotyl.** The shoot apex, or terminal bud, located above the point of attachment of the cotyledon(s), is the **plumule.** After the radicle, hypocotyl, cotyledon(s), and plumule have formed, the young plant's development is arrested, usually by desiccation or dormancy. When conditions are right for continuing the developmental program, the seed **germinates,** or sprouts, and the embryo resumes growth.

Because the embryonic plant is nonphotosynthetic, it must be nourished during germination until it becomes photosynthetic and therefore self-sufficient. The cotyledons of many plants function as storage organs and become large, thick, and fleshy as they absorb the food reserves (starches, oils, and proteins) initially produced as endosperm. Seeds that store nutrients in cotyledons have little or no endosperm at maturity. Examples of such seeds are peas, beans, squashes, sunflowers, and peanuts. Other plants, wheat and corn, for example, have thin cotyledons that function primarily to help the young plant digest and absorb food stored in the endosperm. (See Chapter 36 for a discussion of seed germination and early growth.)

Seed size is related to survival in a particular environment

In flowering plants seed size varies considerably, from the microscopic, dustlike seeds of orchids to the giant seeds of the double coconut (*Lodoicea maldivica*), which weigh as much as 27 kg (almost 60 lb). Despite this variation among different species, seed size is a remarkably constant trait within a species.

Assuming that a given plant species invests a fixed amount of its energy in reproduction, is it more advantageous to produce a large number of small seeds, or a few big ones? Observing the seed sizes that predominate in different environments, biologists have suggested that in some environments, a smaller seed seems advantageous, whereas in others a larger seed may be better.

Seed size for each plant species probably represents a tradeoff between the requirements for dispersal and for successful establishment of seedlings. For example, plants that grow in widely scattered open sites (such as old fields) usually produce smaller seeds, perhaps because they can be more easily dispersed over large areas than can larger seeds. However, wide dispersal is probably less important for plants adapted to densely

Focus On Seed Banks

To preserve older, more diverse varieties of plants, many countries are collecting plant **germplasm,** which is any plant material used in breeding. Germplasm includes seeds, plants, and plant tissues of traditional crop varieties. The International Plant Genetics Resource Institute in Rome, Italy, is the scientific organization that oversees plant germplasm collections worldwide. More than 100 seed collections, called *seed banks,* exist around the world and collectively hold more than 3 million samples of thousands of different kinds of plants (see figure). The U.S. National Plant Germplasm System in Fort Collins, Colorado, stores seeds of about 250,000 different species and varieties.

Most seed banks help preserve the genetic variation within different varieties of crops and their wild relatives. Farmers typically stop planting local varieties when newer, improved varieties become available. The newer varieties have desirable genetic characteristics such as a greater yield, but the local, discarded varieties also contain valuable genes. Each local variety's characteristic combination of genes gives it distinctive nutritional value, size, color, flavor, resistance to disease, and adaptability to different climates and soil types. Maintaining the genetic diversity present in local crop varieties and their wild relatives helps preserve genes we may need in the future. The gene combinations of local varieties are potentially valuable to agricultural breeders because they can be transferred to other varieties, either by traditional breeding methods or by genetic engineering.

Seed banks offer the advantage of storing a large amount of live plant genetic material in a very small space. Seeds stored in seed banks are safe from habitat destruction, climate changes, disease, predators, and general neglect. In some instances, seeds from seed banks have even been used to reintroduce a plant species that has become extinct in the wild.

Image not available due to copyright restrictions

There are some disadvantages to seed banks. Seeds don't stay alive forever and must be periodically germinated so that new seeds can be collected. Growing, harvesting, and returning seeds to storage is the most expensive aspect of storing plant material in seed banks. According to the U.N. Food and Agricultural Organization, many countries establish seed banks but do not provide the funds to pay for periodic replanting.

Many types of plants, such as avocados and coconuts, cannot be stored as seeds. The seeds of these plants do not tolerate being dried out, which is necessary before they are sealed in moisture-proof containers for storage at −18°C (−0.4°F). If 20% or more moisture remains in a frozen seed, it will probably die. Some seeds cannot be stored successfully because they only stay viable for a short time—a few months or even just a few days. Cryopreservation in liquid nitrogen at −160°C, or −256°F, is a new method being developed for certain kinds of seeds. Seeds stored at this temperature survive for longer periods than seeds stored at warmer temperatures.

Perhaps the most important disadvantage of seed banks is that plants stored in this manner remain stagnant in an evolutionary sense. Removed from their natural habitats, they are no longer subject to the forces of natural selection. As a result, they may be less fit for survival when they are reintroduced into the wild.

Despite their shortcomings, seed banks are increasingly viewed as an important way to safeguard seeds for future generations. For example, the Millennium Seed Bank Project at the Royal Botanic Gardens (Kew Gardens) in Great Britain is currently collecting and storing seeds from 10% of the world's plant species, including all species native to Great Britain.

vegetated areas such as forests. These plants generally produce larger seeds with an ample food reserve that may confer a greater likelihood of successfully establishing seedlings in a shaded environment. The stored energy may allow the young seedling to grow tall enough to reach adequate sunlight for photosynthesis.

Other ecological factors are associated with seed size. Larger seeds are typical of many plants that live in arid habitats, possibly because the food stored in a large seed lets a young seedling establish an extensive root system quickly, enabling it to survive the dry climate. Island plants also produce larger seeds than similar species on the nearby mainland. In this case, biologists hypothesize that large seeds are less likely to be widely dispersed and therefore less likely to fall into the ocean, where chances of survival are slim. Seeds that remain dormant in the soil for a long period tend to be smaller; the exact reason for this tendency is not known.

Despite many associations of seed size with specific environments, the general principles concerning the adaptive advantages of large seeds versus small seeds remain to be determined.

Fruits are mature, ripened ovaries

After double fertilization takes place within the ovule, the ovule develops into a seed (just described), and the ovary surround-

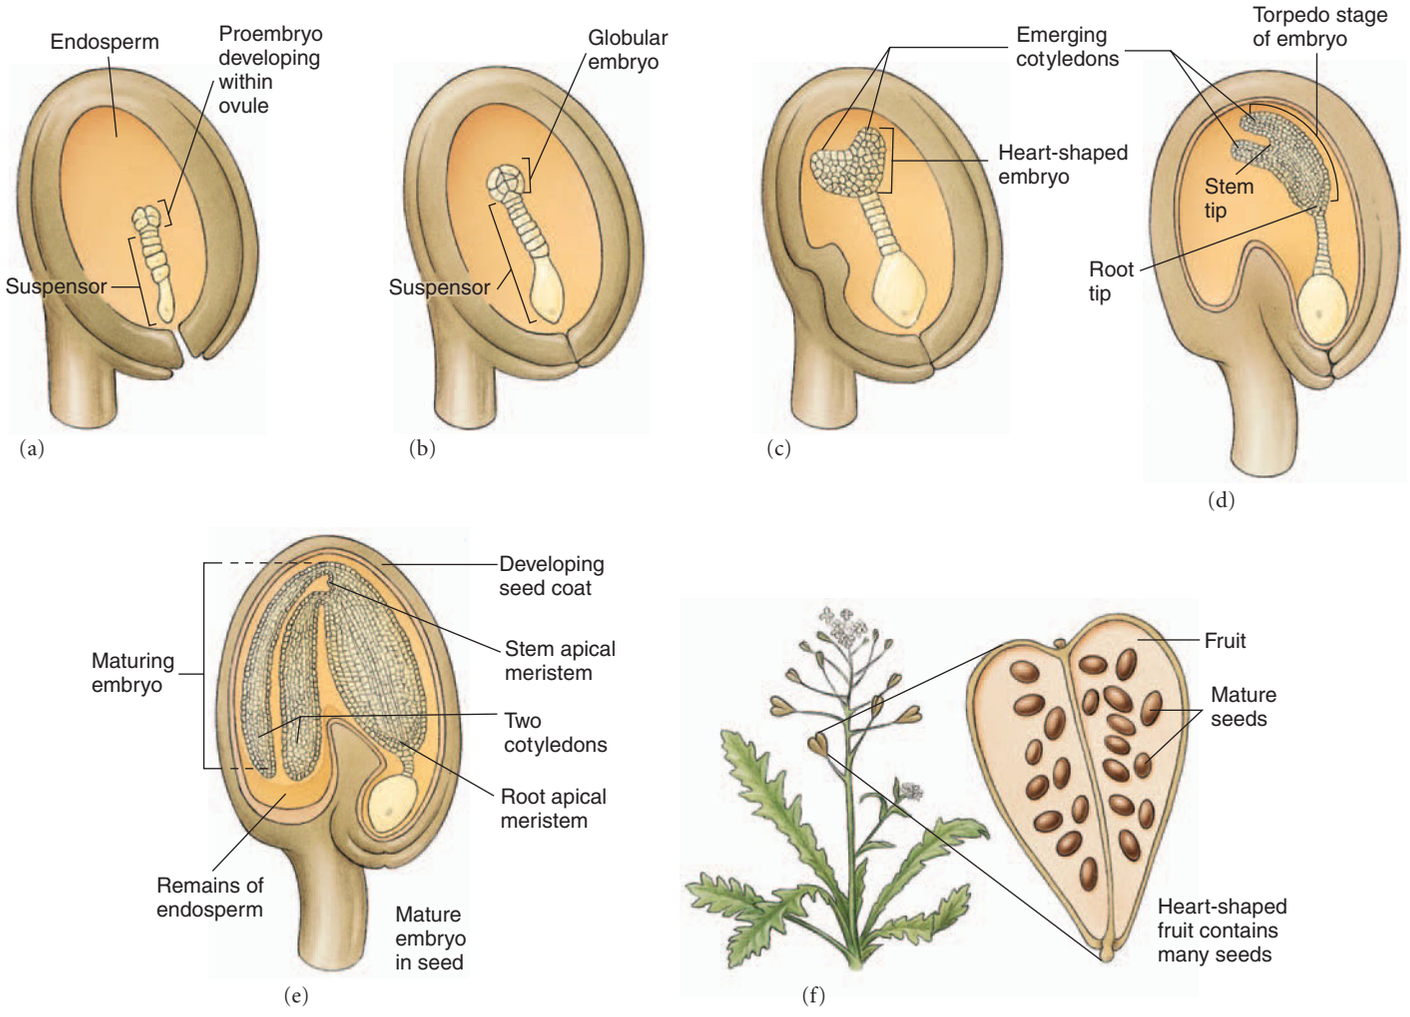

FIGURE **35-7** **Embryonic development.**

(a) The proembryo in shepherd's purse (*Capsella bursa-pastoris*) is the earliest multicellular stage of the embryo (the ovule is shown apart from the ovary). **(b)** As cell division continues, the embryo becomes a ball of cells, called the globular stage. **(c)** As the two cotyledons begin to emerge, the embryo is shaped like a heart. **(d)** The cotyledons continue to elongate, forming the torpedo stage. **(e)** A maturing embryo within the seed. The food originally stored in the endosperm has been almost completely depleted during embryonic growth and development, and most of the food for the embryonic plant is stored in its cotyledons. **(f)** A longitudinal section through a heart-shaped fruit of shepherd's purse reveals numerous tiny seeds, each containing a mature embryo. Each seed developed from an ovule.

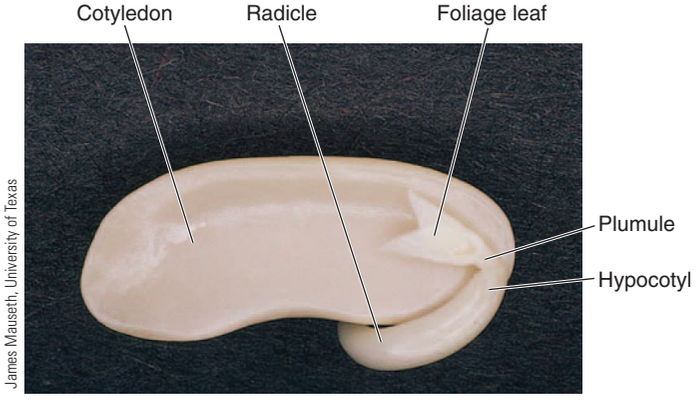

FIGURE **35-8** **Seed structure.**

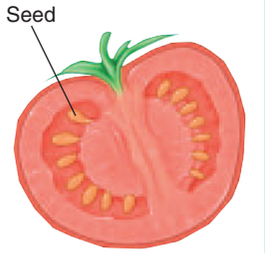
A bean seed has been dissected—its seed coat and one of its two cotyledons were removed—to show the radicle, hypocotyl, remaining cotyledon, and plumule with its foliage leaf at the shoot apex. This particular seed had begun germinating, so its radicle is larger than in an ungerminated seed.

ing it develops into a **fruit.** For example, a pea pod is a fruit, and the peas within it are seeds. A fruit may contain one or more seeds; some orchid fruits contain several thousand to a few million seeds! Fruits provide protection for the enclosed seeds and sometimes aid in their dispersal.

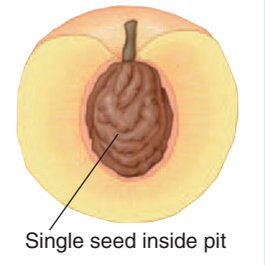
There are several types of fruits; their differences result from variations in the structure or arrangement of the flowers from which they were formed. The four basic types of fruits—simple fruits, aggregate fruits, multiple fruits, and accessory fruits—are summarized in Figure 35-9.

Most fruits are simple fruits. A **simple fruit** develops from a single pistil, which may consist of a single carpel or several fused carpels. At maturity, simple fruits may be fleshy or dry. Two examples of simple, fleshy fruits are berries and drupes. A **berry**



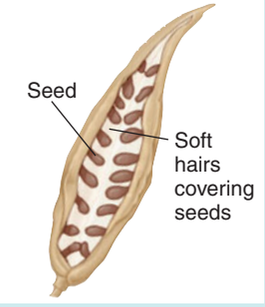
Berry (simple fruit)
A simple, fleshy fruit in which the fruit wall is soft throughout.

Tomato *(Lycopersicon lycopersicum)*



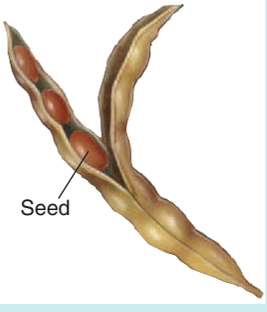
Drupe (simple fruit)
A simple, fleshy fruit in which the inner wall of the fruit is hard and stony (the pit).

Peach *(Prunus persica)*



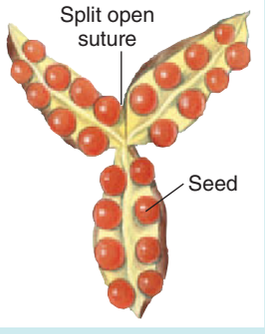
Follicle (simple fruit)
A simple, dry fruit that splits open along one suture to release its seeds.

Milkweed *(Asclepias syriaca)*



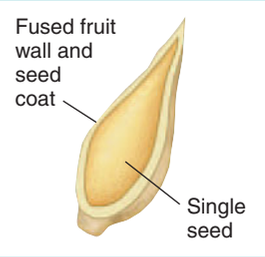
Legume (simple fruit)
A simple, dry fruit that splits open along two sutures to release its seeds.

Green bean *(Phaseolus vulgaris)*



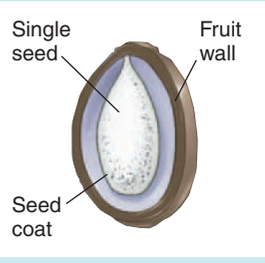
Capsule (simple fruit)
A simple, dry fruit that splits open along three or more sutures or pores to release its seeds.

Iris *(Iris)*



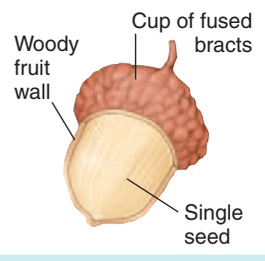
Caryopsis (simple fruit)
A simple, dry fruit in which the fruit wall is fused to the seed coat.

Wheat *(Triticum)*



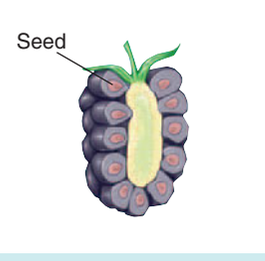
Achene (simple fruit)
A simple, dry fruit in which the fruit wall is separate from the seed coat.

Sunflower *(Helianthus annuus)*



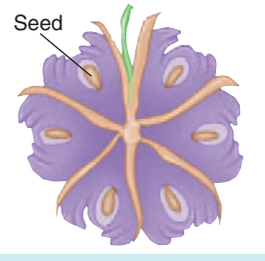
Nut (simple fruit)
A simple, dry fruit that has a stony wall, is usually large, and does not split open at maturity.

Oak *(Quercus)*



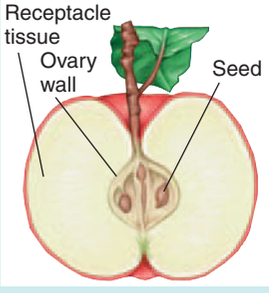
Aggregate fruit
A fruit that develops from a single flower with several to many pistils (i.e., carpels are not fused into a single pistil).

Blackberry *(Rubus)*



Multiple fruit
A fruit that develops from the ovaries of a group of flowers.

Mulberry *(Morus)*



Accessory fruit
A fruit composed primarily of tissue (such as the receptacle) other than ovary tissue.

Apple *(Malus sylvestris)*

ACTIVE FIGURE **35-9** **Fruit types.**

Fruits are botanically classified into four groups—simple, aggregate, multiple, and accessory fruits—based on their structure and mechanism of seed dispersal.

BiologyNow™ Learn how fruit types relate to the environment by clicking on this figure on your BiologyNow CD-ROM.

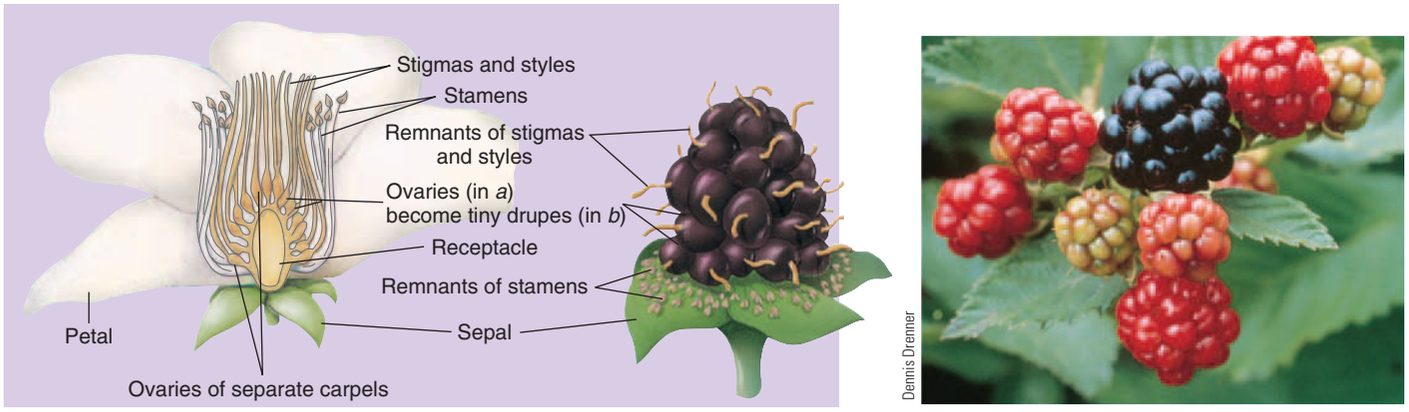


FIGURE **35-10** **An aggregate fruit.**

(a) Cutaway view of a blackberry (*Rubus*) flower, showing the many separate carpels in the center of the flower. **(b)** A developing blackberry fruit is an aggregate of tiny drupes. The little "hairs" on the blackberry are remnants of stigmas and styles. **(c)** Developing blackberry fruits at various stages of maturity.

is a fleshy fruit that has soft tissues throughout and contains few to many seeds; a blueberry is a berry, as are grapes, cranberries, bananas, and tomatoes. Many so-called berries do not fit the botanical definition. Strawberries, raspberries, and mulberries, for example, are not berries; these three fruits are discussed shortly.

A **drupe** is a simple, fleshy or fibrous fruit that contains a hard, stony pit surrounding a single seed. Examples of drupes include peaches, plums, olives, avocados, and almonds. The almond shell is actually the stony pit, which remains after the rest of the fruit has been removed.

Many simple fruits are dry at maturity; some of these split open, usually along seams, called *sutures,* to release their seeds. A milkweed pod is an example of a **follicle,** a simple, dry fruit that splits open along one suture to release its seeds. A **legume** is a simple, dry fruit that splits open along two sutures. Pea pods are legumes, as are green beans, although both are generally harvested before the fruit has dried out and split open. Pea seeds are usually removed from the fruit and consumed, whereas in green beans the entire fruit and seeds are eaten. A **capsule** is a simple, dry fruit that splits open along multiple sutures or pores. Iris, poppy, and cotton fruits are capsules.

Other simple, dry fruits, such as **caryopses** (sing., *caryopsis*), or **grains,** don't split open at maturity. Each caryopsis contains a single seed. Because the seed coat is fused to the fruit wall, a caryopsis looks like a seed rather than a fruit. Kernels of corn and wheat are fruits of this type.

An **achene** is similar to a caryopsis in that it is simple and dry, does not split open at maturity, and contains a single seed. However, the seed coat of an achene is not fused to the fruit wall. Instead, the single seed is attached to the fruit wall at one point only, permitting an achene to be separated from its seed. The sunflower fruit is an example of an achene. One can peel off the fruit wall (the shell) to reveal the sunflower seed within.

Nuts are simple, dry fruits that have a stony wall and do not split open at maturity. Unlike achenes, nuts are usually large and are often derived from a compound pistil. Examples of nuts include chestnuts, acorns, and hazelnuts. Many so-called nuts do not fit the botanical definition. Peanuts and brazil nuts, for example, are seeds, not nuts.

Aggregate fruits are a second main type of fruit. An **aggregate fruit** is formed from a single flower that contains several to many separate (free) carpels (Fig. 35-10). After fertilization, each ovary from each individual carpel enlarges. As they enlarge, the ovaries may fuse together to form a single fruit. Raspberries, blackberries, and magnolia fruits are examples of aggregate fruits.

A third type is the **multiple fruit,** formed from the ovaries of many flowers that grow in proximity on a common floral stalk. The ovary from each flower fuses with nearby ovaries as it develops and enlarges after fertilization. Pineapples, figs, and mulberries are multiple fruits (Fig. 35-11).

Accessory fruits are the fourth type. They differ from other fruits in that plant tissues in addition to ovary tissue make up the fruit. For example, the edible portion of a strawberry is the red, fleshy receptacle. Apples and pears are also accessory fruits; the outer part of each of these fruits is an enlarged *floral tube,* consisting of receptacle tissue along with portions of the calyx, that surrounds the ovary (Fig. 35-12).

Seed dispersal is highly varied

Wind, animals, water, and explosive dehiscence disperse the various seeds and fruits of flowering plants. Effective methods of seed dispersal have made it possible for certain plants to expand their geographic range. In some cases, the seed is the actual agent of dispersal, whereas in others the fruit performs this role. In tumbleweeds, such as russian thistle, the entire plant is the agent of dispersal because it detaches and blows across the ground, scattering seeds as it bumps along. Tumbleweeds are lightweight and are sometimes blown many kilometers by the wind.

Wind is responsible for seed dispersal in many plants. Plants such as maple trees have winged fruits adapted for wind dispersal. Light, feathery plumes enable other seeds or fruits to be transported by wind, often for considerable distances. Both dan-

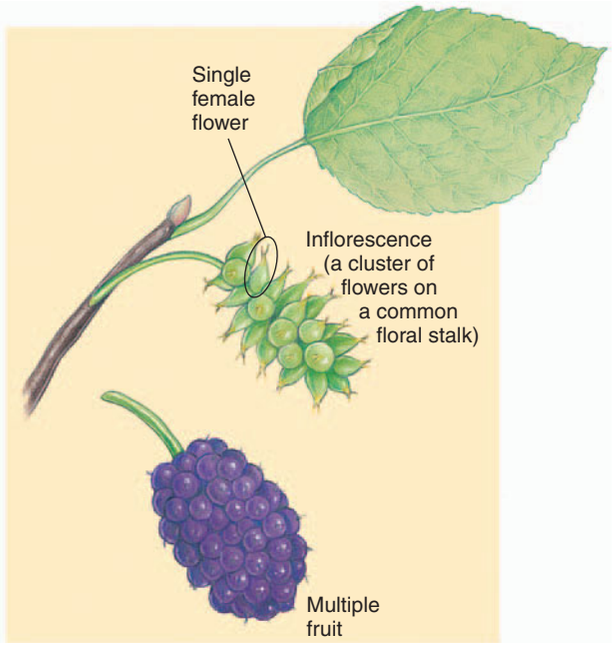

FIGURE **35-11** **A multiple fruit.**

Mulberry (*Morus*) is formed from the ovaries of many flowers that fused to become a multiple fruit. Mulberry flowers are imperfect and contain either stamens or pistils. Also shown is an inflorescence of female flowers from which the mulberry fruit develops.

delion fruits and milkweed seeds (Fig. 35-13a) have this type of adaptation.

Some plants have special structures that aid in dispersal of their seeds and fruits by animals. The spines and barbs of burdock burs and similar fruits catch in animal fur and fall off as the animal moves about (Fig. 35-13b). Fleshy, edible fruits are also adapted for animal dispersal. As the animal eats these fruits, it either discards or swallows the seeds. Many seeds that are swallowed have thick seed coats and are not digested, but instead pass through the digestive tract and are deposited in the animal's feces some distance from the parent plant. In fact, some seeds do not germinate unless they have passed through an animal's digestive tract; the animal's digestive juices probably aid germination by helping break down the seed coat. Some edible fruits apparently contain chemicals that function as laxatives that speed seeds through an animal's digestive tract; the less time these seeds spend in the gut, the more likely they are to germinate.

Animals such as squirrels and many bird species also help disperse acorns and other fruits and seeds by burying them for winter use. Many buried seeds are never used by the animal and germinate the following spring. Ants collect the seeds of many plants and take them underground to their nests. Ants disperse and bury seeds for hundreds of different plant species in almost every terrestrial environment, from northern coniferous forests to tropical rain forests to deserts.

Both ants and flowering plants benefit from their association. The ants ensure the reproductive success of the plants whose seeds they bury, and the plants supply food to the ants. A seed that is collected and taken underground by ants often contains a special structure called an *elaiosome,* or *oil body,* that protrudes from the seed (Fig. 35-14). Elaiosomes are a nutritious food for ants, which carry seeds underground before removing the elaiosome. Once an elaiosome is removed from a seed, the ants discard the undamaged seed in an underground refuse pile, which happens to be rich in organic material (such

Seed (and fruit) dispersal.

(a) The feathery plumes of milkweed (*Asclepias syriaca*) seeds make them buoyant for dispersal by wind. **(b)** Burdock (*Arctium minus*) burs (the hooked fruits) are carried away from the parent plant after sticking to bird feathers, mammal fur, or human clothing.

as ant droppings and dead ants) and contains the minerals required by young seedlings. Thus ants not only bury the seeds away from animals that might eat them but also place the seeds in rich soil that is ideal for germination and seedling growth.

The coconut is an example of a fruit adapted for dispersal by water. The coconut has air spaces that make it buoyant and capable of being carried by ocean currents for thousands of kilometers. When it washes ashore, the seed may germinate and grow into a coconut palm tree.

Some seeds are dispersed neither by wind, animals, nor water. Such seeds are found in fruits that use *explosive dehiscence,* in which the fruit bursts open suddenly and quite often violently, forcibly discharging its seeds (Fig. 35-15). Pressures due to differences in **turgor** or to drying out cause these fruits to burst open. The fruits of plants such as touch-me-not and bitter cress split open so explosively that seeds are scattered a meter or more.

ASEXUAL REPRODUCTION IN FLOWERING PLANTS

Learning Objectives

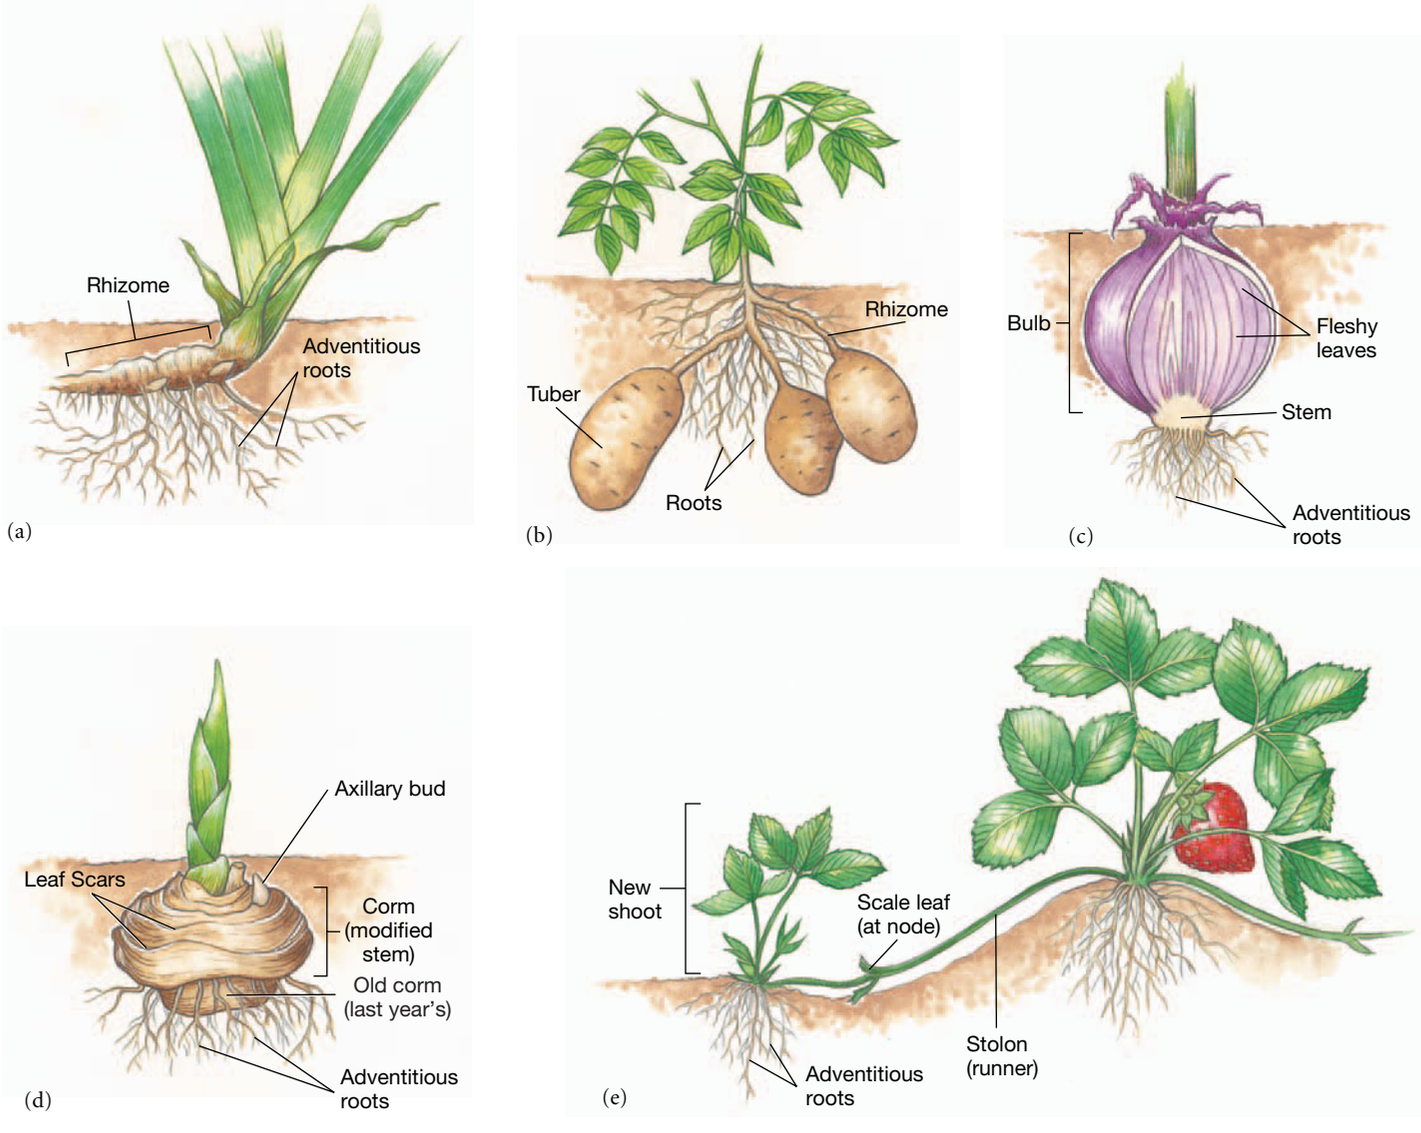
9 Explain how the following structures may be used to propagate plants asexually: rhizomes, tubers, stolons, corms, bulbs, plantlets, and suckers.

10 Define *apomixis,* and explain how it occurs.

Flowering plants have many kinds of asexual reproduction, several of which involve modified stems: rhizomes, tubers, bulbs, corms, and stolons. A **rhizome** is a horizontal underground stem that may or may not be fleshy. Fleshiness indicates the rhizome is used for storing food materials such as starch (Fig. 35-16a). Although rhizomes resemble roots, they are really stems, as indicated by the presence of scalelike leaves, buds, nodes, and internodes. (Roots have none of these features.) Rhizomes frequently branch in different directions. Over time, the old portion of the rhizome dies, and the two branches eventually separate to become distinct plants. Irises, bamboos, ginger, and many grasses are examples of plants that reproduce asexually by forming rhizomes.

FIGURE **35-16** **Modified Stems.**

(a) Irises have horizontal underground stems called rhizomes. New aerial shoots arise from buds that develop on the rhizome. **(b)** Potato plants form rhizomes, which enlarge into tubers (the potatoes) at the ends. **(c)** A bulb is a short underground stem to which overlapping, fleshy leaves are attached; most of the bulb consists of leaves. **(d)** A corm is an underground stem that is almost entirely stem tissue surrounded by a few papery scales. **(e)** Strawberries reproduce asexually by forming stolons, or runners. New plants (shoots and roots) are produced at every other node.



Some rhizomes produce greatly thickened ends called **tubers,** which are fleshy underground stems enlarged for food storage. When the attachment between a tuber and its parent plant breaks, often as a result of the death of the parent plant, the tuber grows into a separate plant. Potatoes and elephant's ear (*Caladium*) are examples of plants that produce tubers (Fig. 35-16b). The "eyes" of a potato are axillary buds, evidence that the tuber is an underground stem rather than a storage root such as sweet potatoes or carrots.

A **bulb** is a modified underground bud in which fleshy storage leaves are attached to a short stem (Fig. 35-16c). A bulb is globose (round) and covered by paper-like bulb scales, which are modified leaves. It frequently forms axillary buds that develop into small daughter bulbs (bulblets). These new bulbs are initially attached to the parent bulb, but when the parent bulb dies and rots away, each daughter bulb can become established as a separate plant. Lilies, tulips, onions, and daffodils are some plants that form bulbs.

A **corm** is a very short, erect underground stem that superficially resembles a bulb (Fig. 35-16d). Unlike the bulb, whose food is stored in underground leaves, the corm's storage organ is a thickened underground stem covered by papery scales (modified leaves). Axillary buds frequently give rise to new corms; the death of the parent corm separates these daughter corms, which then become established as separate plants. Familiar garden plants that produce corms include crocus, gladiolus, and cyclamen.

Stolons, or **runners,** are horizontal, aboveground stems that grow along the surface and have long internodes (Fig. 35-16e). Buds develop along the stolon, and each bud gives rise to a new shoot that roots in the ground. When the stolon dies, the daughter plants live separately. The strawberry plant produces stolons.

Some plants form detachable **plantlets** (small plants) in notches along their leaf margins. *Kalanchoe,* whose common name is "mother of thousands," has meristematic tissue that gives rise to an individual plantlet at each notch in the leaf (Fig. 35-17). When these plantlets reach a certain size, they drop to the ground, root, and grow.

Some plants reproduce asexually by producing **suckers,** aboveground shoots that develop from adventitious buds on roots (Fig. 35-18). Each sucker grows additional roots and becomes an independent plant when the parent plant dies. Examples of plants that form suckers include black locust, pear, apple, cherry, blackberry, and aspen. A quaking aspen (*Populus tremuloides*) colony in the Wasatch Mountains of Utah contains at least 47,000 tree trunks formed from suckers that can be traced back to a single individual; this massive "organism" occupies almost 43 hectares (106 acres). Some weeds, such as field bindweed, produce many suckers. These plants are difficult to control, because pulling the plant out of the soil seldom removes all the roots, which can grow as deep as 3 m (10 ft). In fact, in response to wounding, the roots produce additional suckers, which can be a considerable nuisance to humans.

Apomixis is the production of seeds without the sexual process

Sometimes flowering plants produce embryos in seeds without meiosis and the fusion of gametes. This asexual process is **apomixis.** For example, an embryo may develop from a diploid cell in the ovule rather than from a diploid zygote that forms from the union of two haploid gametes. Seed production by apomixis is a form of asexual reproduction. Because there is no fusion of gametes, the embryo is virtually genetically identical to the maternal genotype. However, the advantage of apomixis over other methods of asexual reproduction is that the seeds

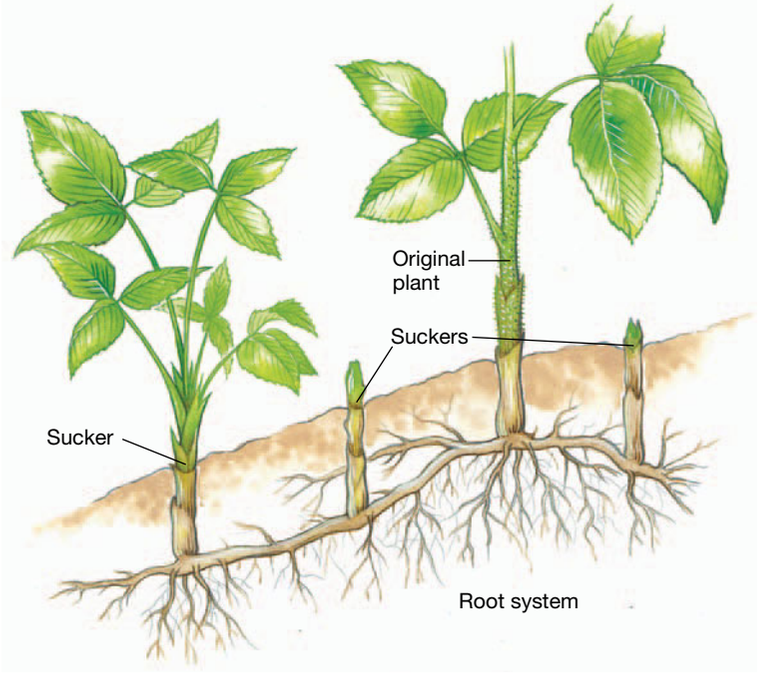
FIGURE **35-17** **Plantlets.**

The "mother of thousands" (*Kalanchoe*) produces detachable plantlets along the margins of its leaves. The young plantlets drop off and root in the ground.

Jerome Wexler/Photo Researchers, Inc.

FIGURE **35-18** **Suckers in various stages of development.**

All the suckers are connected to one another through the root system.



and fruits produced by apomixis can be dispersed by methods associated with sexual reproduction. Apomixis occurs in various species of more than 40 angiosperm families. Examples of plants that can reproduce by apomixis include dandelions, citrus trees, mango, blackberries, garlic, and certain grasses.

Plant biologists are actively engaged in identifying the genes involved in asexual reproduction by apomixis. If researchers can transfer these genes to crop plants that possess superior traits such as high yield, they may be able to develop apomictic crop plants whose traits do not get lost or diluted during the genetic shuffling of sexual reproduction.

Review

- How are rhizomes and tubers involved in asexual reproduction?
- How are corms and bulbs similar? How are they different?
- What is apomixis? How does the ability to reproduce by apomixis help a plant survive?

A COMPARISON OF SEXUAL AND ASEXUAL REPRODUCTION

Learning Objective

11 State the differences between sexual and asexual reproduction, and discuss the evolutionary advantages and disadvantages of each.

Sexual and asexual reproduction are suited for different environmental circumstances. As you know, sexual reproduction results in offspring that are genetically different from the parents; that is, the parental genotypes are not preserved in the offspring. This genetic diversity of offspring may be selectively advantageous, particularly in an unstable, or changing, environment. (We define *environment* broadly to include all external conditions, both living and nonliving, that affect an organism.) If a plant species that reproduces sexually (and is therefore genetically diverse) is exposed to increasing annual temperatures as a result of global warming, for example, some of the individuals may be more fit than either the parents or other offspring. The genetic diversity from sexual reproduction may also let the individuals of a species exploit new environments, thereby expanding their range.

You have seen that asexual reproduction results in offspring that are virtually genetically identical to the parent; that is, the parental genotype is preserved. Assuming the parent is well adapted to its environment (has a favorable combination of alleles), this genetic similarity may be selectively advantageous if the environment remains stable (unchanging) for several generations. None of the offspring of asexual reproduction is more fit than the parent, but neither is any of them less fit.

Despite the apparent advantages of asexual reproduction, most plant species whose reproduction is primarily asexual occasionally reproduce sexually. Even in what appears a stable environment, plants are exposed to changing selective pressures, such as changes in the number and kinds of predators and parasites, the availability of food, competition from other species, and climate. Sexual reproduction permits species whose reproduction is primarily asexual to increase their genetic variability so at least some individuals are adapted to the changing selective pressures in a stable environment.

Sexual reproduction has some disadvantages

Although the genetic diversity produced by sexual reproduction is advantageous to a species' long-term survival, sexual reproduction is a "costly" form of reproduction. Sexual reproduction requires both male and female gametes, which must meet for reproduction to occur. The many adaptations of flowers for different modes of pollination represent one cost of sexual reproduction.

Sexual reproduction produces some individuals with genotypes that are well adapted to the environment, but it also produces some individuals that are less well adapted. Therefore, sexual reproduction is usually accompanied by high death rates among offspring, particularly when selective pressures are strong. As discussed in Chapter 17, however, this aspect of sexual reproduction is an important part of evolution by natural selection.

Every biological process involves tradeoffs, and sexual reproduction is no exception. Although sexual reproduction has its costs, the adaptive advantages of sexual reproduction clearly outweigh any disadvantages.

Review

- How does sexual reproduction in plants differ from asexual reproduction?
- What is the adaptive advantage of sexual reproduction? Why is sexual reproduction considered a "costly" form of reproduction?

BiologyNow™ Assess your understanding of **sexual and asexual reproduction** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Label the parts of a flower on a diagram, and describe the functions of each part (see Figure 35-1).

- Sexual reproduction occurs in the flower. A flower may contain sepals, petals, stamens, and carpels (pistils).
- **Sepals** cover and protect the flower parts when the flower is a bud. **Petals** play an important role in attracting animal pollinators to the flower.
- **Stamens** produce pollen grains. Each stamen consists of a thin stalk (the **filament**) attached to a saclike structure (the **anther**).

- The **carpel** is the female reproductive unit. A **pistil** may consist of a single carpel or a group of fused carpels. Each pistil has three sections: a **stigma,** on which the pollen grains land; a **style,** through which the pollen tube grows; and an **ovary** that contains one or more **ovules.**

2 Tell where eggs and pollen grains are formed within the flower.

- Pollen forms within pollen sacs in the anther. Each **pollen grain** contains two cells. One generates two sperm cells, and the other produces a **pollen tube** through which the sperm cells reach the ovule.
- An egg and two **polar nuclei,** along with several other nuclei, are formed in the ovule. Both egg and polar nuclei participate directly in fertilization.

3 Compare the evolutionary adaptations that characterize flowers pollinated in different ways (by insects, birds, bats, and wind).

- Flowers pollinated by insects are often yellow or blue and have a scent.
- Bird-pollinated flowers are often yellow, orange, or red and do not have a strong scent.
- Bat-pollinated flowers often have dusky white petals and are scented.
- Plants pollinated by wind often have smaller petals or lack petals altogether and do not produce a scent or nectar; wind-pollinated flowers make large amounts of pollen.

4 Define *coevolution,* and give examples of ways that plants and their animal pollinators have affected one another's evolution.

- **Coevolution** is reciprocal adaptation caused by two different species (such as flowering plants and their animal pollinators) forming an interdependent relationship and affecting the course of one another's evolution. For example, certain flowers have evolved large, showy petals and scent, whereas bees have evolved hairy bodies that catch and hold sticky pollen grains.

5 Distinguish between pollination and fertilization.

- **Pollination** is the transfer of pollen grains from anther to stigma. After pollination, **fertilization,** the fusion of gametes, occurs.
- Flowering plants have **double fertilization.** In the ovule, the egg fuses with one sperm cell, forming a zygote (fertilized egg) that eventually develops into a multicellular embryo in the **seed.** The two polar nuclei fuse with the second sperm cell, forming a triploid nutritive tissue called **endosperm.**

6 Trace the stages of embryo development in flowering plants, and list and define the main parts of seeds.

- A dicot embryo develops in the seed in an orderly fashion, from proembryo to globular embryo to the heart stage to the torpedo stage. The mature flowering plant embryo consists of a **radicle,** a **hypocotyl,** a **plumule,** and **cotyledons** (one in monocots or two in dicots).
- A mature seed contains both a young embryo and nutritive tissue (stored in the **endosperm** or cotyledons) for use during germination.

7 Explain the relationships among the following: ovules, ovaries, seeds, and fruits.

- Ovules are structures with the potential to develop into seeds, whereas ovaries are structures with the potential to develop into fruits. Seeds are enclosed within **fruits,** which are mature, ripened ovaries.

8 Distinguish among simple, aggregate, multiple, and accessory fruits; give examples of each type; and cite several different methods of seed and fruit dispersal.

- **Simple fruits** develop from a single pistil that consists of one carpel or several fused carpels. Some simple fruits (**berries, drupes**) are fleshy at maturity, whereas others (**follicles, legumes, capsules, caryopses, achenes, nuts**) are dry.
- **Aggregate fruits** develop from a single flower with many separate ovaries. **Multiple fruits** develop from the ovaries of many flowers growing in close proximity on a common axis. In **accessory fruits,** the major part of the fruit consists of tissue other than ovary tissue.
- Seeds and fruits are adapted for various means of dispersal, including animals, wind, water, and explosive dehiscence.

9 Explain how the following structures may be used to propagate plants asexually: rhizomes, tubers, stolons, corms, bulbs, plantlets, and suckers.

- Rhizomes, tubers, bulbs, corms, and stolons are stems specialized for asexual reproduction. A **rhizome** is a horizontal underground stem. A **tuber** is a fleshy underground stem enlarged for food storage. A **bulb** is a modified underground bud with fleshy storage leaves attached to a short stem. A **corm** is a short, erect underground stem covered by papery scales. A **stolon** is a horizontal aboveground stem with long internodes.
- Some leaves have meristematic tissue along their margins and give rise to detachable **plantlets.**
- Roots may develop adventitious buds that develop into **suckers.** Suckers produce additional roots and may give rise to new plants.

10 Define *apomixis,* and explain how it occurs.

- **Apomixis** is the production of seeds and fruits without sexual reproduction.

11 State the differences between sexual and asexual reproduction, and discuss the evolutionary advantages and disadvantages of each.

- Sexual reproduction involves the union of two gametes; the offspring produced by sexual reproduction are genetically variable. Asexual reproduction involves the formation of offspring without the fusion of gametes; the offspring are virtually genetically identical to the single parent.
- The parental genotypes are not preserved in the offspring of sexual reproduction. Genetic diversity among offspring produced by sexual reproduction may be selectively advantageous, particularly in an unstable, or changing, environment. Genetic diversity may also let individuals exploit new environments. However, sexual reproduction is costly because both male and female gametes must be produced and must meet.
- The parental genotype is preserved in asexual reproduction. Genetic similarity may be selectively advantageous if the environment remains stable (unchanging) for several generations. In asexual reproduction all individuals can produce offspring. Despite the apparent advantages of asexual reproduction, most plant species whose reproduction is primarily asexual occasionally reproduce sexually, thereby increasing their genetic variability.

POST-TEST

1. In flowering plants, the _____ is/are large (multicellular) and nutritionally independent. (a) gametes (b) microspores (c) megaspores (d) mature gametophyte (e) mature sporophyte
2. The normal order of whorls from the flower's periphery to the center is (a) sepals ⟶ petals ⟶ carpels ⟶ stamens (b) stamens ⟶ carpels ⟶ sepals ⟶ petals (c) sepals ⟶ petals ⟶ stamens ⟶ carpels (d) petals ⟶ carpels ⟶ stamens ⟶ sepals (e) carpels ⟶ stamens ⟶ petals ⟶ sepals
3. The pistil consists of (a) stigma, style, and stamen (b) anther and filament (c) sepal and petal (d) stigma, style, and ovary (e) radicle, hypocotyl, and plumule
4. The petals of a flower are collectively called a(an) (a) calyx (b) capsule (c) carpel (d) cotyledon (e) corolla
5. The transfer of pollen grains from anther to stigma is (a) fertilization (b) double fertilization (c) pollination (d) germination (e) apomixis
6. The observation that insects with long mouthparts, pollinate long, tubular flowers, whereas insects with short mouthparts, pollinate short flowers, is explained by (a) coevolution (b) germination (c) double fertilization (d) apomixis (e) explosive dehiscence
7. The process of _____ in flowering plants involves one sperm cell fusing with an egg cell and one sperm cell fusing with two polar nuclei. (a) coevolution (b) germination (c) double fertilization (d) apomixis (e) pollination
8. The nutritive tissue in the seeds of flowering plants that is formed from the union of a sperm cell and two polar nuclei is called the (a) plumule (b) endosperm (c) cotyledon (d) hypocotyl (e) radicle
9. The _____ is a multicellular structure that anchors the embryo and aids in nutrient uptake from the endosperm (a) proembryo (b) ovule (c) suspensor (d) cotyledon (e) pollen tube
10. After fertilization the ovule develops into a _____, and the ovary into a _____ (a) fruit; seed (b) seed; fruit (c) calyx; corolla (d) corolla; calyx (e) follicle; legume
11. In plants that lack endosperm in their mature seeds, the cotyledons function (a) to enclose and protect the seed (b) to aid in seed dispersal (c) as an absorptive embryonic root (d) to store food reserves (e) to attach the embryo within the ovule
12. _____ fruits develop from many ovaries of a single flower, whereas _____ fruits develop from the ovaries of many separate flowers (a) multiple; accessory (b) simple; accessory (c) aggregate; multiple (d) accessory; aggregate (e) simple; multiple
13. Apples, strawberries, and pears are examples of what kind of fruit? (a) accessory (b) simple (c) multiple (d) aggregate (e) legume
14. A horizontal, underground stem that may or may not be fleshy and that is often specialized for asexual reproduction is called a (a) stolon (b) bulb (c) corm (d) rhizome (e) tuber
15. Place the following events in the correct order: (1) pollen tube grows into ovule (2) insect lands on flower to drink nectar (3) embryo develops within the seed (4) fertilization occurs (5) pollen carried by insect contacts stigma (a) 2-5-1-4-3 (b) 1-4-2-5-3 (c) 3-2-5-1-4 (d) 5-1-3-4-2 (e) 2-5-4-3-1
16. In flowering plant reproduction, the multicellular female gametophyte is also called a(an) (a) pollen grain (b) embryo sac (c) generative cell (d) endosperm (e) hypocotyl
17. A simple, dry fruit that splits open along one suture to release its seeds is a(an) (a) berry (b) legume (c) achene (d) caryopsis (e) follicle

CRITICAL THINKING

1. Draw pictures to show the kinds of flowers that form simple, aggregate, multiple, and accessory fruits.
2. Is seed dispersal by ants an example of coevolution? Why or why not?
3. Using what you have learned in this chapter, speculate whether it is more likely that offspring of asexual reproduction develop in close proximity to or widely dispersed from the parent plant. Explain your reasoning. How could you design an experiment to test your hypothesis?
4. Which type of reproduction, sexual or asexual, might be more beneficial in the following circumstances, and why? (a) a perennial (plant that lives more than two years) in a stable environment, (b) an annual (plant that lives one year) in a rapidly changing environment, (c) a plant adapted to an extremely narrow climate range.
5. Using what you have learned in this chapter, offer an explanation of why telephone poles and wires strung across grassy fields or plains often have tree seedlings growing under them.

Plant Growth and Development

Dwight Kuhn

Black-eyed Susan. This plant (*Rudbeckia hirta*), which grows to 0.9 m (3 ft), produces flowers in response to the shortening nights of spring and early summer.

CHAPTER OUTLINE

- Germination and Early Growth
- Light Signals and Plant Development
- Nastic Movement and Tropisms
- Plant Hormones and Development

As you learned in Chapter 16, the ultimate control of plant growth and *development,* which includes all the changes that take place during the entire life of an individual, is genetic. If the genes required for development of a particular trait, such as the shape of a leaf, the color of a flower, or the type of root system, are not present, that characteristic does not develop. When a particular gene is present, its *expression,* that is, how it exhibits itself as an observable feature of an organism, is determined by a variety of factors, including signals from other genes and from the environment. The location of a cell in the young plant body has a profound effect on gene expression during development. Experiments suggest that chemical signals from adjacent cells help the cell "perceive" its location within the plant body. Each cell's spatial environment helps determine what that cell ultimately becomes.

Environmental cues, such as changing day length and variations in precipitation and temperature, also exert an important influence on gene expression, as they do on all aspects of plant growth and development. The initiation of sexual reproduction is often under environmental control, particularly in temperate latitudes, and plants switch from vegetative growth (in which their leaves, stems, and roots grow) to reproductive growth after receiving the appropriate signals from the environment. Such control is important for the plant's survival because the timing of sexual reproduction is critical for reproductive success: All flowering plants in temperate climates must flower and form seeds before the onset of winter induces **dormancy,** a temporary state of reduced physiological activity. Many flowering plants are sensitive to changes in the relative amounts of daylight and darkness that accompany the changing seasons, and these plants flower in response to those changes (see photograph). Other plants have temperature requirements that induce sexual reproduction. Plants, then, continually perceive information from the environment and use this information to help regulate normal growth and development.

Growth and development are controlled by plant *hormones,* organic compounds that are present in very low concentrations

in plant tissues and that act as chemical signals between cells. **Germination**—the process of a seed sprouting—and the growth of young seedlings into mature plants are aspects of growth and development. A plant's responses to changes in various conditions in its environment, including temperature, light, gravity, and touch, are other aspects of growth and development. We consider all of these topics in this chapter. ■

GERMINATION AND EARLY GROWTH

Learning Objectives

1. Discuss genetic and environmental factors that affect plant growth and development.
2. Summarize the influence of internal and environmental factors on the germination of seeds.

In Chapter 35 you learned how pollination and fertilization are followed by seed and fruit development in flowering plants. Each seed develops from an ovule and contains an embryonic plant and food to provide nourishment for the embryo during germination.

Seed germination requires favorable environmental conditions

Within a given species, the precise requirements for seed germination represent evolutionary adaptations that protect the young seedlings from adverse environmental conditions. Environmental cues, such as the presence of water and oxygen, proper temperature, and sometimes the presence of light penetrating the soil surface, influence whether or not a seed germinates.

No seed germinates unless it has absorbed water. The embryo in a mature seed is dehydrated, and a watery environment is necessary for active metabolism. When a seed germinates, its metabolic machinery is turned on, and numerous materials are synthesized and others degraded. Therefore, water is an absolute requirement for germination. The absorption of water by a dry seed is **imbibition.** As a seed imbibes water, it often swells to several times its original, dry size (Fig. 36-1). Cells imbibe water by adhesion of water onto and into materials such as cellulose, pectin, and starches within the seed. Water molecules are attracted to and bound to these materials by *adhesion,* the attraction between unlike materials (see Chapter 2).

Germination and subsequent growth require a great deal of energy. Because young plants obtain this energy by converting the energy of food molecules stored in the seed's endosperm or cotyledons to ATP during aerobic respiration, much oxygen is usually needed during germination. Some plants, such as rice, carry out *alcohol fermentation* (see Fig. 7-13b) during the early stages of germination and seedling growth. Fermentation enables rice plants to grow and become established in flooded soil, an environment that would suffocate most young plants.

Temperature is another environmental factor that affects germination. Each species has an optimal, or ideal, temperature at which the germination percentage is highest. For most plants, the optimal germination temperature is between 25°C and 30°C (77°F and 86°F). Some seeds, such as those of apples, require prolonged exposure to low temperatures before their seeds break dormancy and germinate. Some of the environmental factors needed for germination help ensure the survival of the young plant. The requirement of a prolonged low-temperature period ensures that seeds adapted to temperate climates germinate in the spring rather than the fall.

Some plants, especially those with tiny seeds, such as lettuce, require light for germination. A light requirement ensures that a tiny seed germinates only if it is close to the soil surface. If such a seed were to germinate several centimeters below the soil surface, it might not have enough food reserves to grow to the surface. But if this light-dependent seed remains dormant until the soil is disturbed and it is brought to the surface, it has a much greater likelihood of survival.

Some seeds do not germinate immediately

A mature seed is often dormant and may not germinate immediately even if growing conditions are ideal. In certain seeds, internal factors, which are under genetic control, prevent germination even when all external conditions are favorable. Many seeds are dormant because certain chemicals are present or absent or because the seed coat restricts germination. For example, the seeds of many desert plants contain high concentrations of *abscisic acid* (discussed later in this chapter), which inhibits germination under unfavorable conditions. Abscisic acid is washed out only when rainfall is sufficient to support the plant's growth after the seed germinates.

Some seeds, such as certain legumes, have extremely hard, thick seed coats that prevent water and oxygen from entering, thereby inducing dormancy. *Scarification,* the process of scratching or scarring the seed coat (physically with a knife or chemically with an acid) before sowing it, induces germination in these plants. Two examples of how scarification occurs in nature are when these seeds pass through the digestive tracts of

animals or when the seed coats are partially digested by soil bacteria.

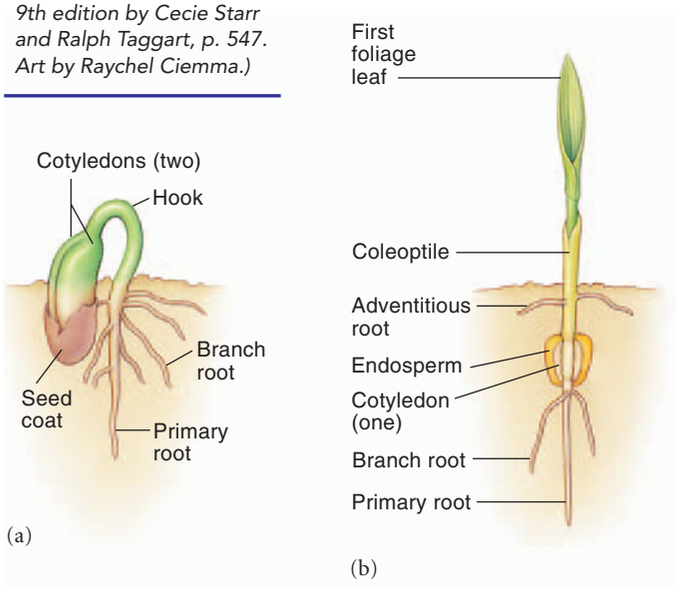
Dicots and monocots exhibit characteristic patterns of early growth

Once conditions are right for germination, the first part of the plant to emerge from the seed is the **radicle,** or embryonic root. As the root grows and forces its way through the soil, it encounters considerable friction from soil particles. A root cap protects the delicate apical meristem of the root tip (see Chapter 34). The shoot is next to emerge from the seed. (Recall from Chapter 31 that a *shoot* is a collective term for a vertical stem with its leaves and reproductive structures.) Stem tips are not protected by a structure comparable to a root cap, but plants have ways to protect the delicate stem tip as it grows through the soil to the surface. The stem of a bean seedling (a dicot), for instance, curves over to form a hook so that the stem tip and cotyledons are actually *pulled up* through the soil (Fig. 36-2a). Corn and other grasses (monocots) have a special sheath of cells called a **coleoptile** that surrounds and protects the young shoot (Fig. 36-2b). First, the coleoptile pushes up through the soil, and then the leaves and stem grow through the tip of the coleoptile.

Certain parts of a plant grow throughout its life. This **indeterminate growth,** the ability to grow indefinitely, is characteristic of stems and roots, both of which arise from apical meristems. Hypothetically, stems and roots could continue growing forever. In contrast, many leaves and flowers have **determinate growth;** that is, they stop growing after reaching a certain size. The size of leaves and flowers with determinate growth varies from species to species and from individual to individual, depending on the plant's genetic programming and on environmental conditions, such as availability of sunlight, water, and essential nutrient minerals.

FIGURE **36-2** **Germination and seedling growth.**

(a) Common bean, a dicot. The hook in the stem protects the delicate stem tip as it grows through the soil. Once the shoot emerges from the soil, the hook straightens. **(b)** Corn, a monocot. The coleoptile, a sheath of cells, emerges first from the soil. The shoot and leaves grow through the middle of the coleoptile. *(From* Biology, Unity and Diversity of Life, *9th edition by Cecie Starr and Ralph Taggart, p. 547. Art by Raychel Ciemma.)*



Review

- What factors influence the germination of seeds?
- Why are plant growth and development so sensitive to environmental cues?

BiologyNow™ Assess your understanding of **germination and early growth** by taking the pretest on your BiologyNow CD-ROM.

LIGHT SIGNALS AND PLANT DEVELOPMENT

Learning Objectives

3 Explain how varying amounts of light and darkness induce flowering, and describe the role of phytochrome in flowering, including a brief discussion of phytochrome signal transduction.

4 Define *circadian rhythm,* and give an example.

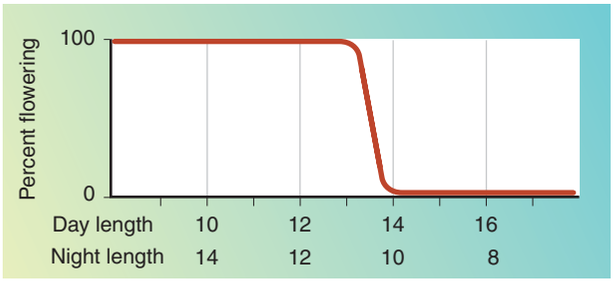
5 Distinguish between phytochrome and cryptochrome.

Photoperiodism is any response of a plant to the relative lengths of daylight and darkness. Initiation of flowering at the shoot apical meristem is one of several physiological activities that are photoperiodic in many plants. Plants are classified into four main groups—short-day, long-day, intermediate-day, and day-neutral—on the basis of how photoperiodism affects their transition from vegetative growth to flowering.

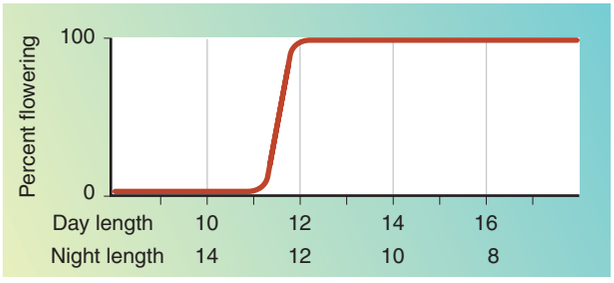
Short-day plants (also called **long-night plants**) flower when the night length is equal to or greater than some critical period (Fig. 36-3a). There are two kinds of short-day plants: qualitative and quantitative. In *qualitative short-day plants,* flowering occurs only in short days, whereas in *quantitative short-day plants,* flowering is accelerated by short days. The initiation of flowering in short-day plants is not due to the shorter period of daylight but to the long, uninterrupted period of darkness. The minimum critical night length varies considerably from one plant species to another but falls between 12 and 14 hours for many. Examples of short-day plants are florist's chrysanthemum, cocklebur, and poinsettia, which typically flower in later summer or fall. Poinsettias, for example, typically initiate flower buds in early October in the Northern Hemisphere and flower about 8 to 10 weeks later; hence their traditional association with Christmas. Short-day plants detect the lengthening nights of late summer or fall, and they flower at that time.

Long-day plants (also called **short-night plants**) flower when the night length is equal to or less than some critical period (Fig. 36-3b). In *qualitative long-day plants,* flowering occurs only in long days, whereas in *quantitative long-day plants,* long days accelerate flowering. Plants such as spinach, black-eyed Susan (see Chapter introduction photo) and the model research plant *Arabidopsis thaliana* flower in late spring or summer and are long-day plants. These plants detect the shortening nights of spring and early summer, and they flower at that time.

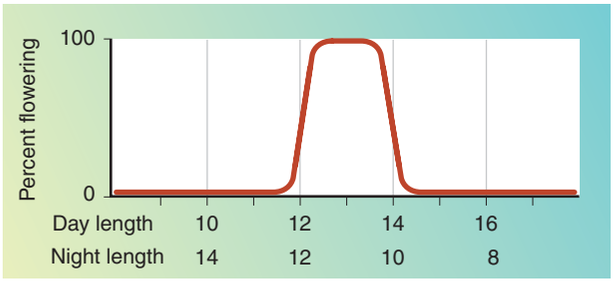
Intermediate-day plants do not flower when night length is either too long or too short (Fig. 36-3c). Sugarcane and coleus



(a) Short-day plant



(b) Long-day plant



(c) Intermediate-day plant

FIGURE **36-3**

Generalized photoperiodic responses in short-day, long-day, and intermediate-day plants.

(a) Short-day plants flower when the night length is equal to or exceeds a certain critical length in a 24-hour period. **(b)** Long-day plants flower when the night length is equal to or less than a certain critical length in a 24-hour period. The critical length varies among different species; short-day plants may require a shorter night length than long-day plants, as shown. **(c)** Intermediate-day plants have a narrow night length requirement.

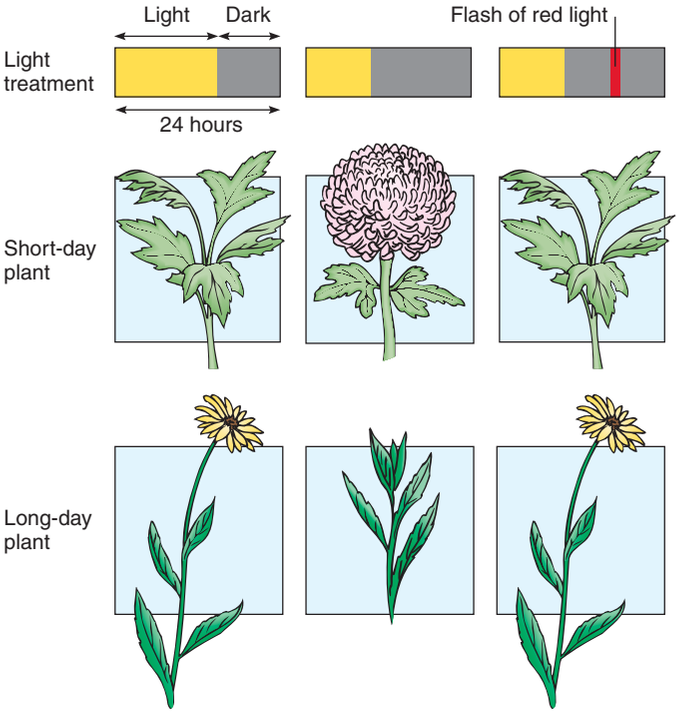


FIGURE **36-4**

Photoperiodic responses of short-day and long-day plants.

A short-day plant flowers when it is grown under long-night conditions *(top middle),* but it does not flower when exposed to a long night interrupted with a brief flash of red light *(top right).* A long-day plant does not flower when grown under long-night conditions *(bottom middle)* unless the long night is interrupted with a brief flash of red light *(bottom right).*

are intermediate-day plants. These plants flower when exposed to days and nights of indeterminate length.

Some plants, called **day-neutral plants,** do not initiate flowering in response to seasonal changes in the period of daylight and darkness but instead respond to some other type of stimulus, external or internal. Cucumber, sunflower, corn, and onion are examples of day-neutral plants. Many of these plants originated in the tropics where day length does not vary appreciably during the year. (In contrast, short-day, long-day, and intermediate-day plants are temperate, or mid-latitude, species.)

Plant biologists have experimented with the effects of various light regimens on flowering. Figure 36-4 shows how flowering in long-day and short-day plants is affected by different light treatments, including a short-day/long-night regimen with a *night break,* a short burst of light in the middle of the night.

Phytochrome detects day length

For a plant or any organism to have a biological response to light, it must contain a light-sensitive substance, called a *photoreceptor,* to absorb the light. The main photoreceptor for photoperiodism and many other light-initiated plant responses (such as germination and seedling establishment) is **phytochrome,** a family of about 5 blue-green pigment proteins, each of which is coded for by a different gene. A mixture of phytochrome proteins is present in cells of all vascular plants examined so far. For example, five members of the phytochrome family, designated phyA, phyB, phyC, phyD, and phyE, occur in *Arabidopsis thaliana.*

Much current knowledge of phytochrome in *Arabidopsis* is based on various mutant plants that do not express a specific phytochrome gene, such as the gene that codes for phyA. By studying the physiological response of plants that do not produce an individual phytochrome, biologists have concluded that the individual forms of phytochrome have both unique and overlapping functions. PhyB appears to exert its influence at all stages of the plant life cycle, whereas the other forms of

phytochrome have narrower functions at specific stages in the life cycle.

PhyA and phyB may have antagonistic (opposite) effects on flowering. In long-day plants, phyB may inhibit flowering and phyA may induce flowering. Flowering occurs more rapidly in long-day plants with mutations in the gene that codes for phyB; such mutations reduce or eliminate the production of phyB. In contrast, flowering is delayed or prevented in long-day plants with mutations in the gene that codes for phyA.

Each member of the phytochrome family exists in two forms and readily converts from one form to the other after absorption of light of specific wavelengths. One form, designated **Pr** (for *r*ed-absorbing *p*hytochrome), strongly absorbs light with a relatively short red wavelength (660 nm). In the process, the shape of the molecule changes to the second form of phytochrome, **Pfr,** so designated because it absorbs *f*ar-*r*ed light, which is light with a relatively long red wavelength (730 nm) (Fig. 36-5). When Pfr absorbs far-red light, it reverts back to the original form, Pr. Pfr is the active form of phytochrome, triggering or inhibiting physiological responses such as flowering.

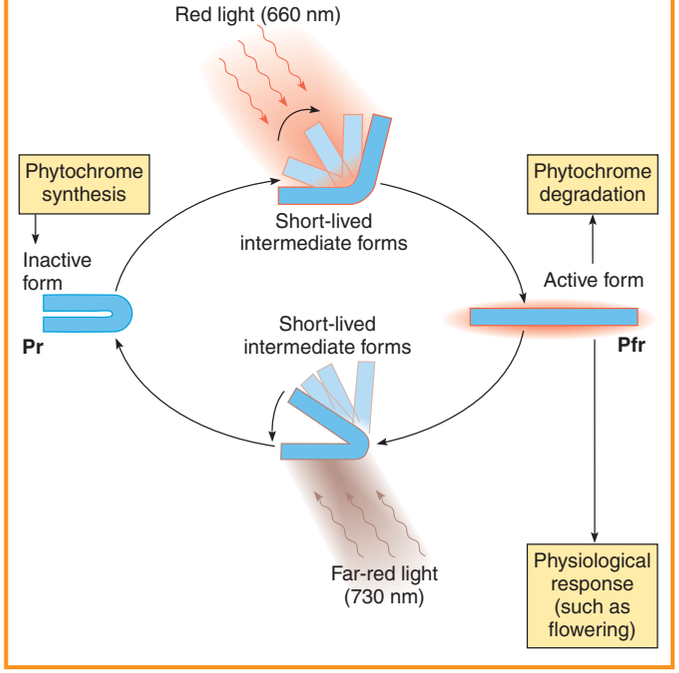
What does a pigment that absorbs red light and far-red light have to do with daylight and darkness? Sunlight consists of various amounts of the entire spectrum of visible light, in addition to ultraviolet and infrared radiation. Because sunlight contains more red than far-red light, however, when a plant is exposed to sunlight, the level of Pfr increases. During the night, the level of Pfr slowly decreases as Pfr, which is less stable than Pr, is degraded.

The importance of phytochrome to plants cannot be overemphasized. Timing of day length and darkness is the most reliable way for plants to measure the change from one season to the next. This measurement, which synchronizes the stages of plant development, is crucial for survival, particularly in environments where the climate has an annual pattern of favorable and unfavorable seasons.

FIGURE **36-5** **Phytochrome.**

This pigment occurs in two forms, designated Pr and Pfr, and readily converts from one form to the other. Red light (660 nm) converts Pr to Pfr, and far-red light (730 nm) converts Pfr to Pr.

KEY CONCEPT: Phytochrome is a unique photoreversible pigment that undergoes changes in conformation on exposure to light of different wavelengths.



Competition for sunlight among shade-avoiding plants involves phytochrome

Plants sense the proximity of nearby plants, which are potential competitors, and react by changing the way they grow and develop. Many plants, from small herbs to large trees, compete for light, a response known as **shade avoidance,** in which plants tend to grow taller when closely surrounded by other plants. If successful, the shade-avoiding plant projects its new growth into direct sunlight, increasing its chances of survival.

Since the 1970s, botanists have recognized the environmental factor that triggers shade avoidance: Plants perceive changes in the ratio of red to far-red light that result from the presence of nearby plants. The leaves of neighboring plants absorb much more red light than far-red light. (Recall from Chapter 8 that the green pigment chlorophyll used in photosynthesis strongly absorbs red light.) In a densely plant-populated area, the ratio of red light to far-red light (r/fr) decreases. The greater relative amount of far-red light triggers a series of responses that cause the shade-avoiding plant, which is adapted to full light environments, to grow taller or flower earlier. Figure 36-6 shows an interesting application of additional (reflected) far-red light without the reduction in incoming sunlight that occurs in shade avoidance.

When a plant is using many of its resources for stem elongation, it has fewer resources for new leaves and branches, storage tissues, or reproductive tissues. However, for a shade-avoiding plant that is shaded by its neighbors, a rapid increase in stem length is advantageous, because once this plant is taller than its neighbors it obtains a larger share of unfiltered sunlight.

Phytochrome is involved in other responses to light, including germination

Phytochrome is involved in the light requirement that some seeds have for germination. Seeds with a light requirement must be exposed to light containing red wavelengths. Exposure to red light converts Pr to Pfr, and germination occurs. Many temperate forest species with small seeds require light for germination. (Larger seeds generally do not have a light requirement.) This adaptation enables the seeds to germinate at the optimal time. During early spring, sunlight, including red light, penetrates the bare branches of overlying deciduous trees and reaches the soil between the trees. As spring temperatures warm, the seeds on the soil absorb red light and germinate. During their early growth, the newly germinated seedlings do not have to compete with the taller trees for sunlight.

Cary Wolinsky

FIGURE **36-6** **Colored mulches and plant growth processes.**

The red mulch reflects far-red light from the ground to the tomato plants. The plants, absorbing the extra far-red light, react as if nearby plants are present. Their aboveground growth is greater, and their fruits ripen earlier. Manipulating mulch colors also modifies yield, flavor, and nutrient content.

Other physiological functions under the influence of phytochrome include sleep movements in leaves (discussed later); shoot dormancy; leaf abscission (see Chapter 32); and pigment formation in flowers, fruits, and leaves.

Phytochrome acts by signal transduction

PROCESS OF SCIENCE

Some phytochrome-induced responses are very rapid and short-term, whereas others are slower and long-term. The rapid responses probably involve reversible changes in the properties of membranes, altering cell ionic balances. Red light, for example, causes potassium ion (K^+) channels to open in cell membranes involved in plant movements caused by changes in turgor (discussed later). Exposure to far-red light causes the K^+ channels to close. Slower phytochrome-induced responses involve the selective regulation of transcription of numerous genes. For example, phytochrome activates transcription of the gene for the small subunit of *Rubisco,* an enzyme involved in photosynthesis (see Chapter 8).

Each phytochrome molecule consists of a protein attached to a light-absorbing photoreceptor. Biologists hypothesize the absorption of light by the photoreceptor portion of phytochrome elicits a change in the shape of the larger protein component. This change in turn triggers one or more signal transduction pathways. In **signal transduction,** a receptor converts an extracellular signal into an intracellular signal that causes some change in the cell. Signal transduction amplifies the original signal and ultimately results in a physiological or developmental response, such as promotion or inhibition of flowering. (It may be helpful to review the general discussion of signal transduction in Chapter 5.)

Some biologists have focused on elucidating phytochrome signal transduction. One important research tool is mutant plants that respond as if they were exposed to a particular light stimulus even when they are not. Research indicates that the active form of phytochrome moves from the cytoplasm into the nucleus, where it affects gene expression by activating a **transcription factor** (see Chapter 13). When activated, the transcription factor, which binds to the promoter of a gene, either turns on or represses transcription that leads to protein synthesis. (Recall from Chapters 12 and 13 that the **promoter** is the nucleotide sequence in DNA to which RNA polymerase attaches to begin transcription.) Biologists have identified **phytochrome-interacting factor (PIF-3),** a transcription factor involved with phytochrome signaling.

The pathway in phytochrome signal transduction with PIF-3 is elegantly simple (Fig. 36-7). In step ①, inactive phytochrome (Pr) in the cytoplasm absorbs red light and is converted into the active form, Pfr, which ② moves into the nucleus. ③ There, phytochrome binds to the transcription factor PIF3 (which is already bound to the promoter) and ④ activates (or represses) the transcription of light-responsive genes. The signal transduction pathway, as currently understood, is summarized as follows:

Red light ⟶ conversion of Pr to Pfr ⟶ movement of Pfr to nucleus ⟶ formation of Pfr-PIF3 complex bound to promoter region ⟶ light-responsive gene switched on (or off)

The signal transduction pathway is shut down by far-red light, which is absorbed by the Pfr in the Pfr-PIF3 complex in the nucleus. When Pfr is converted to Pr, it dissociates from PIF3.

The signal transduction pathway just described is not the end of the story. There are probably other non-PIF3 pathways by which phytochrome regulates light-responsive gene expression. Some of the molecules that may be involved in other phytochrome-mediated signaling pathways include Ca^{2+}, calmodulin, G proteins, and cyclic guanosine monophosphate (cGMP); these molecules are also implicated in signal transduction pathways in animals (see Chapter 47).

Light influences circadian rhythms

Almost all organisms, including plants, animals, fungi, eukaryotic microorganisms, and many prokaryotes, appear to have an internal timer, or biological clock, that approximates a 24-hour cycle, the time it takes for Earth to rotate around its own axis. These internal cycles, known as **circadian rhythms** (from the Latin *circum,* "around," and *diurn,* "daily"), help the organism detect the time of day. In contrast, photoperiodism enables a plant to detect the time of year.

One example of a circadian rhythm in plants is the opening and closing of stomata, independent of light and darkness. Plants

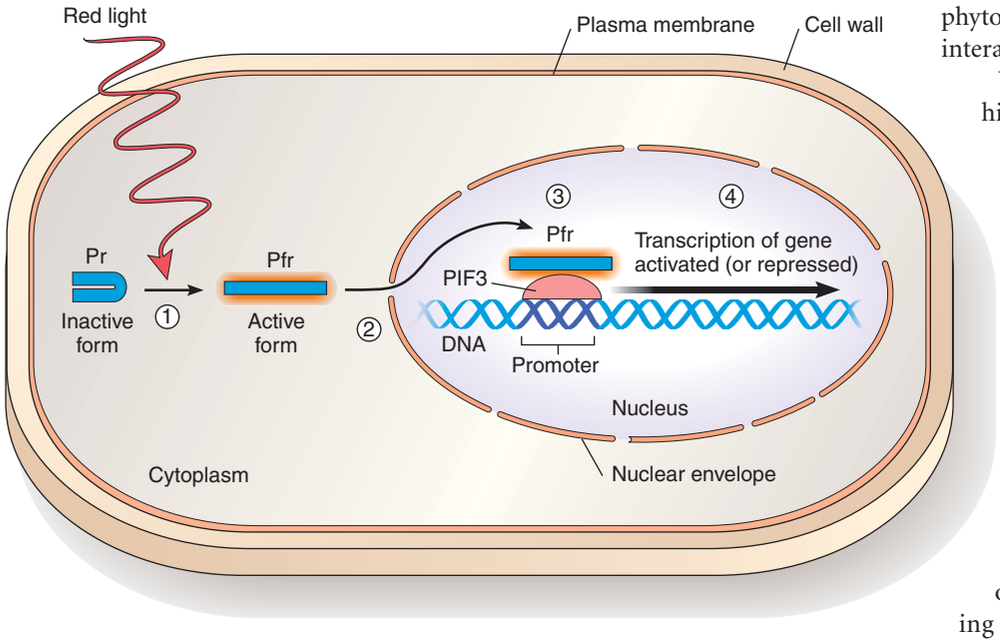


FIGURE **36-7** **Phytochrome signal transduction.**
The numbered steps are explained in the text.

placed in continual darkness for extended periods continue to open and close their stomata on an approximate 24-hour cycle. **Sleep movements** observed in the common bean and other plants are another example of a circadian rhythm (Fig. 36-8). During the day, bean leaves are horizontal, possibly for optimal light absorption, but at night the leaves fold down or up, a movement that orients them perpendicular to their daytime position. The biological significance of sleep movements is unknown at this time.

When constant environmental conditions are maintained, circadian rhythms repeat every 20 to 30 hours, at least for several days. In nature, the rising and setting of the sun reset the biological clock so that the cycle repeats every 24 hours.

For many plants, two photoreceptors—the red light–absorbing phytochrome and the blue light–absorbing **cryptochrome**—are implicated in resetting the biological clock. Certain amino acid sequences of the protein portion of phytochrome are homologous with amino acid sequences of clock proteins in fruit flies, fungi, mammals, and bacteria; this molecular evidence strongly supports the circadian clock role of phytochrome. The evidence for cryptochrome as a clock protein is also convincing. First discovered in plants, cryptochrome counterparts are found in the fruit fly and mouse biological clock proteins. Possibly both photoreceptors are involved in resetting the biological clock in plants: Researchers have evidence that phytochrome and cryptochrome sometimes interact to regulate similar responses.

Why do plants and other organisms exhibit circadian rhythms? Predictable environmental changes, such as sunrise and sunset, occur during the course of each 24-hour period. These predictable changes may be important to an individual organism, causing it to change its physiological activities or its behavior (in the case of animals). It is thought that circadian rhythms help an organism to synchronize repeated daily activities so that they occur at the appropriate time each day. If, for example, an insect-pollinated flower does not open at the time of day that pollinating insects are foraging for food, reproduction will be unsuccessful. Likewise, if a firefly flashes its light on and off at the wrong time of day, it will not find a mate.

Review

- What is phytochrome? What are two roles of phytochrome?
- What is signal transduction?
- In what process is cryptochrome involved?

NASTIC MOVEMENTS AND TROPISMS

Learning Objectives

6 Distinguish between a nastic movement and a tropism.

7 Describe phototropism, gravitropism, thigmotropism, and heliotropism.

You've just seen that some plants have sleep movements. Plants exhibit other kinds of movements in response to environmental stimuli such as light, touch, and gravity. Plants may respond quickly (by nastic movements) or slowly (by tropisms) to adjust the position of their organs. Most of these movements are the result of cell growth.

Changes in turgor induce nastic movements

The sensitive plant (*Mimosa pudica*) dramatically folds its leaves and droops in response to touch (or to an electrical, chemical, or thermal stimulus) (Fig. 36-9). The response, which typically occurs within a few seconds, spreads throughout the plant even if only one leaflet is initially stimulated. When a sensitive plant is touched, an electrical impulse moves down the leaf to special cells housed in structures called **pulvini** (sing., *pulvinus*) at the base of each leaflet, each cluster of leaflets, and each petiole. Each pulvinus is a somewhat swollen joint that acts as a hinge. When the electrical signal reaches cells in the pulvinus, it induces a chemical signal that increases membrane permeability to certain ions. A loss of turgor occurs in certain pulvinus cells as potassium ions (K^+) and chloride ions (Cl^-) exit through the now permeable plasma membrane, causing water to leave the cells by osmosis (see Chapter 5 for a discussion of turgor pressure). The sudden change in turgor causes the leaf movement. Such **nastic movements** occur in response to external stimuli, but the direction of movement is predetermined and is independent of the direction of the stimulus. Nastic movements are temporary and reversible. The movement of K^+, Cl^-, and water back into the pulvinus cells causes the plant part to return to its original position, although recovery takes several to many minutes longer than the original movement.

A tropism is directional growth in response to an external stimulus

A plant may respond to an external stimulus, such as light, gravity, or touch, by directional growth (that is, the direction of growth depends on the direction of the stimulus). Such a directional growth response, called a **tropism,** results in a change in the position of a plant part. Tropisms are irreversible and may be positive or negative, depending on whether the plant grows toward the stimulus (a positive tropism) or away from it (a negative tropism). Tropisms are under hormonal control, which is discussed later in this chapter.

FIGURE **36-10** **Phototropism.**

Stems of corn (*Zea mays*) seedlings grow in the direction of light and therefore exhibit positive phototropism. The bending is caused by greater elongation on the shaded side of a stem than on the lighted side.

Phototropism is the directional growth of a plant caused by light (Fig. 36-10). Most growing shoot tips exhibit positive phototropism by bending (growing) toward light, something you may have observed if you place houseplants near a sunny window. This growth response increases the likelihood that stems and leaves receive adequate light for photosynthesis. The bending response of phototropism is triggered by blue light with wavelengths less than 500 nm. (You may recall from Chapter 32 that blue light also induces stomata to open.)

The photoreceptor that absorbs blue light and triggers the phototropic response is thought to be a yellow pigment. Traditionally, two families of yellow pigments—flavins and carotenoids—were leading candidates for the blue light photoreceptor. In 1998, researchers convincingly demonstrated in *Arabidopsis* that a flavoprotein (a flavin attached to a protein molecule) is the photoreceptor for phototropism. In 2002 the photoreceptor was named **phototropin.** Knowledge of the signal transduction pathway by which blue light triggers phototropism and other responses in plants is the focus of current research. There is evidence that phototropin becomes phosphorylated—that is, a phosphate group is added—in response to blue light. Thus, phosphorylation may be an early step in the blue light–signaling pathway.

Growth in response to the direction of gravity is called **gravitropism.** Most stem tips exhibit negative gravitropism by growing away from the center of Earth, whereas most root tips exhibit positive gravitropism (Fig. 36-11). The root cap is the site of gravity perception in roots; when the root cap is removed, the root continues to grow, but it loses any ability to perceive gravity. Special cells in the root cap possess starch-containing **amyloplasts** that collect toward the bottoms of the cells in response to gravity, and these amyloplasts may initiate at least some of the gravitropic response. If the root is put in a different position, as when a potted plant is laid on its side, the amyloplasts tumble to a new position, always settling in the direction of gravity. The gravitropic response (bending) occurs shortly thereafter and involves the hormone *auxin* (discussed later in the chapter). Despite the movement of amyloplasts in response to gravity, their role in gravitropism is questioned. A mutant *Arabidopsis* plant that lacks amyloplasts in its root cap cells still responds gravitropically when placed on its side, indicating that roots do not necessarily need amyloplasts to respond to gravity. Ongoing research may clarify how roots perceive gravity.

Thigmotropism is growth in response to a mechanical stimulus, such as contact with a solid object. The twining or curling growth of tendrils or stems, which helps attach a climbing plant such as a vine to some type of support, is an example of thigmotropism (see Fig. 32-14b).

Heliotropism, also called **solar tracking,** is the ability of leaves or flowers of certain plants, such as sunflower, soybean, and cot-

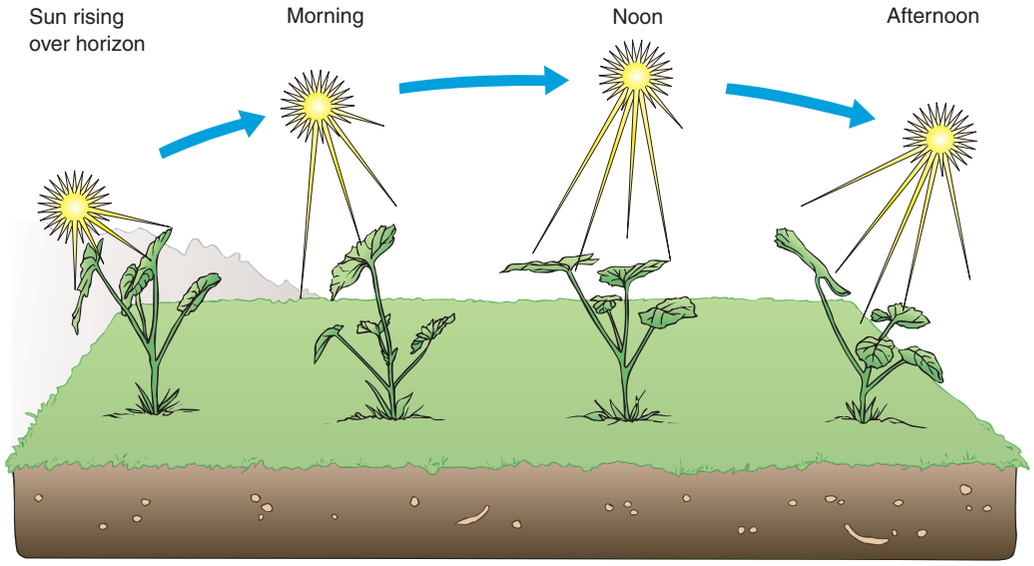
Heliotropism.

Note that the leaves are oriented so they are perpendicular to the sun's rays throughout the day, thereby maximizing the amount of light absorbed.



ton, to follow the sun's movement across the sky (Fig. 36-12). Frequently, the leaves of such plants arrange themselves so that they are perpendicular to the sun's rays, regardless of the time of day or the sun's position in the sky. This positioning allows for maximal light absorption. Many solar trackers have pulvini at the bases of their petioles. Changes in turgor in the cells of the pulvinus help position the leaf in its optimum orientation relative to the sun. Like phototropism, heliotropism is triggered by blue light.

Review

- How do nastic movements and tropisms differ?
- What is phototropism? How does blue light trigger the phototropic response?
- How do gravitropism, thigmotropism, and heliotropism differ?

PLANT HORMONES AND DEVELOPMENT

Learning Objectives

8 Describe a general mechanism of action for plant hormones.

9 List several ways each of these hormones affects plant growth and development: auxins, gibberellins, cytokinins, ethylene, and abscisic acid.

10 Summarize the activities of these plant hormones and hormone-like signaling molecules: brassinolides, salicylic acid, systemin, oligosaccharins, and jasmonates.

A plant **hormone** is an organic compound that acts as a chemical signal eliciting a variety of responses that regulate growth and development. The study of plant hormones is challenging because hormones are effective in extremely small amounts (less than 10^{-6} moles per liter). In addition, the effects of different plant hormones overlap, and it is difficult to determine which hormone, if any, is the primary cause of a particular response. Plant hormones may also stimulate a response at one concentration and inhibit that same response at a different concentration.

For many years, biologists studied five major classes of plant hormones: auxins, gibberellins, cytokinins, ethylene, and abscisic acid. More recently, researchers have uncovered compelling evidence for a variety of signaling molecules, such as brassinolide, salicylic acid, systemin, oligosaccharins, and jasmonic acid. (Table 36-1 summarizes the 10 plant hormones and hormone-like signaling molecules discussed in this chapter.)

Plant hormones act by signal transduction

PROCESS OF SCIENCE

Researchers have used molecular genetic techniques to better understand the biology of plant hormones. *Arabidopsis* mutants are particularly useful. For example, different mutants have defects in hormone synthesis, hormone transport, signal reception, or signal transduction. These mutants enable plant biologists to identify and clone genes involved in these aspects of hormone biology. Studying the mutant phenotypes helps plant biologists establish connections between the mutant genes and specific physiological activities involved in growth and development.

Plant and animal hormones are similar in their basic mechanism of action. Like animal hormones, plant hormones bind to specific receptor proteins on the plasma membrane or in the target cells (Fig. 36-13). As shown in step ①, each receptor has a 3-D shape that binds only with one kind of hormone molecule. ② This binding activates a G protein in the plasma membrane (see Chapter 5). The G protein triggers the production of a **second messenger,** an intracellular signaling molecule that affects the function of the cell. Ions such as Ca^{2+} serve as second messengers in many plant cells. Cyclic AMP (see Fig. 3-25),

TABLE **36-1** Plant Hormones and Signaling Molecules

Hormone	Site of Production	Principal Actions
Auxins (e.g., IAA) 	Shoot apical meristem, young leaves, seeds	Stem elongation, apical dominance, root initiation, fruit development
Gibberellins (e.g., GA_3) 	Young leaves and shoot apical meristems, embryo in seed	Seed germination, stem elongation, flowering, fruit development
Cytokinins (e.g., Zeatin) 	Roots	Cell division, delay of leaf senescence, inhibition of apical dominance, flower development, embryo development, seed germination
Ethylene 	Stem nodes, ripening fruit, damaged or senescing tissue	Fruit ripening, responses to environmental stressors, seed germination, maintenance of apical hook on seedlings, root initiation, senescence and abscission in leaves and flowers
Abscisic acid 	Almost all cells that contain plastids (leaves, stems, roots)	Seed dormancy, responses to water stress
Brassinosteroids (e.g., Brassinolide) 	Unknown	Light-mediated gene expression, cell division, stem elongation, flower development, leaf senescence
Salicylic acid 	Wound (site of infection)	Resistance to disease organisms
Systemin*	Wound (site of herbivore or pathogen attack)	Initiation of defenses against predators (herbivores) or disease organisms
Oligosaccharins* 	Unknown	May function in normal cell growth and development; defense responses to disease organisms
Jasmonates (e.g., Jasmonic acid) 	Leaves? Probably many tissues	Initiation of defenses against predators or disease organisms

*Key Ⓐ = amino acid; [Sug] = sugar.

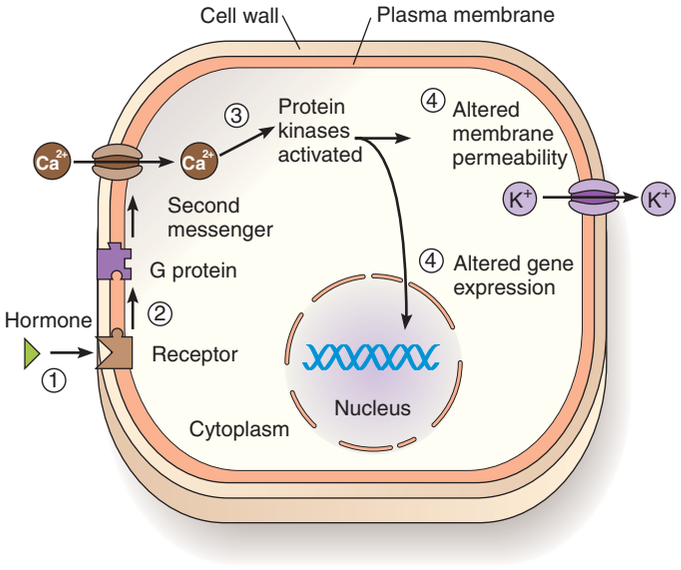

FIGURE **36-13** **General mechanism of action of plant hormones.**

This diagram includes aspects of signal reception, signal transduction, and altered cell activity (responses) that have been demonstrated for various plant hormones. The numbered steps are explained in the text.

an important second messenger in a variety of prokaryotes and eukaryotes, may also be a signaling molecule for at least one plant hormone (auxin).

As shown in ③, once the concentration of Ca^{2+} or other second messenger increases in the cell, it may bind to proteins and activate or inactivate certain enzymes, such as protein kinases. The enzymes can phosphorylate proteins, which alter cell activity in some way, ④ such as altered membrane permeability and/or altered gene expression (that is, altered transcription and/or translation). (Chapter 47 discusses second messengers as they relate to animal hormones.)

Auxins promote cell elongation

PROCESS OF SCIENCE

Charles Darwin, the British naturalist best known for developing the theory of natural selection to explain evolution, also provided the first evidence for the existence of auxins. The experiments that Darwin and his son Francis performed in the 1870s involved positive phototropism, the directional growth of plants toward light. The plants they used were newly germinated canary grass seedlings. As in all grasses, the first part of a canary grass seedling to emerge from the soil is the coleoptile, a protective sheath that encircles the stem. When coleoptiles are exposed to light from only one direction, they bend toward the light. The bending occurs below the tip of the coleoptile.

The Darwins tried to influence this bending in several ways (Fig. 36-14). For example, they covered the tip of the coleoptile as soon as it emerged from the soil. When they covered that part of the coleoptile above where the bend would be expected to occur, the plants did not bend. On other plants, they removed the coleoptile tip and found bending did not occur. When the bottom of the coleoptile where the curvature would occur was shielded from the light, the coleoptile bent toward light. From these experiments, the Darwins concluded that "some influence is transmitted from the upper to the lower part, causing it to bend."

In the 1920s Frits Went, a young Dutch scientist, isolated the phototropic hormone from oat coleoptiles. He removed the coleoptile tips and placed them on tiny blocks of agar for a period of time. When he put one of these agar blocks squarely on a decapitated coleoptile, normal growth resumed. When he placed one of these agar blocks to one side of the tip of a decapitated coleoptile in the dark, bending occurred (Fig. 36-15). This indicated the substance had diffused from the coleoptile tip into the agar and, later, from the agar into the decapitated coleoptile.

ACTIVE FIGURE **36-14** **The Darwins' phototropism experiments.**

(a) Some canary grass coleoptiles were uncovered, some were covered only at the tip, some had the tip removed, and some were covered everywhere but at the tip. The covers were impervious to light. **(b)** After exposure to light coming from one direction, the uncovered plants and the plants with uncovered tips grew toward the light. The plants with tips covered or removed did not bend toward light.

BiologyNow™ See **the Darwin's Experiments** in action by clicking on this figure on your BiologyNow CD-ROM.

(b)

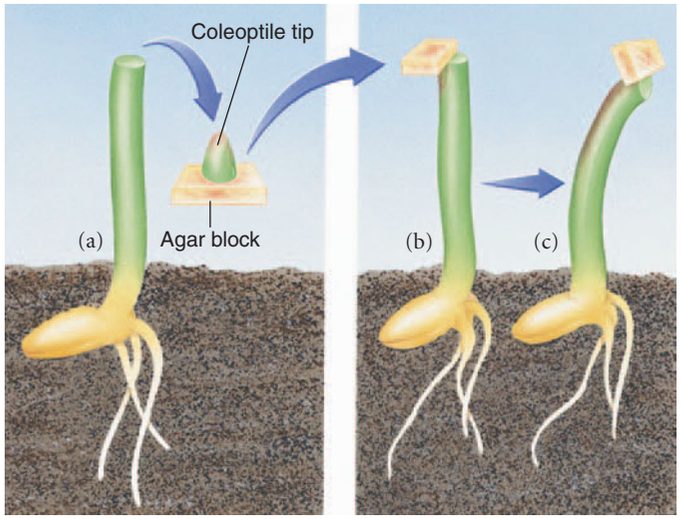

FIGURE **36-15** **Isolating auxin from coleoptiles.**

(a) Coleoptile tips were placed on agar blocks for a period. **(b)** The agar block was transferred to a decapitated coleoptile. It was placed off-center, and the coleoptile was left in darkness. **(c)** The coleoptile bent. This indicated that a chemical moved from the original coleoptile tip to the agar block and from there to one side of the decapitated coleoptile, causing that side to elongate.

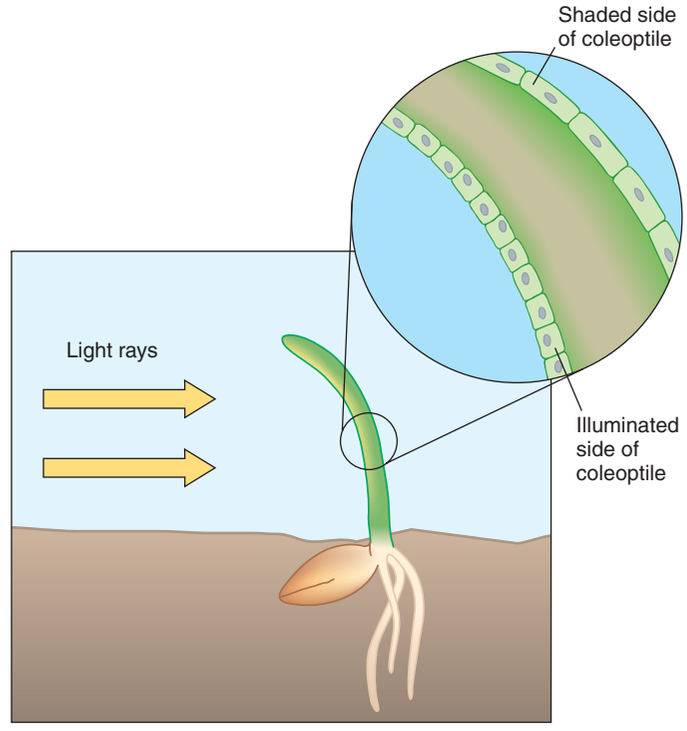

FIGURE **36-16** **Phototropism and the unequal distribution of auxin.**

Auxin travels down the side of the stem or coleoptile *away* from the light, causing cells on the shaded side to elongate. Therefore, the stem or coleoptile bends toward light.

Went named this substance **auxin** (from the Greek *aux,* "enlarge" or "increase"). The purification and elucidation of the primary auxin's chemical structure were accomplished in the mid-1930s by a research team led by U.S. biologist Kenneth Thimann at the California Institute of Technology.

Auxin is a group of several natural (and artificial) plant hormones; the most common and physiologically important auxin is **indoleacetic acid (IAA).** The movement of auxin in the plant is said to be *polar,* or unidirectional. Auxin moves downward along the shoot–root axis from its site of production, usually the shoot apical meristem. Young leaves and seeds are also sites of auxin production.

Auxin's most characteristic action is promotion of cell elongation in stems and coleoptiles. This effect, apparently exerted by acidification of cell walls, increases their plasticity, enabling them to expand under the force of the cell's internal turgor pressure. Auxin's effect on cell elongation also provides an explanation for phototropism. When a plant is exposed to a light from only one direction, some of the auxin migrates laterally to the shaded side of the stem before moving down the stem by polar transport. Because of the greater auxin concentration on the shaded side of the stem, the cells there elongate more than the cells on the light side, and the stem bends toward the light (Fig. 36-16). Auxin is also involved in gravitropism, thigmotropism, and possibly heliotropism.

Auxin exerts other effects on plants. For example, some plants tend to branch out very little when they grow. Growth in these plants occurs almost exclusively from the apical meristem rather than from axillary buds, which do not develop as long as the terminal bud is present. Such plants are said to exhibit **apical dominance,** the inhibition of axillary bud growth by the apical meristem. In plants with strong apical dominance, auxin produced in the apical meristem inhibits axillary buds near the apical meristem from developing into actively growing shoots. When the apical meristem is pinched off, the auxin source is removed, and axillary buds grow to form branches. Apical dominance is often quickly re-established, however, as one branch begins to inhibit the growth of others. Recent evidence indicates that other hormones (ethylene and cytokinin, both discussed later) are also involved in apical dominance. As with other physiological activities, the changing ratios of these hormones may be the factor responsible for apical dominance.

Auxin produced by developing seeds stimulates the development of the fruit. When auxin is applied to certain flowers in which fertilization has not occurred (and, therefore, in which seeds are not developing), the ovary enlarges and develops into a seedless fruit. Seedless tomatoes are produced in this manner.[1] Auxin is not the only hormone involved in fruit development, however.

Some manufactured, or synthetic, auxins have structures similar to IAA. The synthetic auxin naphthalene acetic acid stimulates root development on stem cuttings and is used for asexual

[1] Not all seedless fruits are produced by treatment with auxin. In Thompson seedless grapes, fertilization occurs but the embryos abort, and therefore the seeds fail to develop. Thompson seedless grapes are sprayed with the hormone gibberellin to increase berry size.

Joe Eakes, Color Advantage/Visuals Unlimited

FIGURE **36-17** **Auxin and root development on stem cuttings.**

(Left) Many adventitious roots developed on a honeysuckle (*Lonicera fragrantissima*) cutting placed in a solution with a high concentration of synthetic auxin. *(Middle)* Fewer roots developed in a lower auxin concentration. *(Right)* The cutting placed in water (no auxin) served as a control and did not form roots in the same period.

propagation, particularly of woody plants with horticultural importance (Fig. 36-17). The synthetic auxins 2,4-D and 2,4,5-T are used as selective herbicides (weed killers). These compounds kill plants with broad leaves but, for reasons not completely understood, do not kill grasses. Both herbicides are similar in structure to IAA and disrupt the plants' normal growth processes. Because many of the world's most important crops are grasses (such as wheat, corn, and rice), 2,4-D and 2,4,5-T can be used to kill broadleaf weeds that compete with these crops. The use of 2,4,5-T is no longer allowed in the United States, however, because of its association with dioxins, a group of mildly to very toxic compounds formed as byproducts during the manufacture of 2,4,5-T.

Gibberellins promote stem elongation

In the 1920s, a Japanese biologist was studying a disease of rice in which the young rice seedlings grew extremely tall and spindly, fell over, and died. The cause of the disease, dubbed the "foolish seedling" disease, was a fungus (*Gibberella fujikuroi*) that produces a chemical substance named **gibberellin.** Not until after World War II did scientists in Europe and North America learn of the exciting work done by the Japanese. During the 1950s and 1960s, studies in the United States and Great Britain showed that gibberellins are produced by healthy plants as well as by the fungus that causes foolish seedling disease.

Gibberellins are hormones involved in many normal plant functions. The symptoms of foolish seedling disease are caused by an abnormally high gibberellin concentration in the plant tissue (because both plant and fungus produce gibberellin). Currently, more than 110 naturally occurring gibberellins are known, although many are probably inactive precursors; there are no synthetic gibberellins.

As in foolish seedling disease, gibberellins promote stem elongation in many plants. When gibberellin is applied to a plant, particularly certain dwarf varieties, this elongation may be spectacular. Some corn and pea plants that are dwarfs as a result of one or more mutations grow to a normal height when treated with gibberellin (Fig. 36-18a). Short-stemmed, high-yielding varieties of wheat are short-stemmed because they have a reduced response to gibberellin. These varieties put less of their resources into stem height and more resources into grain production. Gibberellins are also involved in **bolting,** the rapid elongation of a floral stalk that occurs naturally in many plants when they initiate flowering (Fig. 36-18b).

Gibberellins cause stem elongation by stimulating cells to divide as well as elongate. The actual mechanism of cell elongation differs from that caused by auxin, however. Recall that IAA-induced cell elongation involves the acidification of the cell wall. In gibberellin-induced cell elongation, cell wall acidification does not occur; instead, gibberellin increases the mechanical extensibility of a cell wall.

Gibberellins affect several reproductive processes in plants. They stimulate flowering, particularly in long-day plants. In addition, they substitute for the low temperature that biennials require before they begin flowering. If gibberellins are applied to biennials during their first year of growth, flowering occurs without exposure to a period of low temperature. Gibberellins, like auxin, affect the development of fruits. Agriculturalists apply gibberellins to several varieties of grapes to produce larger fruits.

Gibberellins are also involved in seed germination in many plants. In a classic experiment involving barley seed germination, researchers showed that the release of gibberellin from the embryo triggers the synthesis of α-amylase, an enzyme that digests starch in the endosperm. As a result, glucose becomes available for absorption by the embryo. Although enzymes mobilize starch reserves in many types of seeds, gibberellin control of seed enzymes appears restricted to cereals and other grasses. In addition to mobilizing food reserves in newly germinated grass seeds, application of gibberellins substitutes for low-temperature or light requirements for germination in seeds such as lettuce, oats, and tobacco.

Cytokinins promote cell division

During the 1940s and 1950s, researchers were trying to find substances that might induce plant cells to divide in **tissue culture,** a technique in which cells are isolated from plants and grown in a nutrient medium (see *Focus On: Cell and Tissue Culture*). They discovered that cells would not divide without a substance found in coconut milk. Because coconut milk has a complex chemical composition, investigators did not chemically identify the division-inducing substance for some time. Finally, researchers isolated an active substance from a different source, aged DNA from herring sperm. They called it **cytokinin** because it induces cytokinesis, or cytoplasmic division. In 1963 researchers identified the first natural plant cytokinin, zeatin, in corn. Since then similar molecules have been identified in other plants. Biologists have also synthesized several cytokinins. Cytokinins are structurally similar to adenine, a purine base that is part of DNA and RNA molecules.

Cytokinins promote cell division and differentiation of young, relatively unspecialized cells into mature, more specialized cells in intact plants. They are a required ingredient in any plant tissue culture medium and must be present for cells to di-

FIGURE **36-18** **Gibberellin and stem elongation.**

(b) *(left)* Like many biennials, Indian blanket (*Gaillardia pulchella*) grows as a rosette, which is a circular cluster of leaves close to the ground, during its first year. *(right)* It then bolts when it initiates flowering in the second year. The plant in bloom grows to 0.6 m (2 ft).

vide. In tissue culture, cytokinins interact with auxin during the formation of plant organs such as roots and stems (Fig. 36-19). For example, in tobacco tissue culture a high ratio of auxin to cytokinin induces root formation, whereas a low ratio of auxin to cytokinin induces shoot formation.

Cytokinins and auxin also interact in the control of apical dominance. Here their relationship is antagonistic: Auxin inhibits the growth of axillary buds, and cytokinin promotes their growth.

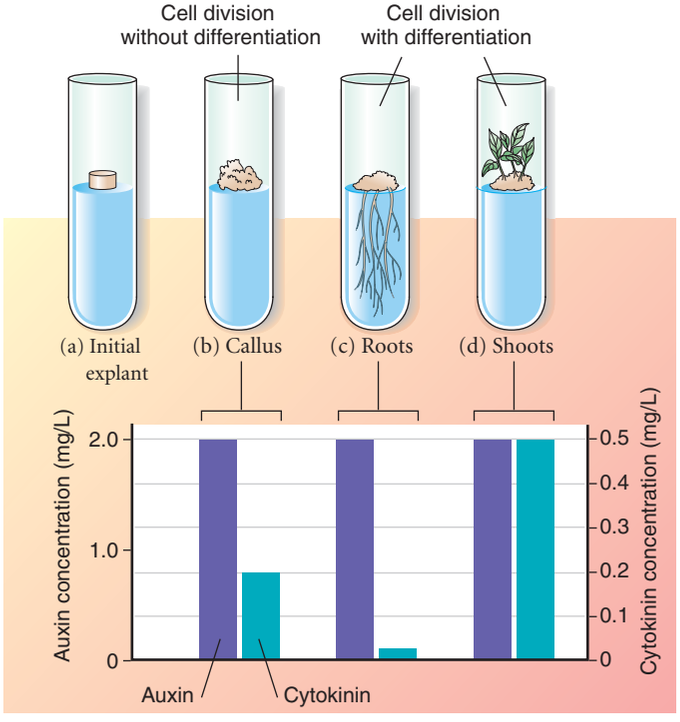

FIGURE **36-19** **Auxin-cytokinin interactions in tissue culture.**

Varying amounts of auxin and cytokinin in the culture media produce different growth responses. **(a)** The initial explant is a small piece of sterile tissue from the pith of a tobacco stem, which is placed on nutrient agar. **(b)** Nutrient agar containing 2.0 mg/L of auxin and 0.2 mg/L of cytokinin causes cells to divide and form a clump of undifferentiated tissue called a callus. **(c)** Agar with a high ratio of auxin (2.0 mg/L) to cytokinin (0.02 mg/L) stimulates root growth. **(d)** Agar with a lower ratio of auxin (2.0 mg/L) to cytokinin (0.5 mg/L) stimulates shoot growth.

Focus On Cell and Tissue Culture

Cells can be isolated from certain plants and grown in a chemically defined, sterile nutrient medium. In initial experiments with such cultures, plant cells could be kept alive, but they did not divide. Researchers later discovered that adding certain natural materials such as the liquid endosperm of coconut, also known as coconut milk, induced cells to divide in culture. By the late 1950s, plant cells from a variety of sources could be cultured successfully, dividing to produce a mass of disorganized, relatively undifferentiated cells, or **callus.**

In 1958, F.C. Steward, a plant physiologist at Cornell University, succeeded in generating an entire carrot plant from a single callus cell derived from a carrot root (see Fig. 16-2). This demonstrated conclusively that each plant cell contains a genetic blueprint for all features of an entire organism. His work also showed that an entire plant can be grown from a single cell, provided the proper genes are expressed at the appropriate times.

Since Steward's pioneering work, biologists have successfully cultured many plants using a variety of cell sources. Plants have been regenerated from different tissues, organ explants (excised organs or parts such as root apical meristems), and single cells. Cell and tissue culture techniques help answer many fundamental questions involving growth and development in plants. These techniques also have great practical potential. Using tissue culture, it is possible to regenerate many genetically identical plants from the cells of a single, genetically superior plant. Many kinds of plants—from orchids and African violets to coastal redwoods—have been cultured in this way.

It is also possible to alter the genetic composition of a cell while it is in culture and then have these changes expressed in the whole plant following regeneration. Thus tissue culture provides a valuable tool to genetic engineers who wish to introduce desirable new traits, such as better nutritional properties, into crop species such as rice (see Fig. 14-16b).

One effect of cytokinins on plant cells is to delay the aging process. Plant cells, like all living cells, go through a natural aging process known as **senescence.** Senescence is accelerated in cells of plant parts that are cut, such as flower stems. Botanists think plants must have a continual supply of cytokinins from the roots. Cut stems, of course, lose their source of cytokinins and therefore age rapidly. When cytokinins are sprayed on leaves of a cut stem of many species, they remain green, whereas unsprayed leaves turn yellow and die.

Courtesy of Dr. Richard M. Amasino, University of Wisconsin

Despite their involvement in regulating many aspects of plant growth and development, cytokinins currently have few commercial applications other than plant tissue culture. However, in 1995, molecular biologists at the University of Wisconsin combined a promoter from a gene activated during normal senescence with a gene that encodes an enzyme involved in cytokinin synthesis. The leaves of transgenic tobacco plants that contained this recombinant DNA produced more cytokinin and therefore lived longer and continued to photosynthesize (Fig. 36-20). This molecular technology has the potential to increase the longevity and productivity of certain crops.

Ethylene promotes abscission and fruit ripening

During the early 20th century, scientists observed that the gas **ethylene** (C_2H_4) has several effects on plant growth, but not until 1934 did they demonstrate that plants produce ethylene. This

FIGURE **36-20** **Cytokinin synthesis and delay of senescence.**

The tobacco (*Nicotiana tabacum*) plant on the left was genetically engineered to produce additional cytokinin as it aged, whereas the tobacco plant of the same age on the right served as a control. Note the extensive senescence and death of older leaves on the control plant. Depending on the variety, tobacco grows 0.9 to 3 m (3 to 10 ft) tall.

natural hormone influences many plant processes. Ethylene inhibits cell elongation, promotes seed germination, promotes apical dominance, and is involved in plant responses to wounding or invasion by disease-causing microorganisms.

Ethylene also has a major role in many aspects of senescence, including fruit ripening. As a fruit ripens, it produces ethylene, which triggers an acceleration of the ripening process. This induces the fruit to produce more ethylene, which further accelerates ripening. The expression "one rotten apple spoils the barrel" is true. A rotten apple is one that is overripe and produces large amounts of ethylene, which diffuses and triggers the ripening process in nearby apples. Humans use ethylene commercially to uniformly ripen bananas and tomatoes. These fruits are picked while green and shipped to their destination, where they are exposed to ethylene before they are delivered to grocery stores (Fig. 36-21).

Plants growing in a natural environment encounter rain, hail, wind, and contact with passing animals. All these mechanical stressors alter their growth and development, making them shorter and stockier than plants grown in a greenhouse. Ethylene regulates such developmental responses to mechanical stimuli, known as **thigmomorphogenesis.** Plants that are mechanically disturbed produce additional ethylene, which in turn inhibits stem elongation and enhances cell wall thickening in supporting cells such as collenchyma and sclerenchyma. These changes are adaptive because shorter, thicker stems are less likely to be damaged by mechanical stressors.

Ethylene is involved in leaf abscission, which is actually influenced by two antagonistic hormones, ethylene and auxin. As a leaf ages (when autumn approaches, for deciduous trees in temperate climates), the level of auxin in the leaf decreases. Concurrently, cells in the abscission layer at the base of the petiole (where the leaf will break away from the stem) begin producing ethylene.

FIGURE **36-21** **Ethylene and fruit ripening.**

Both boxes of tomatoes were picked at the same time, while green. The tomatoes in the box on the right were exposed to an atmosphere containing 100 ppm of ethylene for three days.

Illustration Services

Abscisic acid promotes seed dormancy

In 1963 two different research teams discovered **abscisic acid.** Despite its name, abscisic acid is involved in seed dormancy and in a plant's response to stress; abscisic acid does not induce abscission in most plants. As an environmental stress hormone, abscisic acid particularly promotes changes in plant tissues that are water stressed. (Recall that ethylene also affects plant responses to certain stressors, such as mechanical stressors and wounding.)

Botanists best understand the effect of abscisic acid on plants suffering from water stress. The level of abscisic acid increases dramatically in the leaves of plants exposed to severe drought conditions. The high level of abscisic acid in the leaves activates a signal transduction process that leads to the closing of stomata. The closing of stomata saves the water that the plant would normally lose by transpiration, thereby increasing the plant's likelihood of survival. As knowledge of abscisic acid signaling in guard cells increases, botanists hope to use this information to engineer crops and horticultural plants that are resistant to drought.

The onset of winter is also a type of stress on plants. A winter adaptation that involves abscisic acid is dormancy in seeds. Many seeds have high levels of abscisic acid in their tissues and do not germinate until the abscisic acid washes out. In a corn mutant unable to synthesize abscisic acid, the seeds germinate as soon as the embryos are mature, even while attached to the ear (Fig. 36-22).

Image not available due to copyright restrictions

Abscisic acid is not the only hormone involved in seed dormancy. For example, addition of gibberellin reverses the effects of dormancy. In seeds, the level of abscisic acid decreases during the winter, and the level of gibberellin increases. Cytokinins are also implicated in breaking dormancy. Once again, you see that a single physiological activity such as seed dormancy may be controlled in plants by the interaction of several hormones. The plant's actual response may result from changing ratios of hormones rather than the effect of each individual hormone.

Additional signaling molecules affect growth and development, including plant defenses

Biologists continue to discover new plant hormones and hormone-like signaling molecules . Many of these signaling molecules are involved in defensive responses of plants to disease organisms and insects. Here we briefly consider five groups—the brassinolides, salicylic acid, systemin, oligosaccharins, and jasmonates.

Brassinolides are steroids

Although steroid hormones have crucial roles in animals, their roles in plants are unclear. The **brassinolides** are a group of steroids that may function as plant hormones. Brassinolides appear to be involved in several aspects of growth and development. *Arabidopsis* mutants that cannot synthesize brassinolides are dwarf plants with reduced fertility. Researchers reverse this defect by applying brassinolides. Studies of these mutants suggest that the brassinolides are involved in developmental processes such as cell division and cell elongation.

Salicylic acid is a phenolic compound

For centuries people chewed willow (*Salix*) bark to treat headaches and other types of pain. **Salicylic acid** was first extracted from willow bark and is chemically related to aspirin (acetylsalicylic acid). More recently, biologists have shown that salicylic acid helps plants defend against insect pests and pathogens such as viruses. When a plant is under attack, the concentration of salicylic acid increases, and it spreads systemically throughout the plant. It is thought that salicylic acid binds to a cell receptor, triggering a signal transduction pathway that switches on genes. Presumably, these genes code for proteins that fight infection and promote wound healing.

Plants also use salicylic acid to signal nearby plants. Tobacco plants infected with tobacco mosaic virus release into the air a volatile form of salicylic acid, known as *methyl salicylate,* or *oil of wintergreen.* When nearby healthy plants receive the airborne chemical signal, they begin synthesizing antiviral proteins that enhance their resistance to the virus.

Systemin is a small polypeptide

Although many animal hormones are polypeptides, the first plant polypeptide with hormonal properties was not isolated until 1991. This 18-amino-acid polypeptide, **systemin,** is transported systemically throughout the plant in response to wounding by insects. Systemin may stimulate natural defense mechanisms at extremely low concentrations, as low as one part per trillion. Systemin may trigger the plant to activate genes that produce *protease inhibitors,* molecules that disrupt insect digestion, curbing leaf damage done by caterpillars and other herbivorous (plant-eating) insects. The discovery of systemin in tomato leaves prompted a flurry of research in search of polypeptide regulators and resulted in the discovery of additional polypeptides in other plants.

Oligosaccharins are composed of sugar residues

Oligosaccharins are carbohydrate fragments that consist of short, branched chains of sugar molecules. They are present in extremely small quantities in cells and active at much lower concentrations (100 to 1000 times lower) than hormones such as auxin. Different oligosaccharins may have distinct functions. Some trigger the production of **phytoalexins** (from the Greek *phyto,* "plant," and *alexi,* "to ward off"), antimicrobial compounds that limit the spread of plant pathogens such as fungi. Other oligosaccharins inhibit flowering and induce vegetative growth.

Jasmonates are derivatives of fatty acids

Jasmonates affect several plant processes, such as pollen development, root growth, fruit ripening, and senescence. These lipid-derived plant hormones, which are structurally similar to *prostaglandins* in animals, are also produced in response to the presence of insect pests and disease-causing organisms. Jasmonates trigger the production of enzymes that confer an increased resistance against herbivorous insects (see *On the Cutting Edge: Herbivore Defense Against Plant-Produced Signaling Molecules*). For example, caterpillar-infested tomato plants release volatile chemicals into the air that attract natural caterpillar enemies, such as parasitic wasps that lay their eggs on the caterpillar's bodies. When the eggs hatch, the larvae consume, and ultimately kill, the host insects. In one study, treating plants with jasmonic acid increased parasitism on caterpillar pests twofold over control fields in which the plants did not have jasmonic acid applications. Jasmonates may be of practical value in controlling certain insect pests without the use of chemical pesticides.

Unidentified plant hormones remain to be discovered

PROCESS OF SCIENCE

Experiments in which different tobacco species are grafted together indicate that unidentified flower-promoting and flower-inhibiting substances may exist. *Nicotiana silvestris* is a long-day tobacco plant, and a variety of *Nicotiana tabacum* is a day-neutral tobacco plant. When a long-day tobacco is grafted to a day-neutral tobacco and exposed to short nights, both plants flower (Fig. 36-23). The day-neutral tobacco plant flowers sooner than

ON THE CUTTING EDGE: Herbivore Defense Against Plant-Produced Signaling Molecules

PROCESS OF SCIENCE

Hypothesis: Some plant-eating insects "eavesdrop" on plant defensive signals and respond by activating their own defenses.

Methods: Researchers fed corn earworms diets of plant signaling molecules (either jasmonate or salicylate) and evaluated their responses.

Results: Corn earworms with either jasmonate or salicylic acid in their diets rapidly produced enzymes to counter plant defensive toxins.

Conclusion: Corn earworms use jasmonate and salicylate to activate their production of enzymes that detoxify plant-produced chemicals.

TABLE **36-A** Effects of Jasmonate and Salicylate on Mortality in Corn Earworms

Pre-exposure to signaling molecule	Diet treatment	Percent mortality (after 3 days)
No (control)	Control diet—no toxin	0.0
No (control)	Xanthotoxin	8.9
No (control)	Celery leaves	33.3
Jasmonate	Control diet—no toxin	0.0
Jasmonate	Xanthotoxin	0.0
Jasmonate	Celery leaves	3.0
Salicylate	Control diet—no toxin	3.3
Salicylate	Xanthotoxin	0.0
Salicylate	Celery leaves	7.0

Plants protect themselves from being eaten by producing an array of defensive chemicals that are unpalatable or even toxic to herbivores. However, some herbivores have evolved countermeasures, including the production of enzymes that break down, or detoxify, the plant's defensive chemicals. Insects that respond in this way can eat a variety of host plants. The corn earworm (*Helicoverpa zea),* for example, has more than 100 known host plants; in addition to corn, it eats beans, peas, peppers, potatoes, squash, tomatoes, and many other agriculturally important plants.

Graduate student Xianchun Li and professors Mary Schuler and May Berenbaum from the University of Illinois decided to study the highly successful corn earworm's ability to eavesdrop on its host plant's defenses.* They reared 270 caterpillars and divided them into three different feeding groups. One group of 90 caterpillars ate a diet that contained a small amount of the plant signaling molecule *jasmonate,* another group of 90 ate a diet containing the signaling molecule *salicylate,* and the third group (the control) ate a diet without either signaling molecule.

After 12 hours of feeding, each caterpillar group was subdivided into three groups, each containing 30 caterpillars. One of these subgroups was fed a diet containing *xanthotoxin,* a plant toxin produced in response to jasmonate signaling. The second subgroup was fed a diet of celery leaves; celery is known to produce toxins in response to feeding damage. The third subgroup served as a control and was fed a diet without toxins. The biologists monitored the caterpillars' growth and development, for example, by measuring differences in mortality (see table).

Examine the percent mortality after 3 days: Caterpillars exposed to jasmonate and then fed xanthotoxin had no mortality, compared to a death rate of 8.9% in the control. Caterpillars exposed to jasmonate and then fed celery leaves experienced 3.0% mortality, compared to 33.3% in the contol. The results are similar for caterpillars exposed to salicylate. Exposure to jasmonate or salicylate reduced mortality, presumably because the jasmonate or salicylate activated caterpillar genes coding for enzymes that detoxify plant toxins.

To test the hypothesis that jasmonate activates catepillar genes coding for enzymes that detoxify plant poisons, the researchers used molecular techniques to examine gene expression in the caterpillars. Several cytochrome P450 genes are known to code for enzymes that detoxify plant defensive chemicals in the caterpillar's digestive system. The biologists demonstrated that, after exposure to plant signaling molecules, four of the caterpillar's cytochrome P450 genes are rapidly expressed, either before or at around the same time that plants are synthesizing defensive molecules. (Other researchers demonstrated that, in celery, defensive compounds begin to accumulate 24 hours after the plant is exposed to jasmonate. The compounds reach their maximal concentration in plant tissues about 4 to 6 days after exposure.)

In summary, this research demonstrates that corn earworms detect the signaling molecules jasmonate and salicylate, which plants produce in response to feeding injuries. Jasmonate and salicylate trigger plants to produce defensive toxins, but they also activate genes in corn earworms that code for enzymes that detoxify the plant toxins.

Some researchers have suggested that crop plants could be genetically engineered to produce airborne chemical signals such as jasmonate and salicylate, thereby reducing the number of herbivores feeding on them (see *On the Cutting Edge: New Possibilities for Environmentally Friendly Pest-Control Strategies,* in Chapter 1). However, the results of Li, Schuler, and Berenbaum indicate that the strategy of using signaling molecules to control some insect pests may not produce the desired outcome.

*Li, Xianchun, M.A. Schuler, and M.R. Berenbaum, "Jasmonate and Salicylate Induce Expression of Herbivore Cytochrome P450 Genes," *Nature,* Vol. 419, 17 Oct. 2002.

it normally would. Biologists think that a flower-promoting substance, **florigen,** may be induced in the long-day plant and transported to the day-neutral plant through the graft union, causing the day-neutral tobacco plant to flower sooner than expected. An intact plant may produce florigen in the leaves and transport it in the phloem to the shoot apical meristem. There, it induces a transition from vegetative to reproductive development—that is, to a meristem that produces flowers.

When a botanist grafts a long-day tobacco to a day-neutral tobacco and exposes them to long nights, neither plant flowers. As long as these conditions continue, the day-neutral plants do not flower even when they would normally do so. In this case,

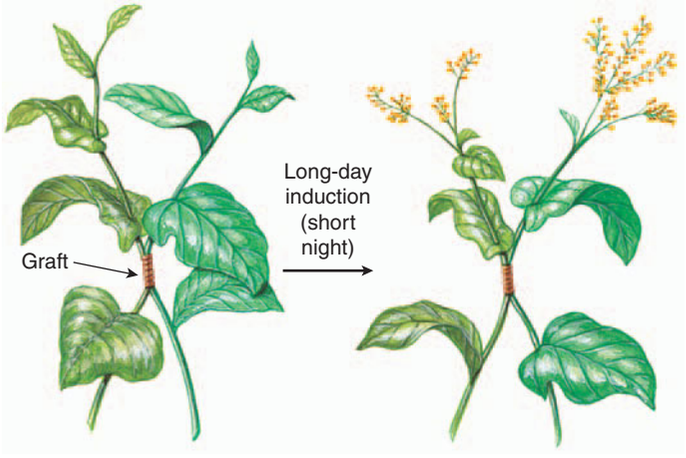

FIGURE 36-23 Evidence for the existence of a flower-promoting substance.

When a long-day tobacco plant (*Nicotiana silvestris*) is grafted to a day-neutral tobacco plant (*N. tabacum*) and both plants are exposed to a long-day/short-night regimen, they both flower. The day-neutral plant flowers sooner than it normally would, presumably because a flower-promoting substance passes from the long-day plant to the day-neutral one through the graft.

the long-day tobacco may produce a flower-inhibiting substance that is transported to the day-neutral tobacco through the graft union. This substance prevents the day-neutral tobacco from flowering. Biologists have not yet isolated and chemically characterized substances that are clearly identifiable as flower promoters (florigen) or flower inhibitors.

Review

- How are signal reception, signal transduction, and altered cell activity part of the general mechanism of action for plant hormones?
- How is auxin involved in phototropism?
- Which hormones are involved in each of the following physiological processes: (a) seed germination, (b) stem elongation, (c) fruit ripening, (d) leaf abscission, (e) seed dormancy?
- How does salicylic acid help plants defend against insects and viruses?

BiologyNow™ Assess your understanding of **plant hormones and development** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Discuss genetic and environmental factors that affect plant growth and development.

- Plant growth and development are controlled by internal factors, such as a cell's location in the plant body, and by environmental factors, such as changing day length. The location of a cell in the young plant body affects gene expression during development by causing some genes in that cell to be turned off and others to be turned on.

2 Summarize the influence of internal and environmental factors on the germination of seeds.

- **Germination** is the process of seed sprouting. Internal factors affecting whether a seed germinates include the maturity of the embryo, the presence or absence of chemical inhibitors, and the presence or absence of hard, thick seed coats.
- External environmental factors that may affect germination include requirements for oxygen, water, temperature, and light. For example, before germinating, dry seeds absorb water by **imbibition.**

3 Explain how varying amounts of light and darkness induce flowering, and describe the role of phytochrome in flowering, including a brief discussion of phytochrome signal transduction.

- **Photoperiodism** is any response of plants to the duration and timing of light and dark. In many plants, flowering is a photoperiodic response; some are **short-day plants,** some are **long-day plants,** and others are **intermediate-day plants.** In **day-neutral plants,** flowering is not affected by photoperiod.
- The photoreceptor in photoperiodism is **phytochrome,** a family of about five blue-green pigments. Each type of phytochrome has two forms, **Pr** and **Pfr,** named by the wavelength of light they absorb. Pfr is the active form, triggering or inhibiting physiological responses such as flowering, **shade avoidance,** and a light requirement for germination. Each type of phytochrome may have both unique and overlapping physiological functions. PhyB seems to exert its influence at all stages of the plant life cycle.
- Some phytochrome-induced responses are rapid and short term (such as changes in membrane properties); others are slower and long term (such as the regulation of gene transcription).
- The absorption of light by phytochrome triggers one or more signal transduction pathways. In **signal transduction,** a receptor converts an extracellular signal into an intracellular signal that causes some change in the cell.

4 Define *circadian rhythm,* and give an example.

- A **circadian rhythm** is a regular period in the growth or activities of a plant or other organism that approximates the 24-hour day and is reset by the rising and setting of the sun. Two plant examples of circadian rhythms are the opening and closing of stomata and **sleep movements.**

5 Distinguish between phytochrome and cryptochrome.

- Both phytochrome and **cryptochrome** are photoreceptors that sometimes interact to regulate similar responses, such as resetting the biological clock. Phytochrome strongly absorbs red light, whereas cryptochrome absorbs blue light.

6 Distinguish between a nastic movement and a tropism.

- Nastic movements and tropisms are the two kinds of plant movements that occur in response to external stimuli. **Nastic movements,** which are temporary and reversible, occur in response to external stimuli, but the direction of movement is independent of the direction of the stimulus.

SUMMARY WITH KEY TERMS *(continued)*

- **Tropisms** are directional growth responses (i.e., the direction of growth is dependent on the direction of the stimulus).

7 Describe phototropism, gravitropism, thigmotropism, and heliotropism.

- **Phototropism** is plant growth in response to the direction of light. **Gravitropism** is plant growth in response to the influence of gravity. **Thigmotropism** is plant growth in response to contact with a solid object. **Heliotropism** is the ability of leaves or flowers to track the sun across the sky.

8 Describe a general mechanism of action for plant hormones.

- Plants produce and respond to **hormones,** organic compounds that act as highly specific chemical signals, eliciting a variety of responses that regulate growth and development. Hormones are effective in extremely small concentrations. The functions of some plant hormones overlap, and many physiological activities of plants are regulated by the interactions of several hormones rather than a single hormone.
- Plant hormones bind to specific receptor proteins in or on target cells. This binding may trigger the production of a **second messenger** such as Ca^{2+}. The second messenger may, in turn, bind to and activate or inactivate certain enzymes. This activation or inactivation may lead to altered membrane permeability and/or altered gene expression.

9 List several ways each of these hormones affects plant growth and development: auxins, gibberellins, cytokinins, ethylene, and abscisic acid.

- **Auxin** is involved in cell elongation; tropisms; **apical dominance,** the inhibition of axillary buds by the apical meristem; and fruit development. Auxin also stimulates root development on stem cuttings. Some synthetic auxins (2,4-D and 2,4,5-T) are selective herbicides.
- **Gibberellins** are involved in stem elongation, flowering, and germination.
- **Cytokinins** promote cell division and differentiation; delay **senescence,** the natural aging process; and interact with auxin and ethylene in apical dominance. Cytokinins induce cell division in **tissue culture,** a technique in which cells are isolated from plants and grown in a nutrient medium.
- **Ethylene** plays a role in ripening fruits; apical dominance; leaf abscission; wound response; **thigmomorphogenesis,** a developmental response to mechanical stressors such as wind; and senescence.
- **Abscisic acid** is an environmental stress hormone involved in stomatal closure caused by water stress and in seed dormancy.

10 Summarize the activities of these plant hormones and hormone-like signaling molecules: brassinolides, salicylic acid, systemin, oligosaccharins, and jasmonates.

- Plant steroids known as **brassinolides** are probably involved in several aspects of plant growth and development, such as cell division and cell elongation.
- **Salicylic acid** helps defend plants against pathogens and insect pests. It may bind to a cell receptor, thereby switching on genes that fight infection and promote wound healing. A volatile form of salicylic acid may serve as an airborne chemical signal from virus-infected plants to healthy ones.
- **Systemin,** a plant polypeptide with hormonal properties, stimulates a natural defense mechanism in which the plant produces protease inhibitors, molecules that disrupt insect digestion.
- **Oligosaccharins,** short, branched chains of sugar molecules, have various functions: they inhibit flowering and stimulate vegetative growth. Oligosaccharins bind to membrane receptors and alter gene expression.
- **Jasmonates** affect several plant processes, such as pollen development, root growth, fruit ripening, and senescence. They are also produced in response to the presence of insect pests and disease-causing organisms.

POST-TEST

1. A plant's response to the relative amounts of daylight and darkness is (a) apical dominance (b) bolting (c) gravitropism (d) photoperiodism (e) phototropism
2. Pfr, the active state of _____ , forms when red light is absorbed. (a) photosystem I (b) phytochrome (c) far-red light (d) phototropin (e) cryptochrome
3. Which of the following represents the correct order in the phytochrome signal transduction pathway? (1) red light (2) light-responsive gene is switched on (or off) (3) movement of Pfr to nucleus (4) conversion of Pr to Pfr (5) formation of PFr-PIF3 complex that is bound to promoter region (a) 1-3-5-4-2 (b) 1-5-3-2-4 (c) 1-2-3-4-5 (d) 1-4-3-2-5 (e) 1-4-3-5-2
4. Which of the following statements about phytochrome is *incorrect?* (a) Phytochrome is the main photoreceptor for photoperiodism. (b) Phytochrome is a family of about five blue-green pigment proteins, each coded by a different gene. (c) Most of our knowledge of phytochrome function is based on mutant corn (*Zea mays*) plants. (d) Each member of the phytochrome family exists in two forms: Pr and Pfr. (e) Phytochrome helps plants sense the presence of nearby plants with which they must compete for light.
5. Which photoreceptor(s) is/are implicated in resetting the biological clock? (a) phytochrome only (b) cryptochrome only (c) gibberellin only (d) cryptochrome and gibberellin (e) phytochrome and cryptochrome
6. In _____, leaves or other plant organs track the sun's movement across the sky. (a) heliotropism (b) thigmotropism (c) phototropism (d) bolting (e) photoperiodism
7. The orientation of the growth of a plant according to the direction of light is called _____, whereas the twining of tendrils is an example of _____. (a) heliotropism; gravitropism (b) photoperiodism; nastic movements (c) phototropism; gravitropism (d) phototropism; thigmotropism (e) photoperiodism; thigmotropism
8. When you prune shrubs to make them "bushier"—that is, to prevent apical dominance—you are affecting the distribution and action of which plant hormone? (a) auxin (b) jasmonic acid (c) systemin (d) ethylene (e) abscisic acid
9. A synthetic _____ known as 2,4-D is used as a selective herbicide. (a) auxin (b) gibberellin (c) cytokinin (d) ethylene (e) abscisic acid

POST-TEST *(continued)*

10. Research on a fungal disease of rice provided the first clues about the plant hormone (a) auxin (b) gibberellin (c) cytokinin (d) ethylene (e) abscisic acid
11. This plant hormone interacts with auxin during the formation of plant organs in tissue culture. (a) florigen (b) gibberellin (c) cytokinin (d) ethylene (e) abscisic acid
12. The plant hormone _____ delays senescence, whereas the plant hormone _____ promotes senescence. (a) cytokinin; auxin (b) auxin; cytokinin (c) cytokinin; ethylene (d) abscisic acid; ethylene (e) gibberellin; auxin
13. The stress hormone that helps plants respond to drought is (a) auxin (b) gibberellin (c) cytokinin (d) ethylene (e) abscisic acid
14. This hormone promotes seed dormancy. (a) auxin (b) gibberellin (c) cytokinin (d) ethylene (e) abscisic acid
15. Which signaling molecule triggers the release of volatile substances that attract parasitic wasps to plant-eating caterpillars? (a) brassinolide (b) jasmonic acid (c) systemin (d) salicylic acid (e) oligosaccharin

CRITICAL THINKING

1. Predict whether flowering in a short-day plant with a minimum critical night length of 14 hours would be expected to occur in the following situations. Explain each answer. (a) The plant is exposed to 15 hours of daylight and 9 hours of darkness. (b) The plant is exposed to 9 hours of daylight and 15 hours of darkness. (c) The plant is exposed to 9 hours of daylight and 15 hours of darkness, with a 10-minute exposure to red light in the middle of the night.
2. If you transplanted the short-day plant discussed in question 1 to the tropics, would it flower? Explain your answer.
3. Many solar-tracking flowers live in cool arctic or alpine environments. The temperature of certain heliotropic flowers is up to 14°F warmer than that of the surrounding air. Insects are drawn to these warm flowers. Given these observations, suggest a possible adaptive explanation for heliotropism in such environments.
4. What biological advantages are conferred on a plant whose stems are positively phototropic and whose roots are positively gravitropic?

The Animal Body: Introduction to Structure and Function

Fritz Polking/Dembinsky Photo Associates

Larger body size does not mean bigger cells. The cells of the Yacare caiman (*Caiman yacare*) and the flambeau butterfly (*Dryas julia*) on its head are all about the same size. The caiman is larger because its genes specify that its body should consist of a larger number of cells.

CHAPTER OUTLINE

- Tissues
- Organs and Organ Systems
- Regulating Body Temperature

As you read in Chapters 28 through 30, scientists have identified more than a million animal species. In those chapters, we introduced you to dramatically diverse animal groups with radically different body structures. Yet despite their differences, animal groups share many characteristics. One of these characteristics is their relatively large size.

Why *are* most animals larger than bacteria, protists, and fungi? Many biologists think the answer is related to *ecological niches,* which are the functional roles of a species within a community. By the time animals evolved, bacteria, protists, and fungi already occupied most available ecological niches. For new species to succeed, they had to displace other organisms from a niche or adapt to a new one. Success in a new niche required a new body plan, and new body plans often involved larger size. Large size gave more opportunity for capturing food. Predators are typically larger than their prey.

To grow larger than their bacterial and protist competitors, animals had to be multicellular. Recall that the size of a single cell is limited by the ratio of its surface area (plasma membrane) to its volume (see Chapter 4). The plasma membrane needs to be large enough relative to the cell's volume to permit passage of materials into and out of the cell, so that the conditions necessary for life can be maintained. In a multicellular animal, each cell has a large enough surface-to-volume ratio to effectively regulate its internal environment. Individual cells live and die and are replaced while the organism continues to maintain itself and thrive. The number of cells, not their individual sizes, is usually responsible for the size of an animal.

In unicellular organisms, such as bacteria and many protists, the single cell carries on all the activities necessary for life. Recall that unicellular and small, flat organisms depend on diffusion for many life processes, including gas exchange and disposal of metabolic wastes. One reason they can be small is that they

do not have complex organ systems. They move about without muscles, coordinate their activities without a nervous system, and process food without a digestive system.

Consider how different the caiman and the butterfly are, not only in size but also in body form and lifestyle (see photograph). In a multicellular organism, cells specialize to perform specific tasks. A **tissue** consists of a group of closely associated, similar cells that carry out specific functions.

Tissues associate to form **organs** such as the heart or stomach. Groups of tissues and organs form the **organ systems** of a complex **organism.** In a large, complex animal, billions of cells may be organized to form tissues, organs, and organ systems.

Cells, tissues, organs, and organ systems work together to maintain appropriate conditions in the body. The tendency to maintain a relatively constant internal environment is called **homeostasis,** and the processes that accomplish the task are **homeostatic mechanisms.** For example, in mammals, nervous, endocrine, and circulatory systems work together to regulate body temperature.

In this chapter we focus on the types and functions of tissues characteristic of animals. We then introduce the organ systems of a complex animal and discuss the important concept of homeostasis, using regulation of body temperature as an example. In the remaining chapters of this unit, we discuss how animals carry out life processes and how the organ systems of a complex animal work together to maintain homeostasis of the organism as a whole. ■

TISSUES

Learning Objectives

1. Compare the structure and function of the four main kinds of animal tissues: epithelial, connective, muscle, and nervous tissues.
2. Describe the main types of epithelial tissue, and state their functions.
3. Compare the main types of connective tissue, and summarize their functions.
4. Contrast the three types of muscle tissue and their functions.
5. Relate the structure of the neuron to its function.

Biologists classify animal tissues as epithelial, connective, muscle, or nervous tissue. Classification of tissues depends on their structure and origin. Each kind of tissue (and subtissue) is composed of cells with characteristic sizes, shapes, and arrangements, and each type of tissue is specialized to perform a specific function or group of functions. For example, some tissues are specialized to transport materials, whereas others contract, enabling the animal to move. Still others secrete hormones that regulate metabolic processes. As we discuss each tissue type, notice the relationship between its form and its function.

Epithelial tissues cover the body and line its cavities

Epithelial tissue (also called **epithelium**) consists of cells fitted tightly together to form a continuous layer, or sheet, of cells. One surface of the sheet is typically exposed because it covers the body (outer layer of the skin) or lines a cavity, such as the lumen (cavity) of the intestine. The other surface of an epithelial layer attaches to the underlying tissue by a noncellular **basement membrane** consisting of tiny fibers and nonliving polysaccharide material that the epithelial cells produce.

Epithelial tissue forms the outer layer of the skin and the linings of the digestive, respiratory, excretory, and reproductive tracts. As a result, everything that enters or leaves the body must cross at least one layer of epithelium. Food taken into the mouth and swallowed is not really "inside" the body until it is absorbed through the epithelium of the gut and enters the blood. To a large extent, the permeabilities of the various epithelial tissues regulate the exchange of substances between the different parts of the body, as well as between the animal and the external environment.

Epithelial tissues perform many functions, including protection, absorption, secretion, and sensation. The epithelial layer of the skin, the **epidermis,** covers the entire body and protects it from mechanical injury, chemicals, bacteria, and fluid loss. The epithelial tissue lining the digestive tract absorbs nutrients and water into the body. Some epithelial cells form **glands** that secrete cell products such as hormones, enzymes, or sweat. Other epithelial cells are sensory receptors that receive information from the environment. For example, epithelial cells in taste buds and in the nose specialize as chemical receptors.

Table 37-1 illustrates the main types of epithelial tissue, indicates their locations in the body, and describes their functions. You can distinguish three types of epithelial cells on the basis of shape. **Squamous** epithelial cells are thin, flat cells shaped like flagstones. **Cuboidal** epithelial cells are short cylinders that from the side appear cube-shaped, like dice. Actually, each cuboidal cell is typically hexagonal in cross section, making it an eight-sided polyhedron. **Columnar** epithelial cells look like columns or cylinders when viewed from the side. The nucleus is usually located near the base of the cell. Viewed from above or in cross section, these cells often appear hexagonal. On its free surface, a columnar epithelial cell may have cilia that beat in a coordinated way, moving materials over the tissue surface. Most of the upper respiratory tract is lined with ciliated columnar epithelium that moves particles of dust and other foreign material away from the lungs.

Epithelial tissue is also classified by the number of layers. **Simple epithelium** is composed of one layer of cells. It is usually located where substances are secreted, excreted, or absorbed, or where materials diffuse between compartments. For example, simple squamous epithelium lines the air sacs in the lungs. The structure of this thin tissue is wonderfully suited to permit diffusion of gases in and out of air sacs.

Stratified epithelium, which has two or more layers, is found where protection is required. Stratified squamous epithelium, which makes up the outer layer of your skin, continuously regenerates as it is sloughed off during normal wear and tear.

The cells of **pseudostratified epithelium** falsely appear layered. Although all its cells rest on a basement membrane, not every cell extends to the exposed surface of the tissue. This arrangement gives the impression of two or more cell layers. Some of the respiratory passageways are lined with pseudostratified epithelium equipped with cilia.

The cells lining blood and lymph vessels, called **endothelium,** have a different embryonic origin from "true" epithelium. However, these cells are structurally similar to squamous epithelial cells and can be included in that category.

A gland consists of one or more epithelial cells specialized to produce and secrete a product such as sweat, milk, mucus, wax, saliva, hormones, or enzymes (Fig. 37-1). Epithelial tissue lining the cavities and passageways of the body typically has some specialized mucus-secreting cells called **goblet cells.** The mucus lubricates these surfaces, offers protection, and facilitates the movement of materials.

Glands are classified as exocrine or endocrine. **Exocrine glands,** like goblet cells and sweat glands, secrete their products onto a free epithelial surface, typically through a duct (tube). **Endocrine glands** lack ducts. These glands release their products, called **hormones,** into the **interstitial fluid** (tissue fluid) or blood; hormones are typically transported by the circulatory system. (Endocrine glands are discussed in Chapter 47.)

An **epithelial membrane** consists of a sheet of epithelial tissue and a layer of underlying connective tissue. Types of epithelial membranes include mucous membranes and serous membranes. A **mucous membrane,** or mucosa, lines a body cavity that opens to the outside of the body, such as the digestive or respiratory tract. The epithelial layer secretes mucus that lubricates the tissue and protects it from drying.

A **serous membrane** lines a body cavity that does not open to the outside of the body. It consists of simple squamous epithelium over a thin layer of loose connective tissue. This type of membrane secretes fluid into the cavity it lines. Examples of serous membranes are the pleural membranes lining the pleural cavities around the lungs and the pericardial membranes lining the pericardial cavity around the heart.

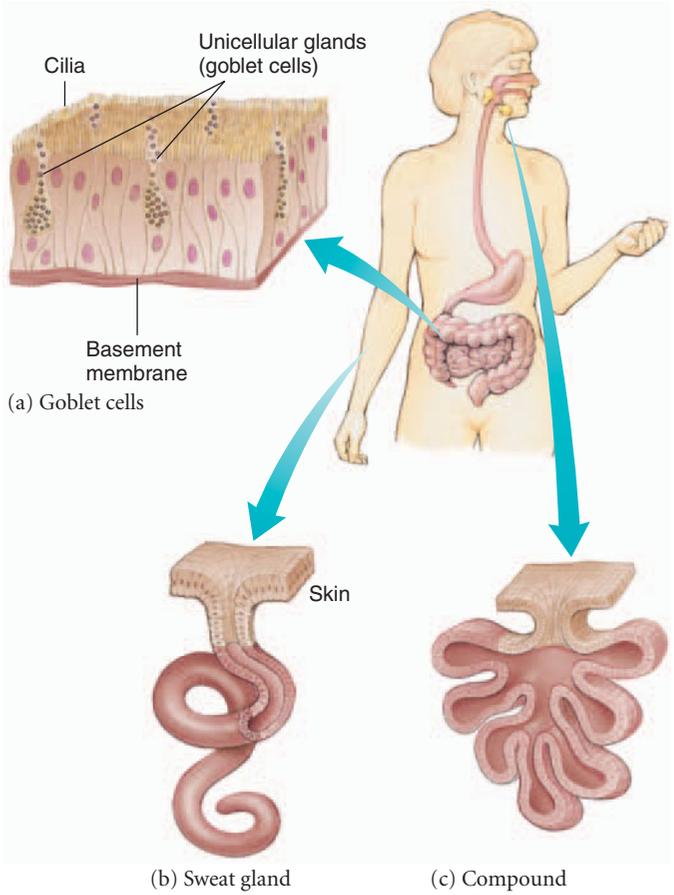

FIGURE **37-1** **Glands.**

A gland consists of one or more epithelial cells. **(a)** Goblet cells are unicellular glands that secrete mucus. **(b)** Sweat glands are simple glands consisting of coiled tubes. Their walls are constructed of simple cuboidal epithelium. **(c)** Compound glands, such as the parotid salivary glands, have branched ducts.

Connective tissues support other body structures

Almost every organ in the body has a framework of **connective tissue** that supports and cushions it. Typically, connective tissues contain relatively few cells. Its cells are embedded in an extensive **intercellular substance** consisting of threadlike, microscopic **fibers** scattered throughout a **matrix,** a thin gel of polysaccharides that the cells secrete. The nature and function of each kind of connective tissue are determined in part by the structure and properties of the intercellular substance.

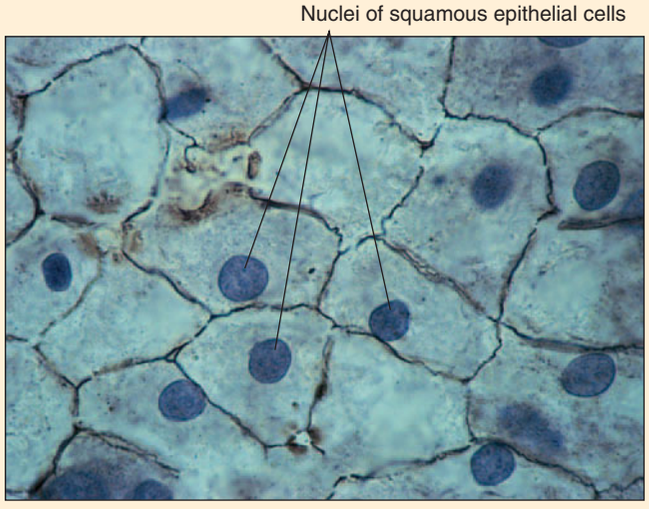
Connective tissue typically contains three types of fibers: collagen, elastic, and reticular. **Collagen fibers,** the most numerous type, are made of **collagens,** a group of fibrous proteins found in all animals (see Fig. 3-22b). Collagens are the most abundant proteins in mammals, accounting for about 25% of their total protein mass. Collagen is very tough (meat is tough because of its collagen content). The tensile strength (ability to stretch without tearing) of collagen fibers is comparable to that of steel. Collagen fibers are wavy and flexible, allowing them to remain intact when tissue is stretched.

Elastic fibers branch and fuse to form networks. They can be stretched by a force and then (like a stretched rubber band) return to their original size and shape when the force is removed. Elastic fibers, composed of the protein elastin, are an important component of structures that must stretch.

Reticular fibers are very thin, branched fibers that form delicate networks joining connective tissues to neighboring tissues. Reticular fibers consist of collagen and some glycoprotein.

The cells of different kinds of connective tissues differ in their shapes and structures and in the kinds of fibers and matrices they secrete. **Fibroblasts** are connective tissue cells that produce the fibers, as well as the protein and carbohydrate complexes, of the matrix. Fibroblasts release protein components that become arranged to form the characteristic fibers. These cells are especially active in developing tissue and are important in

TABLE 37-1 Epithelial Tissues



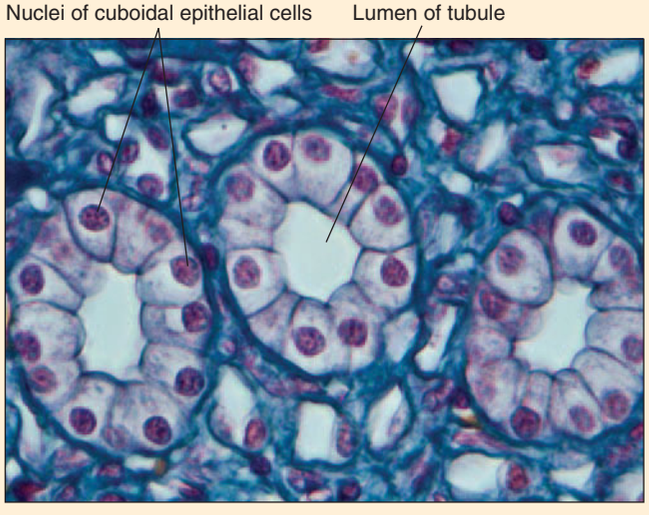
LM of simple squamous epithelium.

Simple Squamous Epithelium

Main Locations
Air sacs of lungs; lining of blood vessels

Functions
Passage of materials where little or no protection is needed and where diffusion is major form of transport

Description and Comments
Cells are flat and arranged as single layer



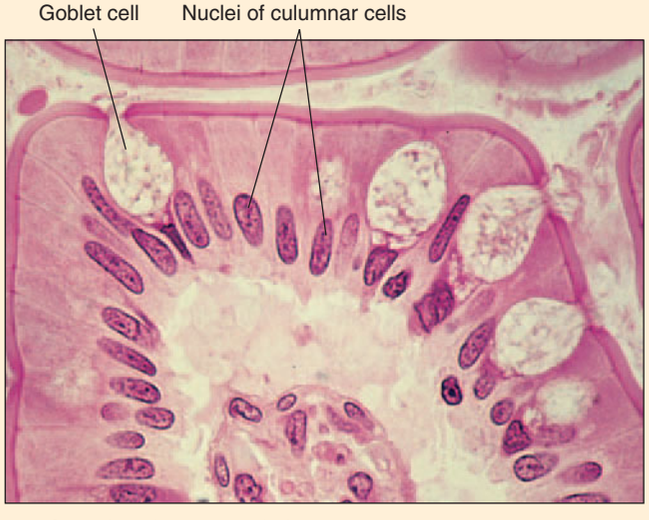
LM of simple cuboidal epithelium.

Simple Cuboidal Epithelium

Main Locations
Linings of kidney tubules; gland ducts

Functions
Secretion and absorption

Description and Comments
Single layer of cells; LM shows cross section through tubules; from the side each cell looks like a short cylinder; some have microvilli for absorption



LM of simple columnar epithelium.

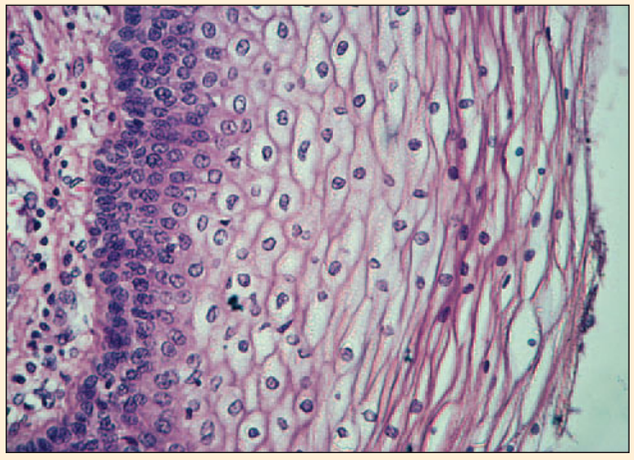
Simple Columnar Epithelium

Main Locations
Linings of much of digestive tract and upper part of respiratory tract

Functions
Secretion, especially of mucus; absorption; protection; movement of layer of mucus

Description and Comments
Single layer of columnar cells; sometimes with enclosed secretory vesicles (in goblet cells); highly developed Golgi complex; often ciliated

TABLE **37-1** **Epithelial Tissues (continued)**



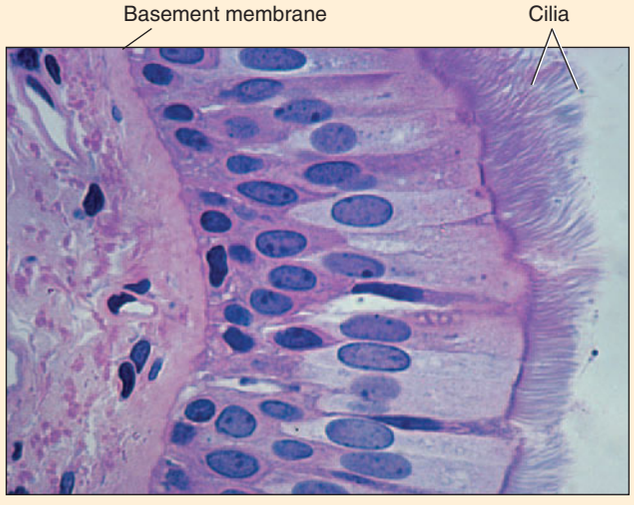
LM of stratified squamous epithelium.

Stratified Squamous Epithelium

Main Locations
Skin; mouth lining; vaginal lining

Functions
Protection only; little or no absorption or transit of materials; outer layer continuously sloughed off and replaced from below

Description and Comments
Several layers of cells, with only the lower ones columnar and metabolically active; division of lower cells causes older ones to be pushed upward toward surface, becoming flatter as they move.



LM of pseudostratified columnar epithelium, ciliated.

Pseudostratified Epithelium

Main Locations
Some respiratory passages; ducts of many glands

Functions
Secretion; protection; movement of mucus

Description and Comments
Ciliated, mucus-secreting, or with microvilli; comparable in many ways to columnar epithelium except that not all cells are the same height. Thus, though all cells contact the same basement membrane, the tissue appears stratified

healing wounds. As tissues mature, the number of fibroblasts decreases and they become less active. **Macrophages,** the body's scavenger cells, commonly wander through connective tissues, cleaning up cell debris and phagocytizing foreign matter, including bacteria.

Some of the main types of connective tissue are (1) loose and dense connective tissues; (2) elastic connective tissue; (3) reticular connective tissue; (4) adipose tissue; (5) cartilage; (6) bone; and (7) blood, lymph, and tissues that produce blood cells. These tissues vary widely in their structural details and in the functions they perform (Table 37-2).

Loose connective tissue is the most widely distributed connective tissue in the vertebrate body. This thin filling between body parts serves as a reservoir for fluid and salts. Nerves, blood vessels, and muscles are wrapped in this tissue. Together with adipose tissue, loose connective tissue forms the subcutaneous (below the skin) layer that attaches skin to the muscles and other structures beneath. Loose connective tissue consists of fibers running in all directions through a semifluid matrix. Its flexibility permits the parts it connects to move.

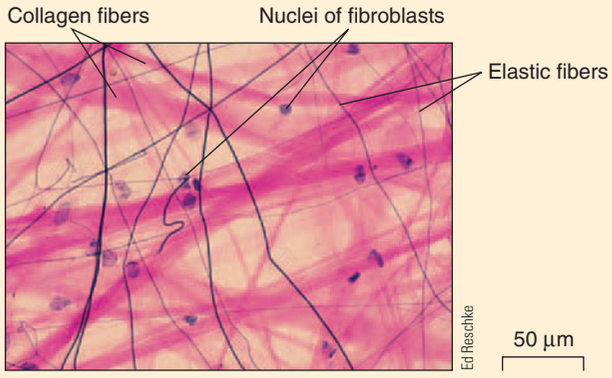
Dense connective tissue, found in the dermis (lower layer) of the skin, is very strong, though somewhat less flexible than loose connective tissue. Collagen fibers predominate. **Tendons,** the cords that connect muscles to bones, and **ligaments,** the cables that connect bones to one another, consist of dense connective tissue in which collagen bundles are arranged in a definite pattern.

Elastic connective tissue consists mainly of bundles of parallel elastic fibers. This tissue is found in structures that must expand and then return to their original size, such as lung tissue and the walls of large arteries.

Reticular connective tissue is composed mainly of interlacing reticular fibers. It forms a supporting internal framework in many organs, including the liver, spleen, and lymph nodes.

The cells of **adipose tissue** store fat and release it when fuel is needed for cellular respiration. Adipose tissue is found in the subcutaneous layer and in tissue that cushions internal organs.

TABLE 37-2 Connective Tissues



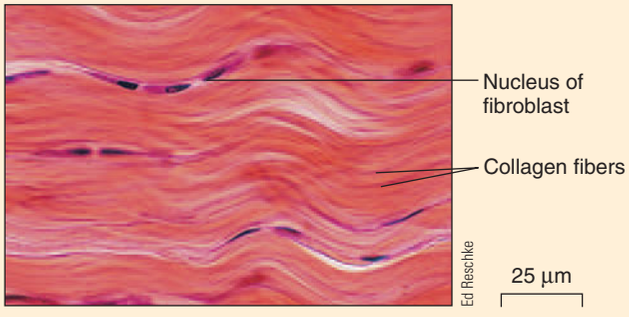
LM of loose connective tissue.

Loose Connective Tissue

Main Locations
Everywhere that support must be combined with elasticity, such as subcutaneous tissue (the layer of tissue beneath the dermis of the skin)

Functions
Support; reservoir for fluid and salts

Description and Comments
Fibers produced by fibroblast cells embedded in semifluid matrix and mixed with miscellaneous other cells



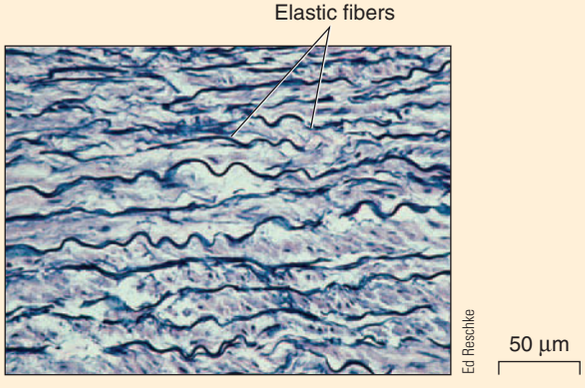
LM of dense connective tissue.

Dense Connective Tissue

Main Locations
Tendons; many ligaments; dermis of skin

Functions
Support; transmission of mechanical forces

Description and Comments
Collagen fibers may be regularly or irregularly arranged



LM of elastic connective tissue.

Elastic Connective Tissue

Main Locations
Structures that must both expand and return to their original size, such as lung tissue and large arteries

Function
Confers elasticity

Description and Comments
Branching elastic fibers interspersed with fibroblasts

LM of reticular connective tissue.

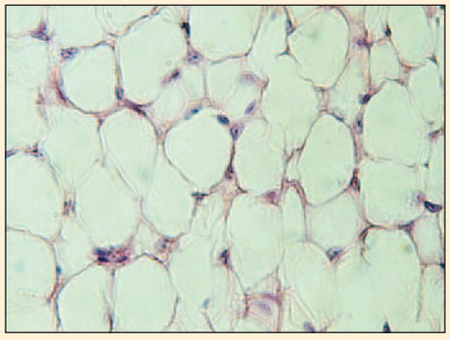
Reticular Connective Tissue

Main Locations
Framework of liver; lymph nodes; spleen

Function
Support

Description and Comments
Consists of cells dispersed in plasma (a fluid interlacing fiber)

TABLE **37-2** Connective Tissues (continued)



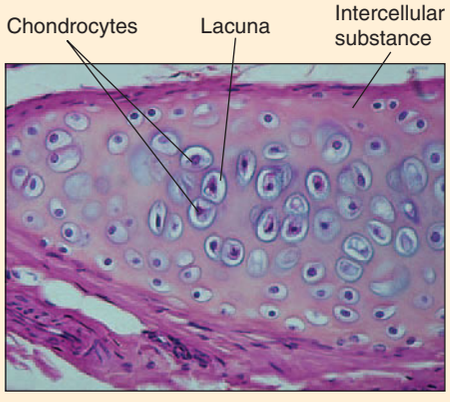
LM of adipose tissue.

Adipose Tissue

Main Locations
Subcutaneous layer; pads around certain internal organs

Functions
Food storage; insulation; support of such organs as mammary glands, kidneys

Description and Comments
Fat cells are star-shaped at first; fat droplets accumulate until typical ring-shaped cells are produced



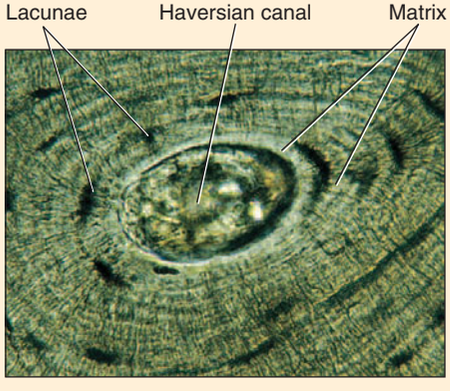
LM of cartilage.

Cartilage

Main Locations
Supporting skeletons in sharks and rays; ends of bones in mammals and some other vertebrates; supporting rings in walls of some respiratory tubes; tip of nose; external ear

Function
Flexible support

Description and Comments
Cells (chondrocytes) separated from one another by intercellular substance; cells occupy lacunae



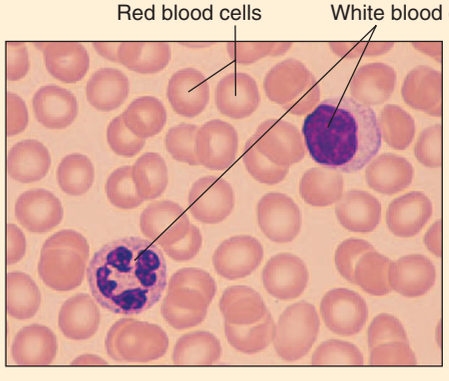
LM of bone.

Bone

Main Locations
Forms skeletal structure in most vertebrates

Functions
Support and protection of internal organs; calcium reservoir; skeletal muscles attach to bones

Description and Comments
Osteocytes in lacunae; in compact bone, lacunae arranged in concentric circles surrounding Haversian canals



LM of blood.

Blood

Main Locations
Within heart and blood vessels of circulatory system

Functions
Transports oxygen, nutrients, wastes, and other materials

Description and Comments
Consists of cells dispersed in fluid intercellular substance

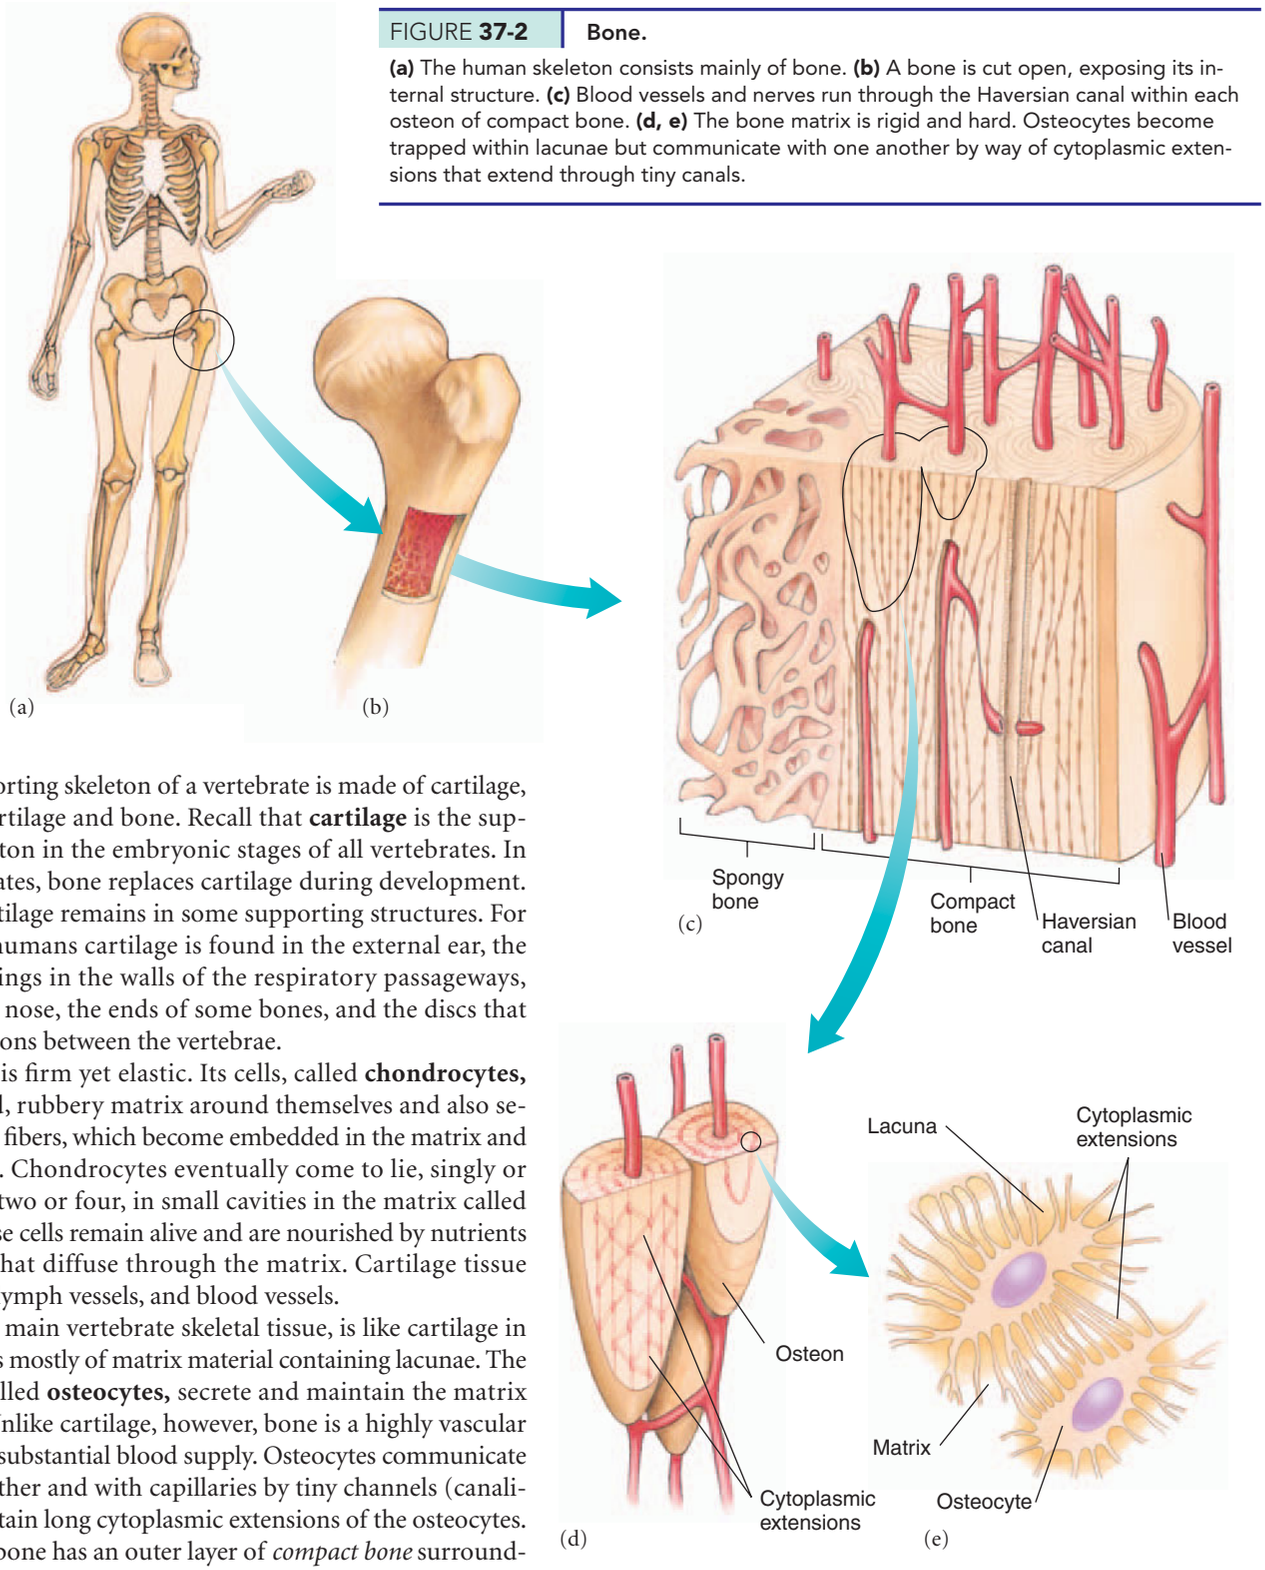


FIGURE **37-2** **Bone.**

(a) The human skeleton consists mainly of bone. **(b)** A bone is cut open, exposing its internal structure. **(c)** Blood vessels and nerves run through the Haversian canal within each osteon of compact bone. **(d, e)** The bone matrix is rigid and hard. Osteocytes become trapped within lacunae but communicate with one another by way of cytoplasmic extensions that extend through tiny canals.

The supporting skeleton of a vertebrate is made of cartilage, or of both cartilage and bone. Recall that **cartilage** is the supporting skeleton in the embryonic stages of all vertebrates. In most vertebrates, bone replaces cartilage during development. However, cartilage remains in some supporting structures. For example, in humans cartilage is found in the external ear, the supporting rings in the walls of the respiratory passageways, the tip of the nose, the ends of some bones, and the discs that serve as cushions between the vertebrae.

Cartilage is firm yet elastic. Its cells, called **chondrocytes,** secrete a hard, rubbery matrix around themselves and also secrete collagen fibers, which become embedded in the matrix and strengthen it. Chondrocytes eventually come to lie, singly or in groups of two or four, in small cavities in the matrix called **lacunae.** These cells remain alive and are nourished by nutrients and oxygen that diffuse through the matrix. Cartilage tissue lacks nerves, lymph vessels, and blood vessels.

Bone, the main vertebrate skeletal tissue, is like cartilage in that it consists mostly of matrix material containing lacunae. The bone cells, called **osteocytes,** secrete and maintain the matrix (Fig. 37-2). Unlike cartilage, however, bone is a highly vascular tissue, with a substantial blood supply. Osteocytes communicate with one another and with capillaries by tiny channels (canaliculi) that contain long cytoplasmic extensions of the osteocytes.

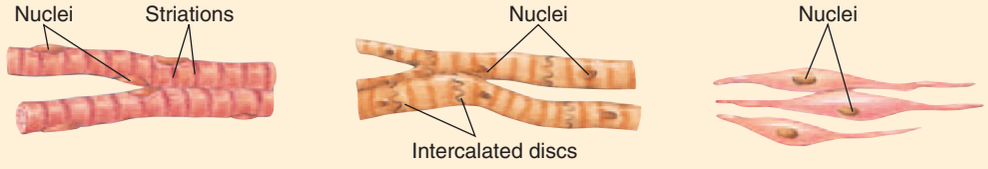
A typical bone has an outer layer of *compact bone* surrounding a filling of *spongy bone.* Compact bone consists of spindle-shaped units called **osteons.** Within each osteon, osteocytes are arranged in concentric layers called *lamellae,* which are formed by the matrix. In turn, the lamellae surround central microscopic channels known as **Haversian canals,** through which capillaries and nerves pass.

Bones are amazingly light and strong. Calcium salts of bone render the matrix very hard, and collagen prevents the bony matrix from being overly brittle. Most bones have a large central **marrow cavity** that contains a spongy tissue called *marrow.* Yellow marrow consists mainly of fat. Red marrow is the connective tissue in which blood cells are produced. Chapter 38 discusses bone in more detail.

Blood and **lymph** are circulating tissues that help other parts of the body communicate and interact. Like other connective tissues, they consist of specialized cells dispersed in an intercellular substance.

TABLE **37-3** Muscle Tissues

	Skeletal	Cardiac	Smooth
Location	Attached to skeleton	Walls of heart	Walls of stomach, intestines, etc.
Type of Control	Voluntary	Involuntary	Involuntary
Shape of Fibers	Elongated, cylindrical, blunt ends	Elongated, cylindrical, fibers that branch and fuse	Elongated, spindle-shaped, pointed ends
Striations	Present	Present	Absent
Number of Nuclei per Fiber	Many	One or two	One
Position of Nuclei	Peripheral	Central	Central
Speed of Contraction	Most rapid	Intermediate (varies)	Slowest
Resistance to Fatigue (with repetitive contraction)	Least	Intermediate	Greatest



Skeletal muscle fibers | Cardiac muscle fibers | Smooth muscle fibers

In mammals, blood consists of **red blood cells, white blood cells,** and **platelets** all suspended within **plasma,** the liquid, noncellular part of the blood. In humans and other vertebrates, red blood cells contain the respiratory pigment which transports oxygen. White blood cells defend the body against disease-causing microorganisms (see Chapter 43). Platelets, small fragments broken off from large cells in the bone marrow, play a key role in blood clotting. Plasma consists of water, proteins, salts, and a variety of soluble chemical messengers such as hormones that it transports from one part of the body to another. We discuss blood in Chapter 42.

Muscle tissue is specialized to contract

Most animals move by contracting the long, cylindrical or spindle-shaped cells of **muscle tissue.** Each muscle cell is called a **muscle fiber,** because of its length. A muscle fiber contains many thin, longitudinal, parallel contractile units called **myofibrils.** Two proteins, **myosin** and **actin,** are the chief components of myofibrils and play a key role in contraction of muscle fibers.

Some invertebrates have skeletal and smooth muscle. Vertebrates have three types of muscle tissue: skeletal, cardiac, and smooth (Table 37-3). **Skeletal muscle** makes up the large muscle masses attached to the bones of the body. Skeletal muscle fibers are very long and each fiber has many nuclei. The nuclei of skeletal muscle fibers are also unusual in their position. They lie just under the plasma membrane, which frees the entire central part of the skeletal muscle fiber for the myofibrils. This adaptation appears to increase the efficiency of contraction. Whereas skeletal muscle fibers are generally under voluntary control, you do not normally contract your cardiac and smooth muscle fibers at will.

Light microscopy shows that both skeletal and cardiac fibers have alternating light and dark transverse stripes, or **striations,** that change their relative sizes during contraction. Striated muscle fibers contract rapidly but cannot remain contracted for a long period. They must relax and rest momentarily before contracting again.

Cardiac muscle is the main tissue of the heart. The fibers of cardiac muscle join end-to-end, and they branch and rejoin, forming complex networks. One or two nuclei lie within each fiber. A characteristic feature of cardiac muscle tissue is the presence of *intercalated discs,* specialized junctions where the fibers join.

Smooth muscle occurs in the walls of the digestive tract, uterus, blood vessels, and many other internal organs. Each spindle-shaped fiber contains a single, central nucleus. (Muscle contraction is discussed in Chapter 38.)

Nervous tissue controls muscles and glands

Nervous tissue consists of neurons and glial cells. **Neurons** are specialized for receiving and transmitting signals. **Glial cells** support and nourish the neurons (Fig. 37-3).

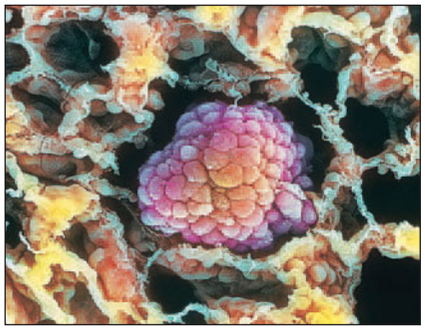
A typical neuron has a **cell body** containing the nucleus, and two types of cytoplasmic extensions (see Chapter 39). **Dendrites** are cytoplasmic extensions specialized for receiving signals and transmitting them to the cell body. The single **axon** transmits signals, called *nerve impulses,* away from the cell body. Axons range in length from 1 or 2 mm to more than a meter. Those extending from the spinal cord down the arm or leg in a human, for example, may be a meter or more in length.

Certain neurons receive signals from the external or internal environment and transmit them to the spinal cord and brain. Other neurons relay, process, or store information. Still others transmit signals from the brain and spinal cord to the muscles and glands. Neurons communicate at junctions called **synapses.**

Focus On Unwelcome Tissues: Cancers

A neoplasm ("new growth"), or **tumor,** is an abnormal mass of cells. A neoplasm may be benign or malignant (cancerous). A **benign** ("kind") tumor tends to grow slowly, and its cells stay together. Because benign tumors form masses with distinct borders, they can usually be removed surgically.

A **malignant** ("wicked") **neoplasm,** or **cancer,** usually grows much more rapidly and invasively than a benign tumor. In fact, two basic defects in behavior that characterize most cancer cells are rapid multiplication and abnormal relations with neighboring cells. Unlike normal cells, which respect one another's boundaries and form tissues in an orderly, organized manner, cancer cells grow helter-skelter on one another and infiltrate normal tissues. They apparently no longer receive or respond appropriately to signals from surrounding cells; communication is lacking (see figure).



Moredum Animal Health LTD/Photo Researchers, Inc.

Lung cancer. Cancer cells in this color-enhanced SEM of human lung tissue multiply rapidly and invade normal tissues, interfering with normal function. A mass of malignant cells (pink) occupies the air sac in the center, and cancer cells that have separated from the main tumor can be seen in other air sacs. Microvilli on the surface of the cancer cells give them a fuzzy appearance.

Earlier in this book (Chapter 16), you learned that cancer results from abnormal expression of specific genes critical for cell division. When a cancer cell multiplies, all the cells derived from it are also abnormal. Unlike the cells of benign tumors, cancer cells do not retain normal structural features. Cancers that develop from connective tissues or muscle are referred to as **sarcomas.** Those that originate in epithelial tissue are called **carcinomas.** Most human cancers are epithelial.

Death from cancer results from **metastasis,** a migration of cancer cells through blood or lymph channels to distant parts of the body. Once there, cancer cells multiply, forming new malignant neoplasms that interfere with the normal functions of the tissues being invaded. Cancer often spreads so rapidly and extensively that surgeons cannot locate or remove all the malignant masses.

Studies suggest that many neoplasms grow to several millimeters in diameter and then enter a dormant stage, which may last for months or even years. Some researchers hypothesize that eventually cells of the neoplasm release a chemical substance that stimulates nearby blood vessels to develop new capillaries that grow into the abnormal mass of cells. Nourished by its new blood supply, the neoplasm begins to grow rapidly. Newly formed blood vessels have leaky walls and so are an important route for metastasis. Malignant cells enter the blood through these walls and are transported to new sites.

Cancer is the second greatest cause of death in the United States. One in three people in the United States gets cancer at some time in his or her life. Currently, the key to survival is early diagnosis and treatment with some combination of surgery, hormonal treatment, radiation therapy, and drugs that suppress mitosis, such as chemotherapy.

Cancer is actually a large family of closely related diseases (there are hundreds of distinct varieties), so treatment must be tailored to the particular type of cancer.

Alleles of some genes appear to affect an individual's level of tolerance to carcinogens (cancer-producing agents). More than 80% of cancer cases are thought to be triggered by carcinogens in the environment. You can decrease risk of developing cancer by following these recommendations:

1. Do not smoke or use tobacco. Smoking is responsible for more than 80% of lung cancer cases and it increases the risk for many other cancers.
2. Avoid prolonged exposure to the sun. When in the sun, use sunscreen or sun block. Exposure to the sun is responsible for almost all the 400,000 cases of skin cancer reported each year in the United States.
3. Eat a healthy diet, including fruit and vegetables. Although research results are not clear, it appears prudent to increase the fiber content of your diet and avoid high-fat, smoked, salt-cured, and nitrite-cured foods.
4. Avoid unnecessary exposure to x-rays.
5. Women should examine their breasts each month, have regular mammograms, and obtain annual Papanicolaou's (Pap) tests.
6. Men should regularly examine their testes and should have prostate examinations yearly after age 50. They should also have the prostate-specific antigen (PSA) blood test. These routine tests detect cancer at an early, more treatable stage.
7. Beginning at age 50, both men and women should be screened for colorectal cancer. Detection and removal of polyps can prevent cancer.

A **nerve** consists of a great many neurons bound together by connective tissue.

In this chapter, we have focused on normal tissues. For a discussion of some abnormal tissues, see *Focus On: Unwelcome Tissues: Cancers.*

Review

- What are the main differences in structure and function between epithelial tissue and connective tissue?
- What type of tissue lines the air sacs of the lungs? How is its structure adapted to its function?

ORGANS AND ORGAN SYSTEMS

Learning Objectives

6 Briefly describe the organ systems of a complex animal.
7 Define *homeostasis,* and contrast negative and positive feedback mechanisms.
8 Summarize the homeostatic actions of each organ system.

Although an animal organ may be composed mainly of one type of tissue, other types are needed to support, protect, provide a blood supply, and transmit information. For example, the heart is mainly cardiac muscle tissue, but it is lined with endothelium and contains blood vessels made of endothelium, smooth muscle, and connective tissue. The heart also has nerves that transmit information and help regulate the rate and strength of its contractions.

An organized group of tissues and organs that together perform a specialized set of functions make up an organ system. We can identify 10 major organ systems that work together to make up a complex animal: **integumentary, skeletal, muscular, digestive, circulatory, respiratory, urinary, nervous, endocrine,** and **reproductive systems.** Table 37-4 and Figure 37-4 summarize their principal organs and functions.

The body maintains homeostasis

To survive and function, the organism must carefully regulate the composition of the fluids that bathe its cells. It must maintain the appropriate concentration of nutrients, oxygen, and other

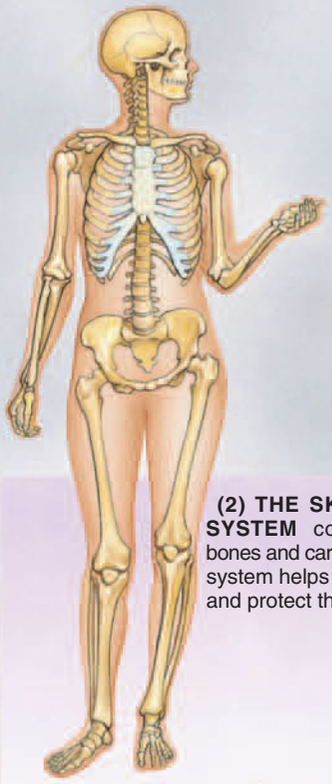
TABLE **37-4** **The Mammalian Organ Systems and Their Functions**

System	Components	Functions	Homeostatic Ability
Integumentary	Skin, hair, nails, sweat glands	Covers and protects body	Sweat glands help control body temperature; as a barrier, the skin helps maintain a steady state
Skeletal	Bones, cartilage, ligaments	Supports and protects body; provides for movement and locomotion; stores calcium	Helps maintain constant calcium level in blood
Muscular	Skeletal muscle; cardiac muscle; smooth muscle	Moves parts of skeleton; provides locomotion; moves internal materials	Ensures vital functions requiring movement, e.g., cardiac muscle circulates the blood
Digestive	Mouth, esophagus, stomach, intestine, liver, pancreas, salivary glands	Ingests and digests food; absorbs nutrients into blood	Maintains adequate supplies of fuel molecules and building materials
Circulatory	Heart, blood vessels, blood; lymph and lymph structures (lymphatic system is a subsystem of the circulatory system)	Transports materials from one part of body to another; defends body against disease organisms	Transports oxygen, nutrients, hormones, wastes; maintains water and salt balance of tissues
Respiratory	Lungs, trachea, and other air passageways	Exchanges gases between blood and external environment	Maintains adequate blood oxygen content and helps regulate blood pH; removes carbon dioxide from the blood
Urinary	Kidney, bladder, and associated ducts	Excretes metabolic wastes; removes excessive substances from blood	Helps regulate volume and composition of blood and body fluids
Nervous	Nerves and sense organs; brain and spinal cord	Receives stimuli from external and internal environment; conducts impulses; integrates activities of other systems	Principal regulatory system
Endocrine	Ductless glands (e.g., pituitary, adrenal, thyroid) and tissues that secrete hormones	Regulates blood chemistry and many body functions	Regulates metabolic activities and blood levels of various substances
Reproductive	Testes, ovaries, and associated structures	Sexual reproduction	Maintains sexual characteristics

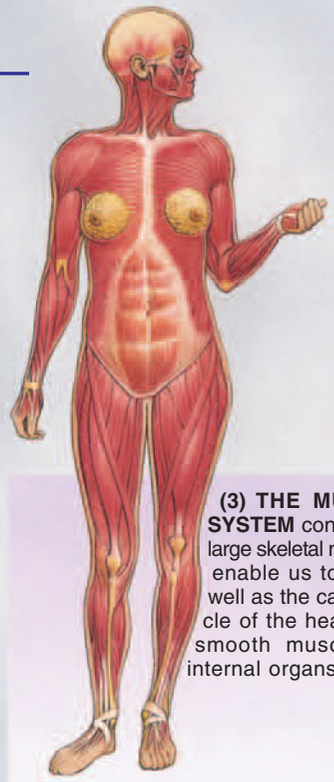
ACTIVE FIGURE **37-4** | **The ten principal organ systems of the human body.**

BiologyNow™ Watch **body systems** work together by clicking on this figure on your BiologyNow CD-ROM.

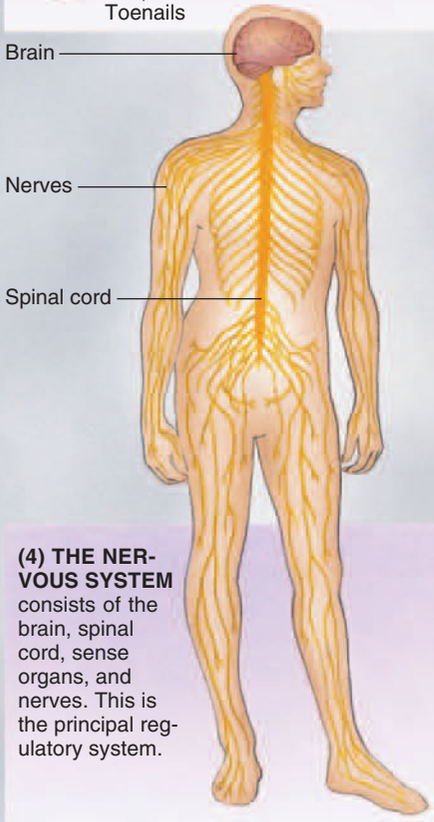
(1) THE INTEGUMENTARY SYSTEM consists of the skin and the structures such as nails and hair that are derived from it. This system protects the body, helps to regulate body temperature, and receives stimuli such as pressure, pain, and temperature.



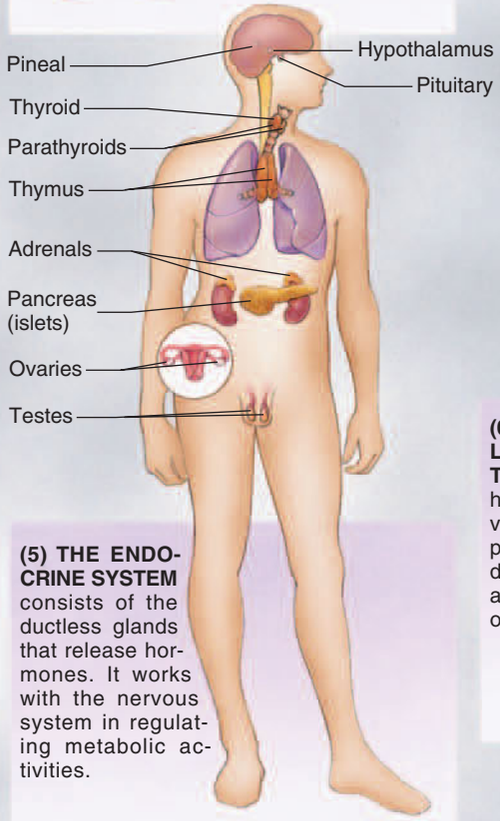
(2) THE SKELETAL SYSTEM consists of bones and cartilage. This system helps to support and protect the body.



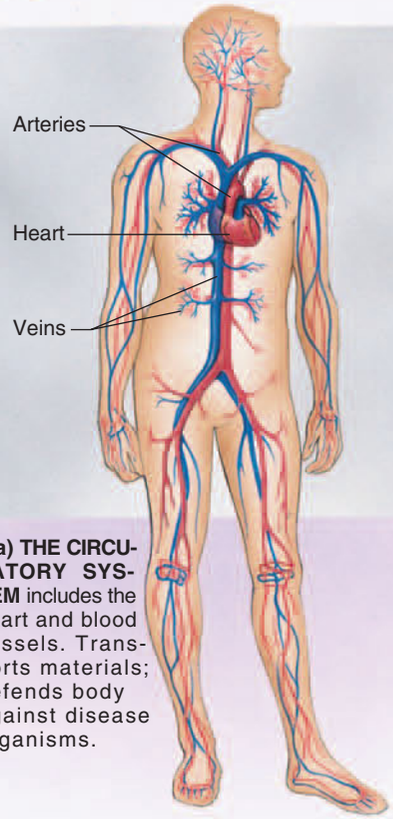
(3) THE MUSCULAR SYSTEM consists of the large skeletal muscles that enable us to move, as well as the cardiac muscle of the heart and the smooth muscle of the internal organs.



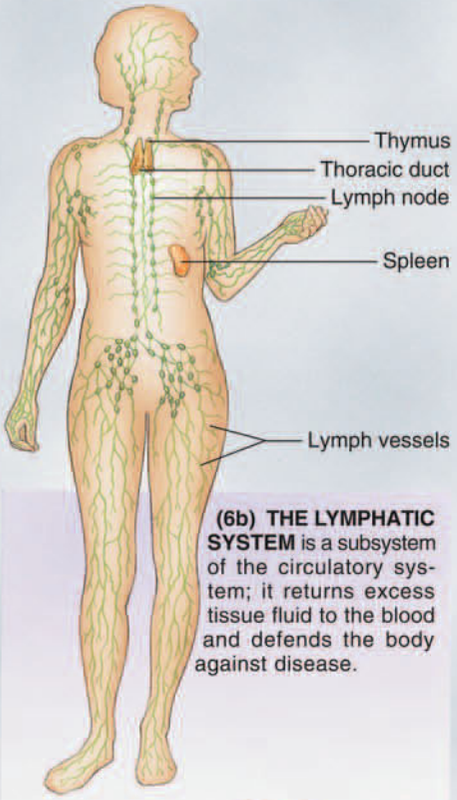
(4) THE NERVOUS SYSTEM consists of the brain, spinal cord, sense organs, and nerves. This is the principal regulatory system.



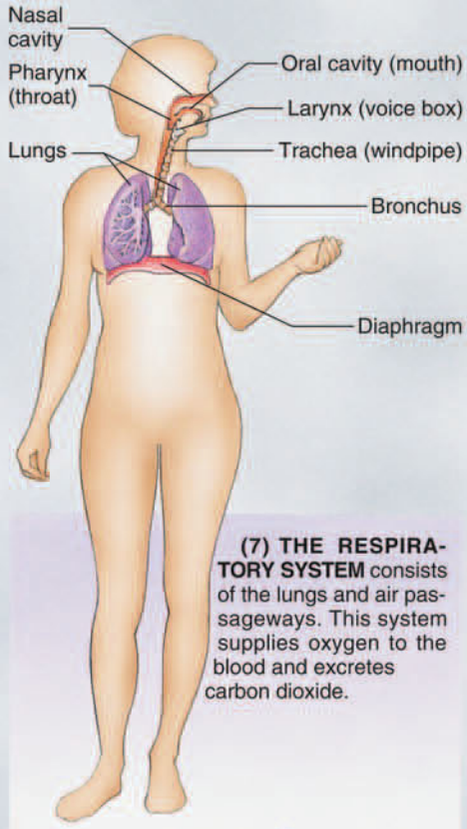
(5) THE ENDOCRINE SYSTEM consists of the ductless glands that release hormones. It works with the nervous system in regulating metabolic activities.



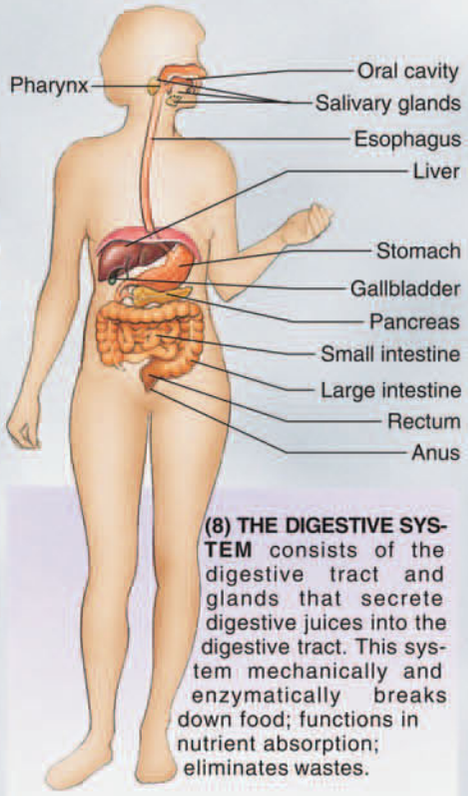
(6a) THE CIRCULATORY SYSTEM includes the heart and blood vessels. Transports materials; defends body against disease organisms.



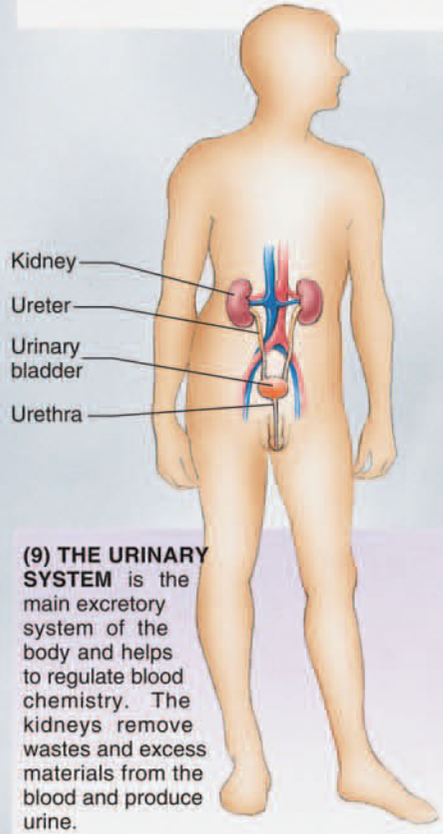
(6b) THE LYMPHATIC SYSTEM is a subsystem of the circulatory system; it returns excess tissue fluid to the blood and defends the body against disease.



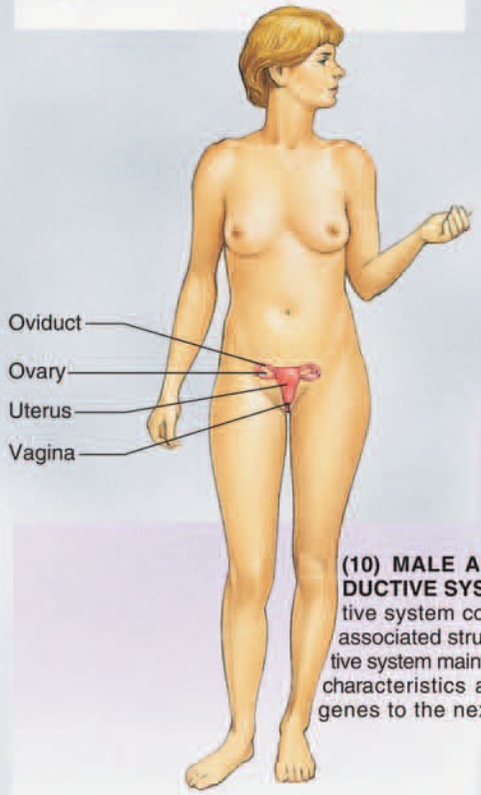
(7) THE RESPIRATORY SYSTEM consists of the lungs and air passageways. This system supplies oxygen to the blood and excretes carbon dioxide.

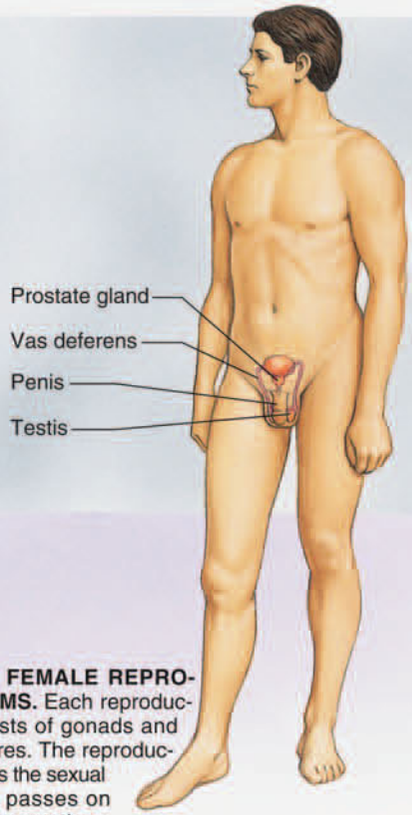


(8) THE DIGESTIVE SYSTEM consists of the digestive tract and glands that secrete digestive juices into the digestive tract. This system mechanically and enzymatically breaks down food; functions in nutrient absorption; eliminates wastes.



(9) THE URINARY SYSTEM is the main excretory system of the body and helps to regulate blood chemistry. The kidneys remove wastes and excess materials from the blood and produce urine.





(10) MALE AND FEMALE REPRODUCTIVE SYSTEMS. Each reproductive system consists of gonads and associated structures. The reproductive system maintains the sexual characteristics and passes on genes to the next generation.

gases, ions, and compounds needed for metabolism at all times. In addition, it must maintain internal temperature and pressure within relatively narrow limits.

Cells, tissues, organs, and organ systems work together to maintain appropriate conditions in the body. The tendency to maintain a balanced internal environment is called **homeostasis,** and the control processes that maintain these conditions are **homeostatic mechanisms.** Homeostasis is a basic concept in physiology. First coined by U.S. physiologist Walter Cannon, the word *homeostasis* is derived from the Greek *homoios,* meaning "same," and *stasis,* "standing." Actually, the internal environment never really stays the same. It is a dynamic equilibrium in which conditions are maintained within narrow limits.

Stressors, changes in the internal or external environment that affect normal conditions within the body, continuously challenge homeostasis. An internal condition that moves out of its homeostatic range (either too high or too low) causes **stress.** An organism functions effectively because very precise homeostatic mechanisms interact continuously to manage stress.

How do homeostatic mechanisms work? Many are **feedback systems,** sometimes called *biofeedback systems.* Such a system consists of a cycle of events in which information about a change (such as a change in temperature) is fed back into the system so that the regulator (the temperature-regulating center in the brain) can control the process (temperature regulation). The desired condition (normal body temperature) is referred to as the **set point.** When body temperature becomes too high or too low, the change serves as input, triggering the regulator to counteract the change. The regulator activates mechanisms that bring the system back to the set point. The return to normal temperature signals the temperature-regulating center to "shut off" the mechanism.

In this type of feedback system, the response counteracts the inappropriate change, restoring the steady state. This is a **negative feedback mechanism,** because the response of the regulator is *opposite* (negative) to the output (Fig. 37-5). Most homeostatic mechanisms in the body are negative feedback systems. When some condition varies too far from the steady state (either too high or too low), a control system using negative feedback brings the condition back to the steady state.

A few **positive feedback mechanisms** also operate in the body. In these systems a deviation from the steady state sets off a series of changes that intensify (rather than reverse) the changes. Although many positive feedback mechanisms are beneficial, they do not maintain homeostasis. A positive feedback cycle operates during the birth of a baby. As the baby's head pushes against the opening of the uterus (cervix), a reflex action causes the uterus to contract. The contraction forces the head against the cervix again, resulting in another contraction, and the positive feedback cycle repeats again and again until the baby is born. Some positive feedback sequences, such as those that deepen circulatory shock following severe hemorrhage, can disrupt steady states and even lead to death.

Homeostatic mechanisms maintain the internal environment within the physiological limits that support life. All organ systems participate in these regulatory processes, but the nervous and endocrine systems play major roles in controlling them. As you continue your study of animal processes, you will learn many ways in which organ systems interact to maintain the *steady state* (normal homeostatic state) of the organism. In the next section, we discuss some homeostatic mechanisms that help regulate body temperature.

Review

- What are the main functions of each organ system?
- What is the basic difference between negative and positive feedback mechanisms?
- How do each of the following organ systems help maintain homeostasis? (a) respiratory (b) urinary (c) endocrine? (You can consult Table 37-4 for help.)

BiologyNow™ Assess your understanding of **organs and organ systems** by taking the pretest on your BiologyNow CD-ROM.

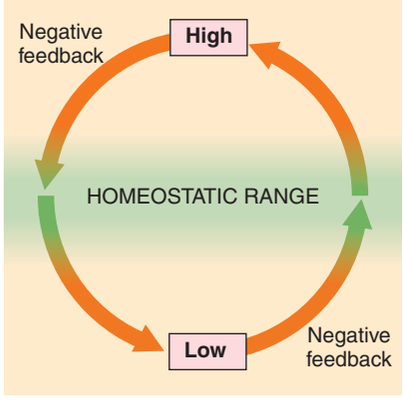


FIGURE **37-5**

Negative feedback mechanisms.

In negative feedback, the response of the regulator is opposite to the output. Regulatory mechanisms bring conditions back to a homeostatic range.

REGULATING BODY TEMPERATURE

Learning Objectives

9 Describe advantages and disadvantages of ectothermy.

10 Describe advantages and disadvantages of endothermy, and describe strategies endotherms use to survive in extreme temperature conditions.

Many animals have elaborate homeostatic mechanisms for regulating body temperature. Some are physiological, others are structural or behavioral. **Thermoregulation** is the ability to maintain body temperature within certain limits, even when the temperature of the environment changes a lot.

Animals produce heat as a byproduct of metabolic activities. Body temperature is determined by the rate at which heat is produced and the rate at which heat is lost to, or gained from, the outside environment.

The strategies for maintaining body temperature that are available to an animal may restrict the type of environment it can inhabit. Each animal species has an optimal environmental temperature range. Some animals, such as snowshoe hares, snowy owls, and weasels, can survive in cold arctic regions. Others, such as the Cape ground squirrel, are adapted to hot tropical climates. Although some animals can survive at temperature extremes, most survive only within moderate temperature ranges.

Ectotherms absorb heat from their surroundings

In most animals, body temperature is determined mainly by the changing temperature of the environment. Such animals are **ectotherms.** Most of the heat for their thermoregulation comes from the sun. An advantage of ectothermy is that such animals use very little energy to maintain a high metabolic rate. An ectotherm's metabolic rate tends to change with the weather. As a result, ectotherms have a much lower daily energy expenditure than do endotherms. They survive on less food and convert more of the energy in their food to growth and reproduction. One disadvantage of ectothermy is that daily and seasonal temperature conditions may limit activity.

Many ectotherms use behavioral strategies to adjust body temperature. For example, lizards may keep warm by burrowing in the soil at night. During the day, lizards take in heat by basking in the sun, orienting their bodies to expose the maximum surface area to the sun's rays (Fig. 37-6a). Other behavioral strategies for regulating temperature include hibernation and migration.

Endotherms derive heat from metabolic processes

Birds and mammals, as well as some species of fish (such as tuna) and insects, are **endotherms,** which means they have homeostatic mechanisms that maintain body temperature despite changes in the external temperature. Important benefits of endothermy include constant body temperature and increased rate of enzyme activity. Endotherms can be active even in low winter temperatures. However, endotherms must pay the high energy cost of thermoregulation during times when they are inactive. You must maintain your body temperature even when you are asleep.

Endotherms have structural adaptations for maintaining body temperature. For example, the insulating feathers of birds, hair of mammals, insulating layers of fat in birds and mammals, and hairs or fur of chitin on some insects are structures that reduce heat loss from the body. Birds and mammals also have behavioral adaptations for maintaining body temperature. For example, the Cape ground squirrel positions its tail to shade its body from the direct rays of the sun. Elephants spray themselves with cool water. We humans put on warm coats and install furnaces in our homes.

Some insects use a combination of structural, behavioral, and physiological mechanisms to regulate body temperature. The "furry" body of the moth helps conserve body heat. When a moth prepares for flight, it contracts its flight muscles with little movement of its wings. The metabolic heat generated enables the moth to sustain the intense metabolic activity needed for flight.

Endotherms have a variety of physiologic mechanisms for maintaining temperature homeostasis. They regulate heat production and regulate heat exchange with the environment. Most of their body heat comes from their own metabolic processes (see *Focus On: Electron Transport and Heat,* Chapter 7).

Breck P. Kent/Animals Animals

(a)

Frans Lanting/ Minden Pictures

(b)

FIGURE **37-6** **Behavioral adaptations for thermoregulation.**

(a) This marine iguana (*Amblyrhynchus cristatus*) is an ectotherm that increases its body temperature by sunning itself. **(b)** The body temperature of this baby sooty tern (*Sterna fuscata*) of Hawaii, an endotherm, is reduced as heat leaves the body through its open mouth.

In mammals, receptors located in the hypothalamus of the brain and in the spinal cord regulate temperature. Heat from metabolic activities can be increased either directly, or indirectly by the action of hormones (such as thyroid hormones) that increase metabolic rate. Heat production is increased by contracting muscles, and in cold weather many animals shiver.

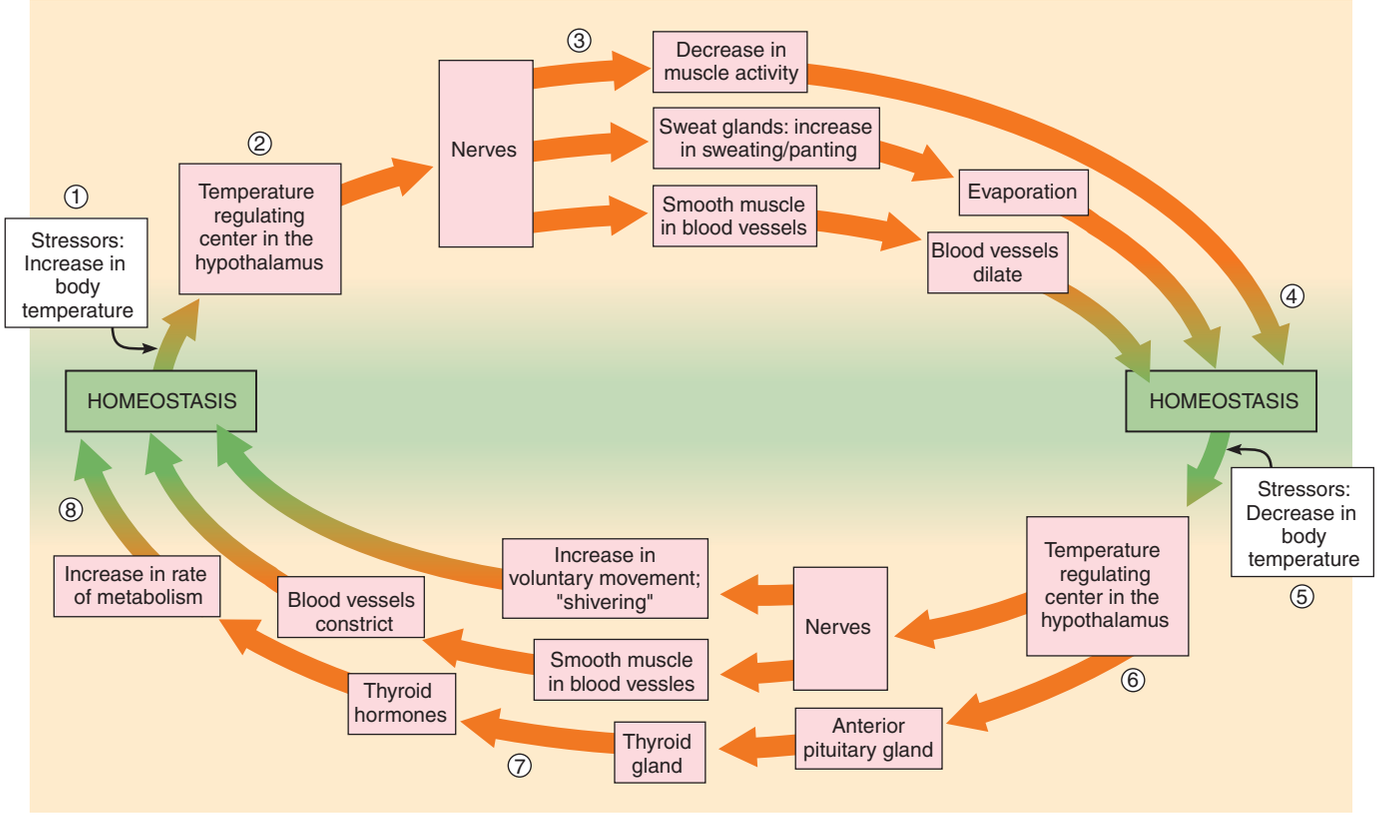
When body temperature rises, birds and many mammals pant and some mammals sweat (Fig. 37-6b). These processes provide fluid for **evaporation,** the conversion of a liquid, such as sweat, to water vapor. Recall from Chapter 2 that when molecules enter the vapor phase, they take their heat energy with them. Heat transfers from the body to the surroundings, resulting in evaporative cooling.

In the human body, about 2.5 million sweat glands secrete sweat, and its evaporation from the skin surface lowers body temperature. Constriction and dilation of capillaries in the skin are also homeostatic mechanisms for regulating body temperature.

In humans, information about body temperature is sent to the temperature-regulating center in the hypothalamus (Fig. 37-7). When your body temperature rises above normal, your hypothalamus sends messages by way of nerves to the sweat glands, increasing sweat secretion. At the same time the hypothalamus sends messages to smooth muscle in the walls of blood vessels in the skin, causing them to dilate. More blood circulates through the skin, bringing heat to the body surface. The skin acts as a heat radiator, allowing heat to radiate from the body surface into the environment. These homeostatic mechanisms help return body temperature to normal.

When body temperature decreases below normal, blood vessels in the skin constrict so less heat is brought to the body surface. Hormonal messages increase heat production by body tissues. Nerves signal muscles to shiver, or let you move muscles voluntarily to increase body temperature.

KEY CONCEPT: The hypothalamus maintains temperature homeostasis by activating mechanisms that cool *(upper arrows)* or warm the body *(lower arrows).*



ACTIVE FIGURE **37-7** **Regulation of temperature in the human body.**

① When stressors increase body temperature above homeostatic levels, ② the temperature-regulating center in the hypothalamus ③ activates homeostatic mechanisms that ④ restore normal body temperature. ⑤ When stressors decrease body temperature, ⑥ the temperature-regulating center ⑦ activates mechanisms that ⑧ increase temperature, again restoring homeostasis.

BiologyNow™ Explore **temperature regulation** in humans and other animals by clicking on this figure on your BiologyNow CD-ROM.

Many animals respond physiologically to changes in environmental temperature

Animals adjust to seasonal changes, a process called **acclimatization.** A familiar example is the thickening of a dog's coat in the winter. As water temperature decreases during fall and winter, a trout's enzyme systems decrease their level of activity, allowing the trout to remain active at the lowest metabolic cost.

When stressed by cold, many animals sink into **torpor,** a decrease in body temperature below normal levels (an adaptive hypothermia). The decrease in body temperature is brought about by a decrease in the temperature set point in the hypothalamus. In a state of torpor, metabolism may be dramatically depressed. Heart and respiratory rates decrease, and animals are less responsive to external stimulation.

Hibernation is long-term torpor in response to winter cold and scarcity of food. **Estivation** is a state of torpor caused by lack of food or water during periods of high temperature. During estivation some mammals retreat to their burrows. The cactus mouse enters a state of hibernation during the winter in response to cold and scarcity of food. In summer, it estivates in response to lack of either food or water.

BiologyNow™ Assess your understanding of **regulating body temperature** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Compare the structure and function of the four main kinds of animal tissues: epithelial, connective, muscle, and nervous tissues.

- A **tissue** consists of a group of similarly specialized cells that associate to perform one or more functions.
- **Epithelial tissue (epithelium)** forms a continuous layer, or sheet, of cells covering a body surface or lining a body cavity. Epithelial tissue functions in protection, absorption, secretion, or sensation.
- In contrast, **connective tissue** consists of relatively few cells separated by **intercellular substance,** which consists of **fibers** scattered through a **matrix.** The intercellular substance contains **collagen fibers, elastic fibers,** and/or **reticular fibers.** Connective tissue contains specialized cells such as **fibroblasts** and **macrophages.** Connective tissue joins other tissues of the body, supports the body and its organs, and protects underlying organs.
- **Muscle tissue** consists of cells specialized to contract. Each cell is an elongated muscle fiber containing many contractile units called **myofibrils.**
- **Nervous tissue** consists of elongated cells called **neurons,** specialized for transmitting impulses, and **glial cells,** which support and nourish the neurons.

2 Describe the main types of epithelial tissue, and state their functions.

- Epithelial cells may be **squamous, cuboidal,** or **columnar** in shape. Epithelial tissue may be **simple, stratified,** or **pseudostratified.** Simple squamous epithelium lines blood vessels and the air sacs in the lungs; it permits exchange of materials by diffusion. Simple cuboidal and columnar epithelia line passageways and are specialized for secretion and absorption. Stratified squamous epithelium forms the outer layer of the skin and lines passageways into the body; it provides protection. Pseudostratified epithelium also lines passageways and protects underlying tissues.
- Some epithelial tissue is specialized to form **glands. Goblet cells** are unicellular glands that secrete mucus. Goblet cells are **exocrine glands** that secrete their product through a duct onto an exposed epithelial surface. In contrast, **endocrine glands** release hormones into the **interstitial fluid** or blood.
- An **epithelial membrane** consists of a sheet of epithelial tissue and a layer of underlying connective tissue. A **mucous membrane** lines a cavity that opens to the outside of the body. A **serous membrane** lines a body cavity that does not open to the outside.

3 Compare the main types of connective tissue, and summarize their functions.

- Some main types of connective tissue are **loose connective tissue, dense connective tissue, elastic connective tissue, reticular connective tissue, adipose tissue, cartilage, bone,** and **blood** (summarized in Table 37-2). Loose connective tissue lies in the subcutaneous tissue and between many body parts. It consists of fibers in a semifluid matrix.
- Cartilage cells, called **chondrocytes,** lie in **lacunae,** small cavities in the cartilage matrix. **Osteocytes** secrete and maintain the matrix of bone. Compact bone consists of spindle-shaped units called **osteons.** Each osteon has a central blood vessel that runs through a **Haversian canal,** surrounded by lamellae, concentric layers containing osteocytes.

4 Contrast the three types of muscle tissue and their functions.

- **Skeletal muscle** is **striated** and under voluntary control. Each elongated, cylindrical **muscle fiber** has several nuclei.
- **Cardiac muscle** is striated; its contraction is involuntary. Its elongated, cylindrical fibers branch and fuse; each fiber has one or two central nuclei.
- **Smooth muscle** contracts involuntarily. Its elongated, spindle-shaped fibers lack striations. Each fiber has a single central nucleus. Smooth muscle is responsible for movement of food through the digestive tract and for movement of other body organs.

5 Relate the structure of the neuron to its function.

- The elongated neurons are adapted for receiving and transmitting information. **Dendrites** receive signals and transmit them to the **cell body.** The **axon** transmits signals away from the cell body to other neurons or to a muscle or gland. A **synapse** is a junction between neurons.

6 Briefly describe the organ systems of a complex animal.

- Tissues and **organs** work together, forming **organ systems.** In complex animals, 10 principal organ systems work together,

SUMMARY WITH KEY TERMS *(continued)*

making up the living **organism.** These include the **integumentary, skeletal, muscular, digestive, circulatory, respiratory, urinary, nervous, endocrine,** and **reproductive systems** (see Table 37-4).

7 Define *homeostasis,* and contrast negative and positive feedback mechanisms.

- **Homeostasis** is the body's automatic tendency to maintain a balanced internal environment, or steady state. This steady state is actually a dynamic equilibrium maintained by **negative feedback** systems in which the regulators respond to counteract the changes caused by **stressors.**

8 Summarize the homeostatic actions of each organ system.

- See Table 37-4

9 Describe advantages and disadvantages of ectothermy.

- Animals have structural, behavioral, and physiologic strategies for **thermoregulation.** In **ectotherms,** body temperature depends to a large extent on the temperature of the environment.
- An advantage of ectothermy is that very little energy is used to maintain a high metabolic rate. As a result, ectotherms can survive on less food. A disadvantage is that activity may be limited by daily and seasonal temperature conditions.

10 Describe advantages and disadvantages of endothermy, and describe strategies endotherms use to survive in extreme temperature conditions.

- **Endotherms** have homeostatic mechanisms for regulating body temperature within a narrow range.
- Advantages include constant body temperature and increased rate of enzyme activity. Many endotherms can carry out their activities even in low winter temperatures. A disadvantage of endothermy is its high energy cost.
- **Acclimatization** is the process of adjustment to seasonal changes. **Torpor** is an adaptive hypothermia; body temperature is maintained below normal levels. **Hibernation** is long-term torpor in response to winter cold.
- **Estivation** is torpor caused by lack of food or water during summer heat.

POST-TEST

1. In a multicellular animal, (a) organ systems are always present (b) cells specialize to perform specific functions (c) small size provides more opportunity for capturing food (d) organelles are more numerous (e) organelles carry on more functions
2. A group of closely associated cells that carry out specific functions is a(an) (a) colony (b) tissue (c) organ system (d) organelle (e) homeostatic mechanism
3. Which tissue consists of cells that fit tightly together to form a sheet of cells? (a) muscle (b) nervous tissue (c) connective tissue (d) epithelial tissue (e) reticular tissue
4. Epithelial cells that produce and secrete a product into a duct form a(an) (a) endocrine gland (b) exocrine gland (c) pseudostratified membrane (d) endocrine or exocrine gland (e) serous membrane
5. A serous membrane (a) lines a body cavity that does not open to the outside of the body (b) consists of loose connective tissue (c) has a framework of reticular connective tissue (d) covers the body (e) lines the digestive and respiratory systems
6. The most numerous fibers in connective tissue are (a) reticular (b) myofibrils (c) collagen (d) elastic (e) glial
7. Dense connective tissue is likely to be found in (a) the outer layer of skin (b) tendons (c) bone (d) the air sacs of lungs (e) the framework of the lymph nodes
8. Osteocytes are most likely to be found in (a) the outer layer of skin (b) bone (c) cartilage (d) lungs (e) blood
9. Tissue that contains fibroblasts and a great deal of intercellular substance is (a) connective tissue (b) muscle tissue (c) nervous tissue (d) pseudostratified epithelium (e) adipose tissue
10. Tissue that contracts and is striated and involuntary is (a) connective tissue (b) smooth muscle (c) skeletal muscle (d) pseudostratified (e) cardiac muscle
11. Glial cells are most characteristic of (a) muscle that is striated and voluntary (b) cardiac muscle tissue (c) nervous tissue (d) stratified epithelium (e) loose connective tissue
12. Tissue that has a hard, rubbery matrix and lacks blood vessels is (a) integumentary tissue (b) bone (c) nervous tissue (d) stratified epithelium (e) cartilage
13. The contractile elements in muscle tissue are (a) myofibrils (b) elastic (c) collagen (d) lacunae (e) stress proteins
14. Which system consists of glands that secrete hormones? (a) integumentary (b) skeletal (c) nervous (d) endocrine (e) exocrine
15. Which system has the homeostatic function of helping to maintain constant calcium level in the blood? (a) integumentary (b) skeletal (c) nervous (d) reproductive (e) exocrine
16. Which system has the homeostatic function of helping to regulate volume and composition of blood and body fluids? (a) integumentary (b) muscular (c) reproductive (d) urinary (e) exocrine
17. Many homeostatic functions are maintained by (a) negative feedback systems (b) positive feedback systems (c) set points (d) stressors (e) exocrine glands
18. An ectotherm (a) may use behavioral strategies to help adjust body temperature (b) has a variety of homeostatic mechanisms to precisely regulate body temperature (c) depends on sensors in the hypothalamus to regulate temperature (d) has a higher rate of enzyme activity than a typical endotherm (e) must expend more energy on thermoregulation than an endotherm
19. The state of torpor caused in some animals by lack of food or water during periods of high temperature is known as (a) positive feedback (b) hibernation (c) endothermy (d) ectothermy (e) estivation

CRITICAL THINKING

1. Imagine that all the epithelium in a complex animal, such as a human, suddenly disappeared. What effects might this have on the body and its ability to function?
2. What would connective tissue be like if it had no intercellular substance? What effect would the absence of intercellular substance have on the body?
3. A high concentration of carbon dioxide in the blood and interstitial fluid results in more rapid breathing. Explain this observation in terms of homeostasis.
4. What are some advantages of multicellularity?

Protection, Support, and Movement

Stephen Dalton

Grasshopper in mid-jump The grasshopper (*Tropidacris dux*) uses powerful muscles in its hind legs to catapult itself into the air. Insect muscles attach to the exoskeleton.

CHAPTER OUTLINE

- Epithelial Coverings
- Skeletal Systems
- Muscle Contraction

In Chapter 37 we described animal tissues, organs, and systems, laying the foundation for the more detailed discussions in this and later chapters. Here we focus on epithelial coverings, skeletal systems, and muscle—structures that are closely interrelated in function. In our survey of the animal kingdom (see Chapters 28 to 30), we described many adaptations involving these structures. For example, we discussed how the tough insect exoskeleton contributes to the great biological success of these animals. In this chapter, we compare these systems in several animal groups and then focus on their structures and functions in mammals.

In addition to protecting underlying tissues, the **epithelial coverings** of animals may be specialized to exchange gases, excrete wastes, regulate temperature, or secrete substances such as poison or mucus. Most animals are also protected by a **skeletal system.** Whether it is a fluid-filled compartment, a shell, or a system of bones, the skeletal system provides support for the body and typically protects internal organs. In vertebrates, bones store calcium and are important in maintaining homeostatic levels of calcium in the blood.

The skeletal system and **muscular system** work together to produce movement. Muscle tissue is specialized to contract. Although a few animals remain rooted to one spot, sweeping their surroundings with tentacles, **locomotion**—movement from place to place in the environment—is characteristic of most animals. In fact, for most animals dependable, rapid, and responsive movement is key to finding food and escaping from predators. Animals creep, walk, run, jump, swim, or fly (see photograph). Muscles responsible for locomotion anchor to the skeleton, which gives them something firm on which to act. In most vertebrates, bones serve as levers that transmit the force necessary to move various parts of the body.

Muscle powers both locomotion and the physiological actions necessary to maintain homeostasis. Many animals have internal circulating fluids, pumped by hearts and contained by hollow vessels that maintain their pressure with gentle squeezing. Most have digestive systems that push food along with peristaltic contractions. In complex animals, effective movement

depends on the cooperation and interactions of several body systems, including the muscular, skeletal, nervous, circulatory, respiratory, and endocrine systems. ■

EPITHELIAL COVERINGS

Learning Objectives

1. Compare the structure and functions of the external epithelium of invertebrates and vertebrates.
2. Relate the structure of vertebrate skin to its functions.

Epithelial tissue covers all external and internal surfaces of the animal body. The structure and functions of the epithelial covering are adapted to the animal's environment and lifestyle. In both invertebrates and vertebrates, epithelial coverings protect the body. These coverings may also be specialized for secretion or gas exchange, and typically contain receptors that receive sensory signals from the environment.

Invertebrate epithelium may function in secretion or gas exchange

In many invertebrates, the outer epithelium is specialized to secrete protective or supportive layers of nonliving material. In insects and many other animals, the secreted material forms an outer covering called a **cuticle.** Many animals, including corals and mollusks, secrete a shell made mainly of calcium carbonate. In addition to its protective function, the external epithelium of invertebrates may be specialized for secretion or gas exchange. Epithelial cells may also be modified as sensory cells that are selectively sensitive to light, chemical stimuli, or mechanical stimuli such as contact with an object, or pressure.

In many species, the epithelium contains secretory cells that secrete lubricants or adhesives. Such cells may release odorous secretions used for communication or for marking trails. In other species, the cells produce poisonous secretions used for offense or defense.

The earthworm epithelium secretes a lubricating mucus that promotes efficient diffusion of gases across the body wall and also reduces friction during movement through the soil.

Vertebrate skin functions in protection and temperature regulation

The **integumentary system** of vertebrates includes the skin and structures that develop from it. In many fishes, in the African ant-eating pangolin (a mammal; see Fig. 17-13c), and in some reptiles, skin has developed into a set of scales formidable enough to be considered armor. Even human skin has considerable strength.

Derivatives of skin differ considerably among vertebrates. Fish have bony or toothlike scales. Amphibians have naked skin covered with mucus, and some species are equipped with poison glands. Reptiles have epidermal scales, mammals have hair, and birds have feathers that provide even more effective insulation than fur. The feathers of birds and the fur of mammals help maintain body temperature. Skin and its derivatives are often brilliantly colored in connection with courtship rituals, territorial displays, and other kinds of communication.

In mammals, structures derived from skin include claws (modified as fingernails and toenails in primates), hair, sweat glands, oil (sebaceous) glands, and several types of sensory receptors that give us the ability to feel pressure, temperature, and pain. The skin of mammals also contains mammary glands, specialized in females for secretion of milk.

In humans and other mammals, oil glands empty via short ducts into hair follicles. A **hair follicle** is the part of a hair below the skin surface, together with the surrounding epithelial tissue. Oil glands secrete **sebum,** a complex mixture of fats and waxes that inhibits the growth of harmful bacteria.

Although the skin varies among species, the basic structure of skin is the same in all vertebrates. The outer layer of skin, the **epidermis,** is a waterproof protective barrier. The epidermis consists of several strata, or sublayers. The deepest is **stratum basale,** and the most superficial is **stratum corneum** (Fig. 38-1). Pigment cells in stratum basale and in the dermis produce **melanin,** a pigment that contributes to the color of the skin.

In stratum basale, cells divide and are pushed outward as other cells are produced below them. The epidermal cells mature as they move toward the skin surface.

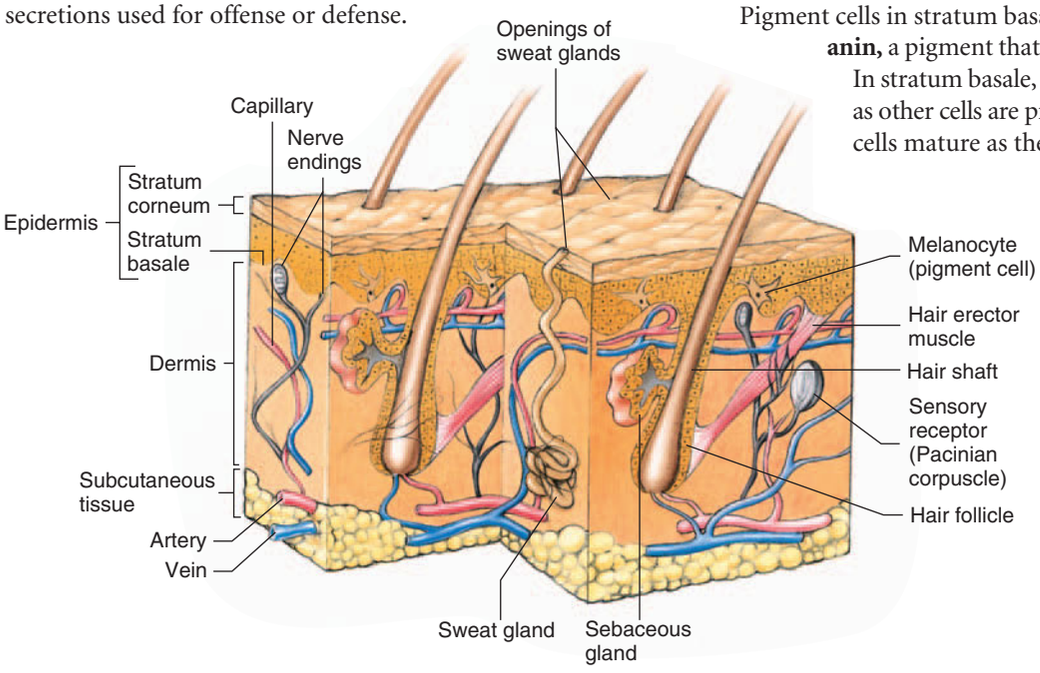

FIGURE **38-1**

Human skin.

The integumentary system of humans and other mammals is a complex organ system consisting of skin and structures such as hair and nails that are derived from the skin. Stratum basale consists of a single layer of epithelial cells.

As they move toward the body surface, epidermal cells manufacture **keratin,** an elaborately coiled protein that gives the skin considerable mechanical strength and flexibility. Keratin is insoluble and serves as a diffusion barrier for the body surface. As epidermal cells move through stratum corneum, they die. When they reach the outer surface of the skin, they wear off and must be continuously replaced.

Beneath the epidermis lies the **dermis** (see Fig. 38-1), a dense, fibrous connective tissue made up mainly of collagen fibers. Collagen imparts strength and flexibility to the skin. The dermis also contains blood vessels that nourish the skin and sensory receptors for touch, pain, and temperature. Hair follicles and, in most mammals, sweat glands lie embedded in the dermis. In birds and mammals, the dermis rests on a layer of **subcutaneous tissue** composed mainly of adipose tissue, that insulates the body from outside temperature extremes.

In humans, exposure to ultraviolet (UV) radiation, the short, invisible rays from the sun, causes the epidermis to thicken and stimulates pigment cells in the skin to produce melanin at an increased rate. Melanin is an important protective screen against the sun because it absorbs some of the harmful UV rays. An increase in melanin causes the skin to darken. The sun tan so prized by sun worshipers is actually a sign that the skin has been exposed to too much UV radiation. When the melanin cannot absorb all the UV rays, the skin becomes inflamed, or sunburned. Because dark-skinned people have more melanin, they suffer less sunburn, wrinkling, and skin cancer, although they are still at risk. UV radiation damages DNA, causing mutations that lead to malignant transformation (see Chapter 16).

Most cases of skin cancer are caused by excessive, chronic exposure to UV radiation. The incidence of *malignant melanoma,* the most lethal type of skin cancer, is increasing faster than any other type of cancer.

Review

- How are the external epithelia of invertebrates and vertebrates alike? How are they different?
- How is the structure of vertebrate skin related to its specific functions?
- What properties does keratin give human skin?
- What is the function of melanin?

BiologyNow™ Assess your understanding of **epithelial coverings** by taking the pretest on your BiologyNow CD-ROM.

SKELETAL SYSTEMS

Learning Objectives

3 Compare the structure and functions of different types of skeletal systems, including the hydrostatic skeleton, exoskeleton, and endoskeleton.

4 Describe the main divisions of the vertebrate skeleton and the bones that make up each division.

5 Describe the structure of a typical long bone, and differentiate between endochondral and intramembranous bone development.

6 Compare the main types of vertebrate joints.

In addition to an epithelial covering, many animals are protected by a hard skeleton that forms the framework of the body. The skeleton also functions in locomotion. In complex animals, muscles typically act on hard structures such as chitin or bone. These skeletal structures transmit and transform mechanical forces generated by muscle contraction into the variety of motions that animals make. Three types of skeletons are hydrostatic skeletons, exoskeletons, and endoskeletons.

In hydrostatic skeletons, body fluids transmit force

Many soft-bodied invertebrates have **hydrostatic skeletons** made of fluid-filled body compartments. Imagine an elongated balloon full of water. If you pull on it, it lengthens and becomes thinner. It does the same if you squeeze it. Conversely, if you push the ends toward the center, it shortens and thickens. Many animals, including cnidarians and annelids, have a hydrostatic skeleton that works something like a balloon filled with water. Fluid in a closed compartment of the body is held under pressure. When muscles in the compartment wall contract, they push against the tube of fluid. Because fluids cannot be compressed, the force is transmitted through the fluid, changing the shape and movement of the body. Most cnidarians, flatworms, annelids, and roundworms have hydrostatic skeletons.

In *Hydra* and other cnidarians, cells of the two body layers are capable of contracting. The contractile cells in the outer epidermal layer lie longitudinally, whereas the contractile cells of the inner layer (the gastrodermis) are arranged circularly around the central body axis (Fig. 38-2). The two groups of cells work in **antagonistic** fashion: What one can do, the other can undo. When the epidermal (longitudinal) layer contracts, the hydra shortens. Because of the fluid in the gastrovascular cavity, force is transmitted so that the hydra thickens as well. In contrast, when the inner (circular) layer contracts, the hydra thins, and its fluid contents force it to lengthen.

Mechanically, the hydra is a bag of fluid. The fluid acts as a hydrostatic skeleton because it transmits force when the contractile cells contract against it. (Although technically not a closed compartment, the gastrovascular cavity functions as a hydrostatic skeleton because its opening is small.) Hydrostatic skeletons permit only crude mass movements of the body or its appendages. Delicate movements are difficult, because force tends to be transmitted equally in all directions throughout the entire fluid-filled body of the animal. For example, it isn't easy for the hydra to thicken one part of its body while thinning another.

The more sophisticated hydrostatic skeleton of the annelid worm lets it move more flexibly. An earthworm's body consists of a series of segments divided by transverse partitions, or septa (see Fig. 29-12). The septa isolate portions of the body cavity and its contained coelomic fluid, permitting the hydrostatic skeletons of each segment to be largely independent of one another. Thus contraction of the circular muscle in the elongating anterior end doesn't interfere with the action of the longitudinal muscle in the segments of the posterior end.

You can find some examples of hydrostatic skeletons even in complex invertebrates equipped with shells or endoskele-

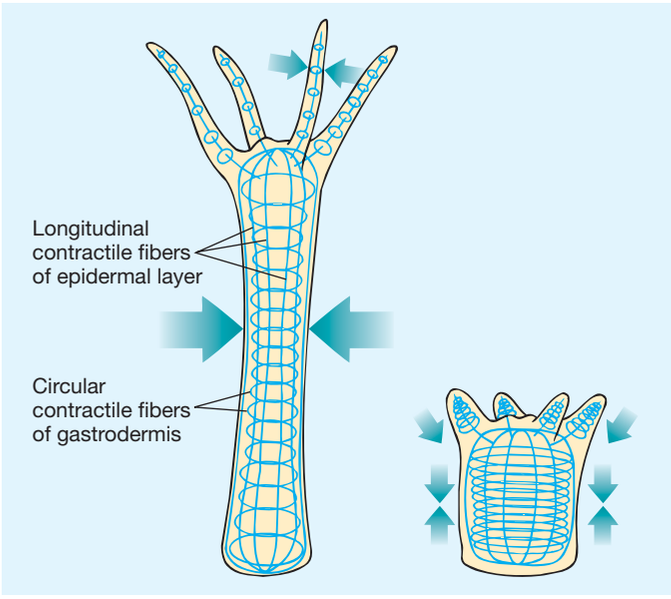

FIGURE **38-2** **Hydrostatic skeleton.**

The longitudinally arranged contractile cells of *Hydra* are antagonistic to the cells arranged in circles around the body axis. **(a)** Contraction of the circular contractile fibers elongates the body. **(b)** Contraction of the longitudinal fibers shortens the body.

tons, and in vertebrates with endoskeletons of cartilage or bone. Sea stars and sea urchins move their tube feet by an ingenious version of the hydrostatic skeleton (see Chapter 30). And even the human penis becomes erect and stiff because of the turgidity of pressurized blood in its internal spaces.

Mollusks and arthropods have nonliving exoskeletons

In most animals, the skeleton is a lifeless shell, or **exoskeleton,** deposited atop the epidermis (cells of the outer epithelium). In mollusks, the exoskeleton is a calcium carbonate shell secreted by the mantle, a thin sheet of epithelial tissue that extends from the body wall. The exoskeleton provides protection, a retreat used in emergencies, with the bulk of the naked, tasty body exposed at other times.

Exoskeletons of arthropods serve not only to protect but also to transmit forces. In this respect they are comparable to the skeletons of vertebrates. The arthropod exoskeleton is a nonliving cuticle that contains the polysaccharide **chitin.** Although it is a continuous, one-piece sheath covering the entire body, the arthropod exoskeleton varies greatly in thickness and flexibility. Large, thick, inflexible plates are separated from one another by thin, flexible joints arranged segmentally. Enough joints are provided to make the arthropod's body as flexible as those of many vertebrates. The arthropod exoskeleton is adapted to a vast variety of lifestyles, and parts of it are modified to function as specialized tools or weapons.

A disadvantage of the rigid arthropod exoskeleton is that to accommodate growth, an arthropod must **molt,** that is, shed its exoskeleton and replace it with a new, larger one (Fig. 38-3). During molting the animal is weak and vulnerable to predators.

Internal skeletons are capable of growth

You are probably most familiar with the **endoskeleton** of echinoderms and chordates. This living internal skeleton consists of plates or shafts of calcium-impregnated tissue (such as cartilage or bone). Composed of living tissue, the endoskeleton grows along with the animal as a whole. The echinoderm endoskeleton consists of spicules and plates of calcium salts embedded in the body wall, beneath an epidermis that covers the body. This endoskeleton forms what amounts to an internal shell that provides support and protection (Fig. 38-4). Many echinoderm endoskeletons bear spines that project to the outer surface.

The internal vertebrate skeleton provides support and protection, and transmits muscle forces. Members of class Chondrichthyes (sharks and rays) have skeletons of cartilage, but in most vertebrates the skeleton consists mainly of bone. Many bones form systems of levers that transmit muscle forces.

FIGURE **38-3** **Molting.**

A greengrocer cicada (*Magicicada*) requires 13 years to mature. It then emerges from the soil, climbs a tree, and molts prior to reproducing.

Judy Davidson/Science Photo Library/Photo Researchers, Inc.

Patricia Jordan/Peter Arnold, Inc.

FIGURE **38-4** **The echinoderm endoskeleton.**

The endoskeleton provides support and protection. As in other echinoderms, the endoskeleton of the red sea star (*Formia milleporella*) is composed of spicules and plates of nonliving calcium salts embedded in the body wall. Photographed in Indonesia.

The vertebrate skeleton has two main divisions

The two main divisions of the vertebrate skeleton are the axial and appendicular skeletons. The **axial skeleton,** located along the central axis of the body, consists of the skull, vertebral column, ribs, and sternum (breastbone). The **appendicular skeleton** consists of the bones of the limbs (arms and legs) plus the bones making up the pectoral (shoulder) girdle and most of the pelvic (hip) girdle; these girdles connect the limbs to the axial skeleton (Fig. 38-5).

The **skull,** the bony framework of the head, consists of the cranial and facial bones. In the human, 8 cranial bones enclose the brain, and 14 bones make up the facial portion of the skull. Several cranial bones that are single in the adult human result from the fusion of 2 or more bones that are separate in the embryo or newborn.

The vertebrate spine, or **vertebral column,** supports the body and bears its weight. In humans it consists of 24 **vertebrae** and 2 bones composed of fused vertebrae, the **sacrum** and **coccyx.** The vertebral column consists of the **cervical** (neck) region, with 7 vertebrae; the **thoracic** (chest) region, with 12 vertebrae; the **lumbar** (back) region, with 5 vertebrae; the **sacral** (pelvic) region, with 5 fused vertebrae; and the **coccygeal** region, also composed of fused vertebrae.

The **rib cage** is a bony "basket" formed by the **sternum** (breastbone), thoracic vertebrae, and, in mammals, 12 pairs of ribs. The rib cage protects the internal organs of the chest, including the heart and lungs. It also supports the chest wall, preventing it from collapsing as the diaphragm contracts with each breath. Each pair of ribs is attached dorsally to a separate vertebra. Of your 12 pairs of ribs, the first 7 are attached ventrally to the sternum; the next 3 are attached indirectly by cartilages; and the last 2, the "floating ribs," have no attachments to the sternum.

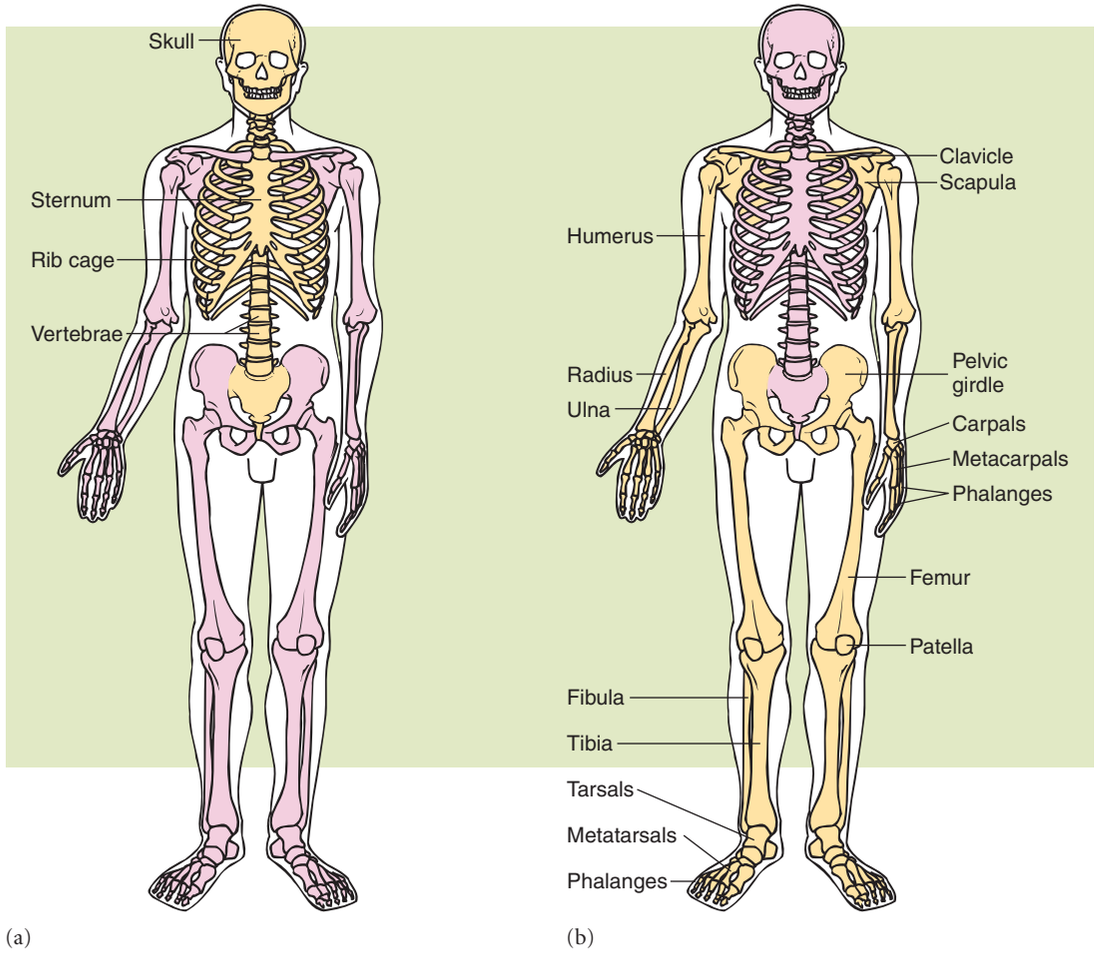

FIGURE **38-5**

The human skeletal system.

(a) Bones of the axial skeleton *(tan),* anterior view. **(b)** Bones of the appendicular skeleton *(tan),* anterior view.

The **pectoral girdle** consists of two collarbones, or **clavicles,** and two shoulder blades, or **scapulas.** The **pelvic girdle** consists of a pair of large bones, each composed of three fused hipbones. Whereas the pelvic girdle is securely fused to the vertebral column, the pectoral girdle is loosely and flexibly attached to it by muscles.

Each human limb consists of 30 bones and terminates in five **digits,** the fingers and toes. The more specialized appendages of other tetrapods may be characterized by four digits (as in the pig), three (as in the rhinoceros), two (as in the camel), or one (as in the horse).

A typical long bone consists of compact and spongy bone

The radius, one of the two bones of the forearm, is a typical long bone (Fig. 38-6). Its numerous muscle attachments are arranged in such a way that the bone rotates about its long axis and also operates as a lever, amplifying the motion generated by the muscles. By themselves, muscles cannot shorten enough to produce large movements of the body parts to which they are attached.

Like other bones, the radius is covered by a connective tissue membrane, the **periosteum,** to which muscle tendons and ligaments attach. The periosteum can produce new layers of bone, thus increasing the bone's diameter. The main shaft of a long bone is its **diaphysis;** each expanded end is an **epiphysis.** In children, a disk of cartilage, the **metaphysis,** lies between the epiphyses and the diaphysis. Metaphyses are growth centers that disappear at maturity, becoming vague **epiphyseal lines.** Long bones have a central cavity that contains **bone marrow.** Yellow marrow consists mainly of a fatty connective tissue; the red marrow in certain bones produces blood cells.

The radius has a thin outer shell of **compact bone,** which is very dense and hard. Compact bone lies primarily near the surfaces of a bone, where it provides great strength. Recall from Chapter 37 that compact bone consists of interlocking spindle-shaped units called **osteons,** or **Haversian systems** (see Fig. 37-2). Within an osteon, **osteocytes** (bone cells) lie in small cavities called **lacunae** (sing., *lacuna*). The lacunae are arranged in concentric circles around central **Haversian canals.** Blood vessels that nourish the bone tissue pass through the Haversian canals. Osteocytes are connected by threadlike extensions of their cytoplasm that extend through narrow channels called *canaliculi.*

Interior to the thin shell of compact bone is a filling of **spongy bone,** which provides mechanical strength. Spongy bone consists of a network of thin strands of bone. Its spaces are filled with bone marrow.

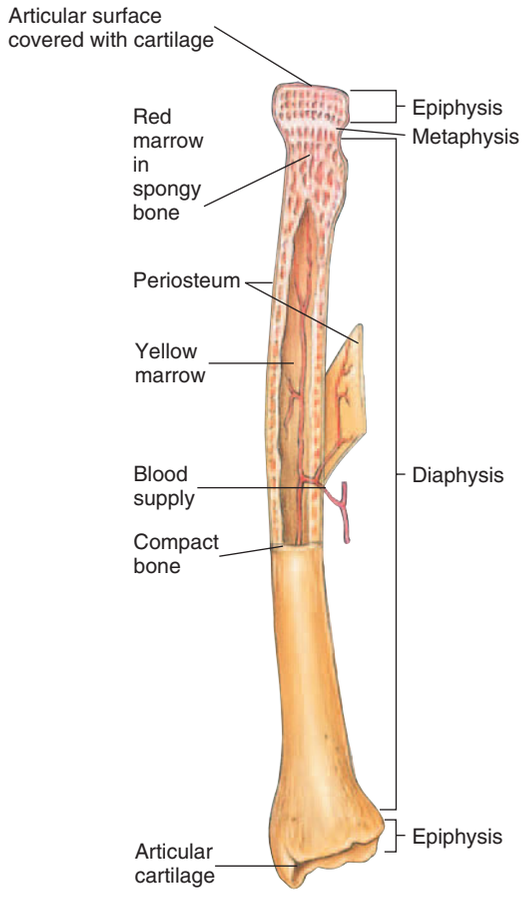

FIGURE **38-6** **A typical long bone.**

A long bone has a thin shell of compact bone and a filling of spongy bone that contains marrow.

Bones are remodeled throughout life

During fetal development, bones form in two ways. Long bones, such as the radius, develop from cartilage templates in a process called **endochondral bone development.** A bone begins to ossify in its diaphysis, and secondary sites of bone production develop in the epiphyses. The part of the bone between the ossified regions can grow. Eventually the ossified regions fuse. In contrast, other bones, including the flat outer bones of the skull, develop from a noncartilage, connective tissue scaffold. This process is known as **intramembranous bone development.**

Osteoblasts are bone-building cells. They secrete the protein collagen, which forms the strong fibers of bone. The compound hydroxyapatite, composed mainly of calcium phosphate, is present in the interstitial fluid. It automatically crystallizes around the collagen fibers, forming the hard matrix of bone. As the matrix forms around the osteoblasts, they become isolated within the lacunae. The trapped osteoblasts are then called *osteocytes.*

Bones are modeled during growth and remodeled continuously throughout life in response to physical stresses and other changing demands. As muscles develop in response to physical activity, the bones to which they are attached thicken and become stronger. As a bone grows, tissue is removed from its interior, especially from the walls of the marrow cavity.

Osteoclasts are large, multinucleated cells that break down (resorb) bone. The osteoclasts move about, secreting hydrogen ions that dissolve the crystals, and enzymes that digest the collagen. Osteoclasts and osteoblasts are synergistic; together they shape bones. The remodeling process is extensive—the adult human skeleton is completely replaced every 10 years!

In *osteoporosis,* the most common progressive degenerative bone disease, bone resorption takes place more rapidly than bone

formation. Patients lose so much bone mass that their bones become fragile, which greatly increases their risk for fracture. Certain drugs inhibit osteoclast-mediated bone resorption. Researchers are also testing drugs that promote osteoblast activity, with the goal of promoting bone formation.

Joints are junctions between bones

Joints, or articulations, are junction sites of two or more bones. Joints facilitate flexibility and movement. At the joint, the outer surface of each bone consists of articular cartilage. One way to classify joints is according to the degree of movement they allow. The *sutures* between bones of the human skull are **immovable joints.** In a suture, bones are held together by a thin layer of dense fibrous connective tissue, which may be replaced by bone in the adult. **Slightly movable joints,** found between vertebrae, are made of cartilage and help absorb shock.

Most joints are **freely movable joints.** Each is enclosed by a joint capsule of connective tissue and lined with a membrane that secretes a lubricant called **synovial fluid.** This viscous fluid reduces friction during movement and also absorbs shock. The joint capsule is typically reinforced by **ligaments,** bands of fibrous connective tissue that connect bones and limit movement at the joint.

With time and use, joints wear down. In *osteoarthritis,* a common joint disorder, cartilage repair does not keep up with degeneration, and the articular cartilage wears out. In *rheumatoid arthritis,* an autoimmune disease, the synovial membrane thickens and becomes inflamed. Synovial fluid accumulates, causing pressure, pain, stiffness, and progressive deformity, leading to loss of function.

MUSCLE CONTRACTION

Learning Objectives

7 Relate the structure and function of insect flight muscles.
8 Describe the structure of skeletal muscle.
9 List, in sequence, the events that take place during muscle contraction.
10 Compare the roles of glycogen, creatine phosphate, and ATP in providing energy for muscle contraction.
11 Describe how muscles work, including the antagonistic action of skeletal muscles.
12 Compare the structures and functions of slow and fast muscle fibers.

Throughout most of the animal kingdom, muscle tissue generates the mechanical forces and motion necessary for locomotion, manipulation of objects, circulation of blood, movement of food through the digestive tract, and many other life processes. Animals with very simple body plans do not have muscle tissue, but all eukaryotic cells do contain the contractile protein **actin.** The major component of microfilaments (see Fig. 4-25), actin is important in many cell processes, including amoeboid movement and attachment of cells to surfaces. In most cells, actin is functionally associated with the contractile protein **myosin.** Actin and myosin are most highly organized in **muscle** cells.

Invertebrate muscle varies among groups

Earlier in the chapter, we discussed the contractile cells of the hydrostatic skeleton of *Hydra* and other cnidarians. In flatworms and most other animal groups, muscle is a specialized tissue organized into definite layers, or straplike bands. Some invertebrate phyla have skeletal and smooth muscle. Bivalve mollusks, such as clams, have two sets of muscles for opening and closing the shell. Smooth muscle, which is capable of slow, sustained contraction, keeps the two shells tightly closed for long periods, even days or weeks at a time. Striated muscle, which contracts rapidly, is used to swim and to shut the shell quickly when the mollusk is threatened. Arthropod muscles are striated, even in the walls of the digestive tract.

PROCESS OF SCIENCE

Insect flight muscles contract more rapidly than any other known muscle, up to 1000 contractions per second. Not surprisingly, insect flight muscles in action have the highest known metabolic rate of any muscle tissue. As you might imagine, these muscles are structurally well adapted to their function. They contain more mitochondria than any known variety of muscle! Insect muscles are also elaborately infiltrated with *tracheae,* tiny air-filled tubes that carry oxygen directly to each fiber.

Insects were the first animals to evolve flight, an adaptation that has contributed to their impressive biological success (see Chapter 29). Just how insects fly has been an aerodynamic mystery, and scientists are working to understand their remarkable ability to maneuver. Somehow insects create lift that is 20 or more times their body weight. A central question has been how their flapping wings generate enough force to keep them airborne. Insect flight involves much more than just flapping the wings up and down. The flapping motion of the insect wing changes direction and speed, and upstrokes alternate with downstrokes at very high rates. At each shift of stroke, the wing rotates about its long axis and tilts to just the right angle for the new direction of motion.

In many flying insects, the striated flight muscles attach not directly to the wings but to the flexible portions of the exoskeleton that articulate with the wings. Each contraction of the muscles "dimples" the exoskeleton in association with a downstroke and sometimes, depending on the exact arrangement of the muscles, on the upstroke as well. When the dimple springs back

into resting position, the muscles attached to it stretch. The stretching immediately initiates another contraction, and the cycle repeats.

The deformation of the exoskeleton is transmitted as a force to the wings, which beat so fast we may perceive the sounds as a musical tone. In the common blowfly, for instance, the wings may beat at 120 cycles *per second*. Yet in the same blowfly, the neurons that innervate those furiously contracting flight muscles are delivering impulses to them at the astonishingly low frequency of 3 per second. The mechanical properties of the musculoskeletal arrangement provide the stimuli for contraction, by stretching the muscle fibers at a high frequency, but the nerve impulses are needed to maintain contraction.

Researchers are using a variety of approaches to unravel the mysteries of insect flight. Some groups of investigators are using computer simulations, and one group has designed a fly robot to use as a model. Another group is painting the wings of honeybees with a dye that responds to changes in air pressure. Under UV light, the dye phosphoresces bright red. Oxygen in the air diminishes the red glow, so regions on the wings that are affected by the highest air pressure phosphoresce least (more oxygen molecules are present in denser air). The researchers can map out the forces acting on the wings by recording the intensity of the red glow. Because a bee's wing-beat cycle takes place in 5 milliseconds, mapping these forces is a major challenge.

A vertebrate muscle may consist of thousands of muscle fibers

In vertebrates, skeletal muscle is the most abundant tissue in the body. Its elongated cells, or **muscle fibers,** are organized in bundles wrapped by connective tissue. The biceps in your arm, for example, consists of thousands of individual muscle fibers and their connective tissue coverings.

Each striated muscle fiber is a long, cylindrical cell with many nuclei (Fig. 38-7). The plasma membrane, known as the **sarcolemma** in a muscle fiber, has multiple inward extensions that form a set of **T tubules** (transverse tubules). The cytoplasm of a muscle fiber is called **sarcoplasm,** and the endoplasmic reticulum is called the **sarcoplasmic reticulum.**

Threadlike structures called **myofibrils** run lengthwise through the muscle fiber. They consist of even smaller structures, the **myofilaments** or simply **filaments.** There are two types of myofilaments: myosin and actin filaments. **Myosin filaments** are thick, consisting mainly of the protein myosin. The thin **actin filaments** consist mostly of the protein actin; they also contain the proteins **tropomyosin** and the **troponin complex** that regulate the actin filament's interaction with myosin filaments.

Myosin and actin filaments are organized into repeating units called **sarcomeres,** the basic units of muscle contraction. Hundreds of sarcomeres connected end-to-end make up a myofibril. Sarcomeres are joined at their ends by an interweaving of filaments called the **Z line.** Each sarcomere consists of overlapping myosin and actin filaments. The filaments overlap lengthwise in the muscle fibers, producing the pattern of transverse bands or striations characteristic of striated muscle (Figs. 38-7 and 38-8). The bands are designated by the letters *A, H,* and *I.*

The **I bands,** which consist of actin filaments, lie at both ends of the sarcomere, immediately adjacent to the Z line. The **A band** is the wide, dark region of overlapping myosin and actin filaments. Within the A band is a narrow, light area, the **H zone,** made up exclusively of myosin filaments; the actin filaments do not extend into this region.

Contraction occurs when actin and myosin filaments slide past each other

Muscle contraction occurs when the sarcomeres, and thus the muscle fibers, shorten. This theory of muscle contraction, known as the **sliding filament model,** was developed in the 1950s by two British biologists, Hugh Huxley and Andrew Huxley. We now know that the muscle shortens as the actin and myosin filaments slide past each other, increasing their overlap. You might think of an extension ladder. The overall ladder length changes as the ends get closer or farther apart, but the length of each ladder section stays the same. The I band and H zone decrease in length, but neither the actin nor myosin filaments themselves shorten.

In a **motor unit,** a motor neuron (a nerve cell that stimulates muscle) is functionally connected with an average of about 150 muscle fibers (Fig. 38-9). Each junction of a motor neuron with a muscle fiber is called a **neuromuscular junction.** When a motor neuron transmits a message, it releases the neurotransmitter **acetylcholine** into the synaptic cleft (a small space) between the motor neuron and each muscle fiber. Acetylcholine binds with receptors on each muscle fiber, causing **depolarization,** a change in the distribution of electrical charge across its sarcolemma. Depolarization can cause an electrical signal, or **action potential,** to be generated in the muscle fiber.

In a muscle fiber, an action potential is a wave of depolarization that travels along the sarcolemma and into the system of T-tubule membranes. Depolarization of the T tubules opens calcium channels in the sarcoplasmic reticulum, releasing stored calcium ions into the myofibrils. Calcium ions bind to a protein in the troponin complex on the actin filaments, which changes the shape of the troponin. This change results in the troponin pushing the tropomyosin away from the active sites on the actin filament (Fig. 38-10 on page 738). These active sites, also called *myosin-binding sites,* are now exposed.

One end of each myosin molecule is folded into two globular structures called *heads.* The rounded heads of the myosin molecules extend away from the body of the myosin filament. Each myosin molecule also has a long tail that joins other myosin tails to form the body of the thick filament. ATP is bound to the myosin when the muscle fiber is at rest (not contracting). Myosin is an adenosine triphosphatase (ATPase), an enzyme that splits ATP, forming ADP and inorganic phosphate (P_i). Myosin converts the chemical energy of ATP into the mechanical energy of sliding filaments.

According to the current model of muscle contraction, the ADP and P_i initially remain attached to the myosin head. The myosin head (with ADP and P_i still bound to it) is in an ener-

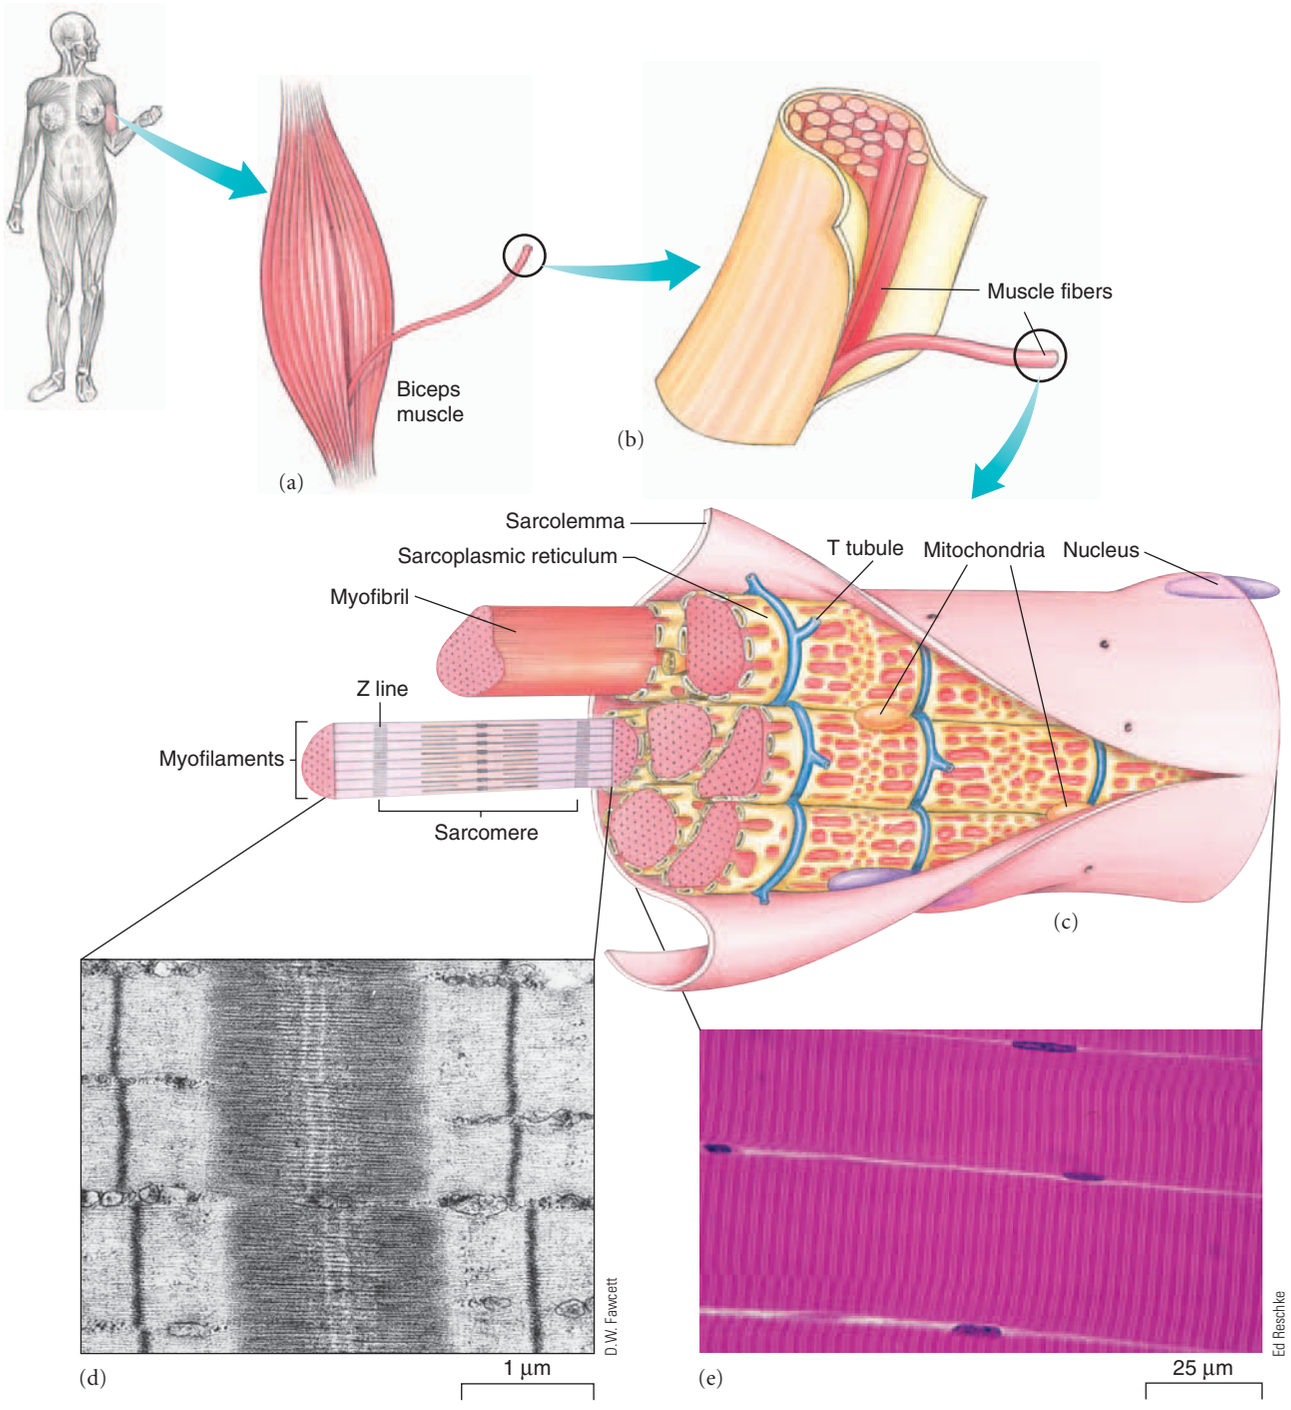

FIGURE **38-7** **Muscle structure.**

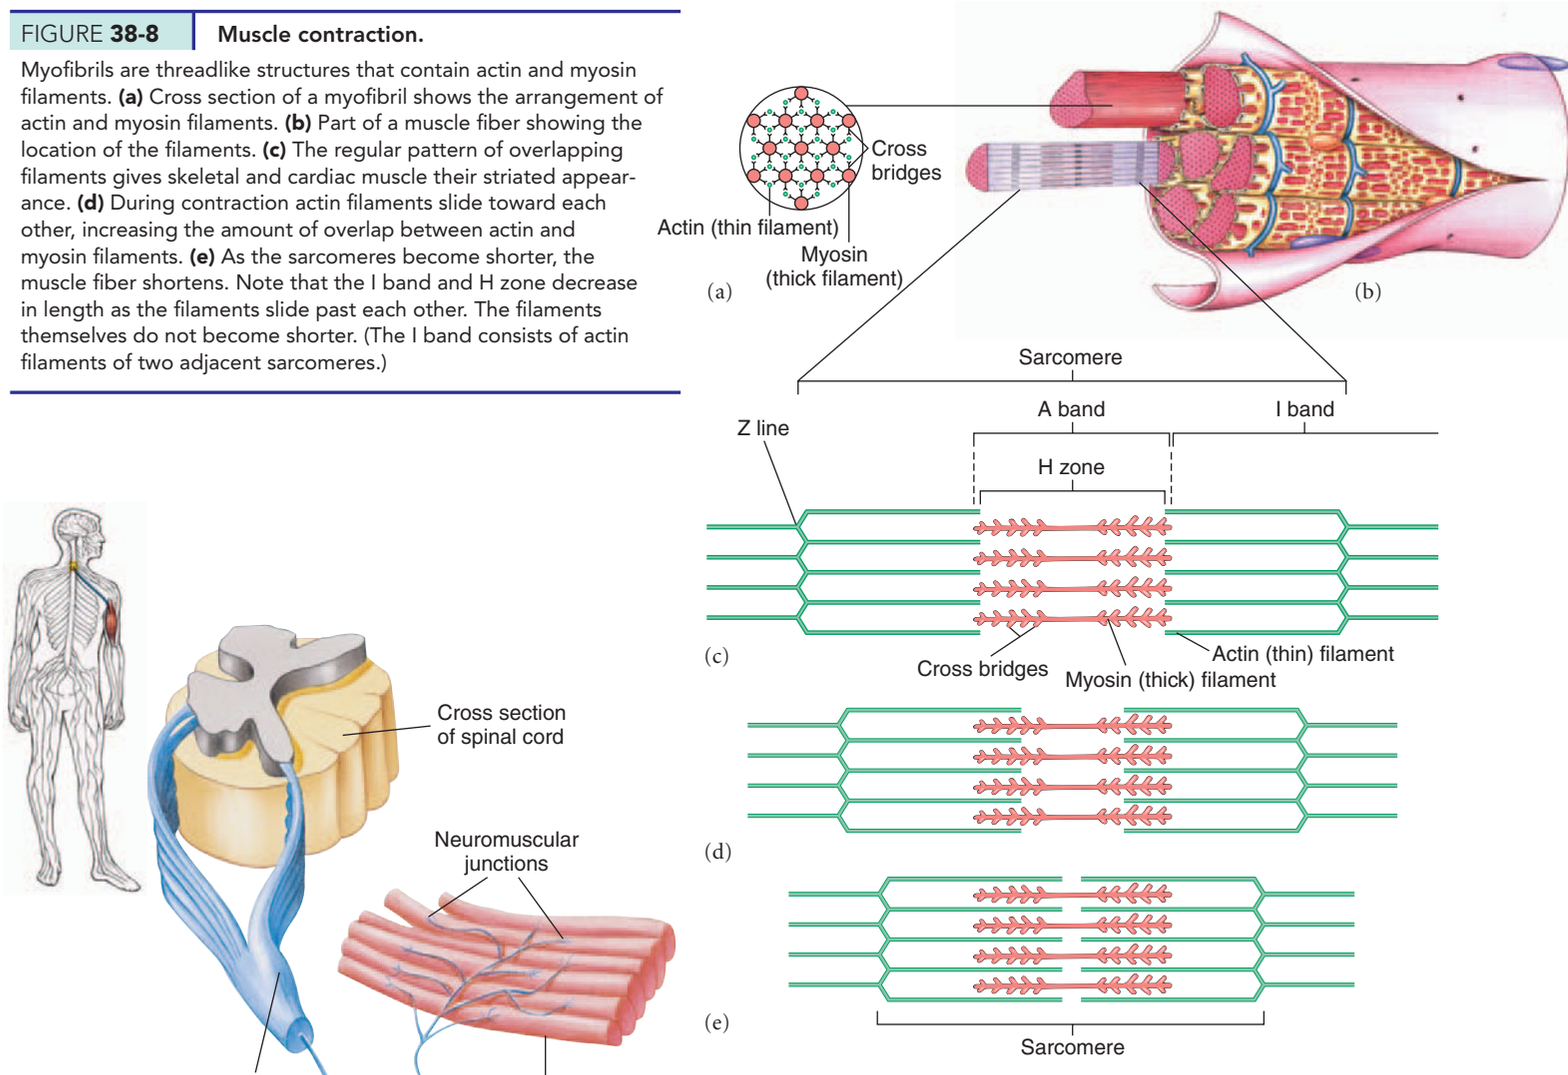
(a) A muscle such as the biceps in the arm consists of many fascicles (bundles) of muscle fibers. **(b)** A fascicle wrapped in a connective tissue covering. **(c)** Part of a muscle fiber showing the structure of myofibrils. The Z lines mark the ends of the sarcomeres. **(d)** TEM of striated muscle. **(e)** LM showing striations.

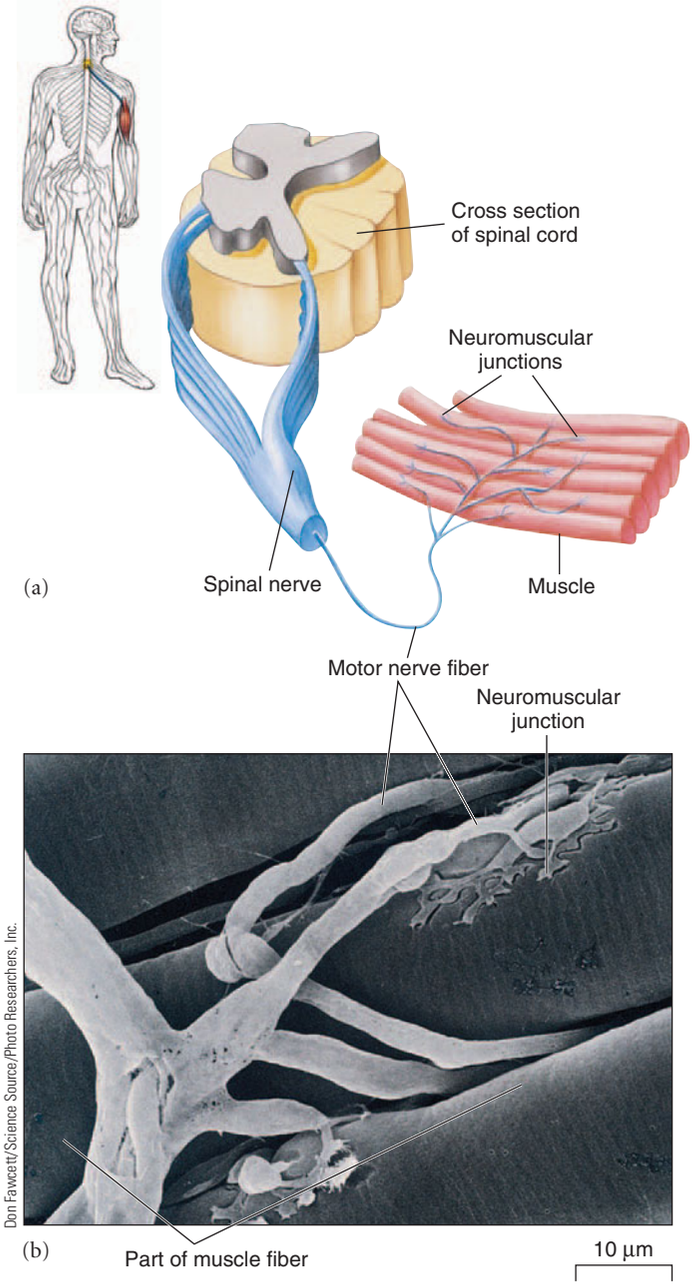
gized state; it is "cocked." The myosin head binds to an exposed active site on the actin filament, forming a **cross bridge** linking the myosin and actin filaments. The inorganic phosphate (P_i) is then released, which triggers a conformational change in the myosin head. The myosin head bends about 45 degrees, in a flexing motion. This movement, the *power stroke,* pulls the actin filament closer to the center of the sarcomere. During the power stroke, the ADP is released.

A new ATP must bind to the myosin head before the myosin can detach from the actin. If sufficient calcium ions are pres-

FIGURE 38-8 Muscle contraction.

Myofibrils are threadlike structures that contain actin and myosin filaments. **(a)** Cross section of a myofibril shows the arrangement of actin and myosin filaments. **(b)** Part of a muscle fiber showing the location of the filaments. **(c)** The regular pattern of overlapping filaments gives skeletal and cardiac muscle their striated appearance. **(d)** During contraction actin filaments slide toward each other, increasing the amount of overlap between actin and myosin filaments. **(e)** As the sarcomeres become shorter, the muscle fiber shortens. Note that the I band and H zone decrease in length as the filaments slide past each other. The filaments themselves do not become shorter. (The I band consists of actin filaments of two adjacent sarcomeres.)





Don Fawcett/Science Source/Photo Researchers, Inc.

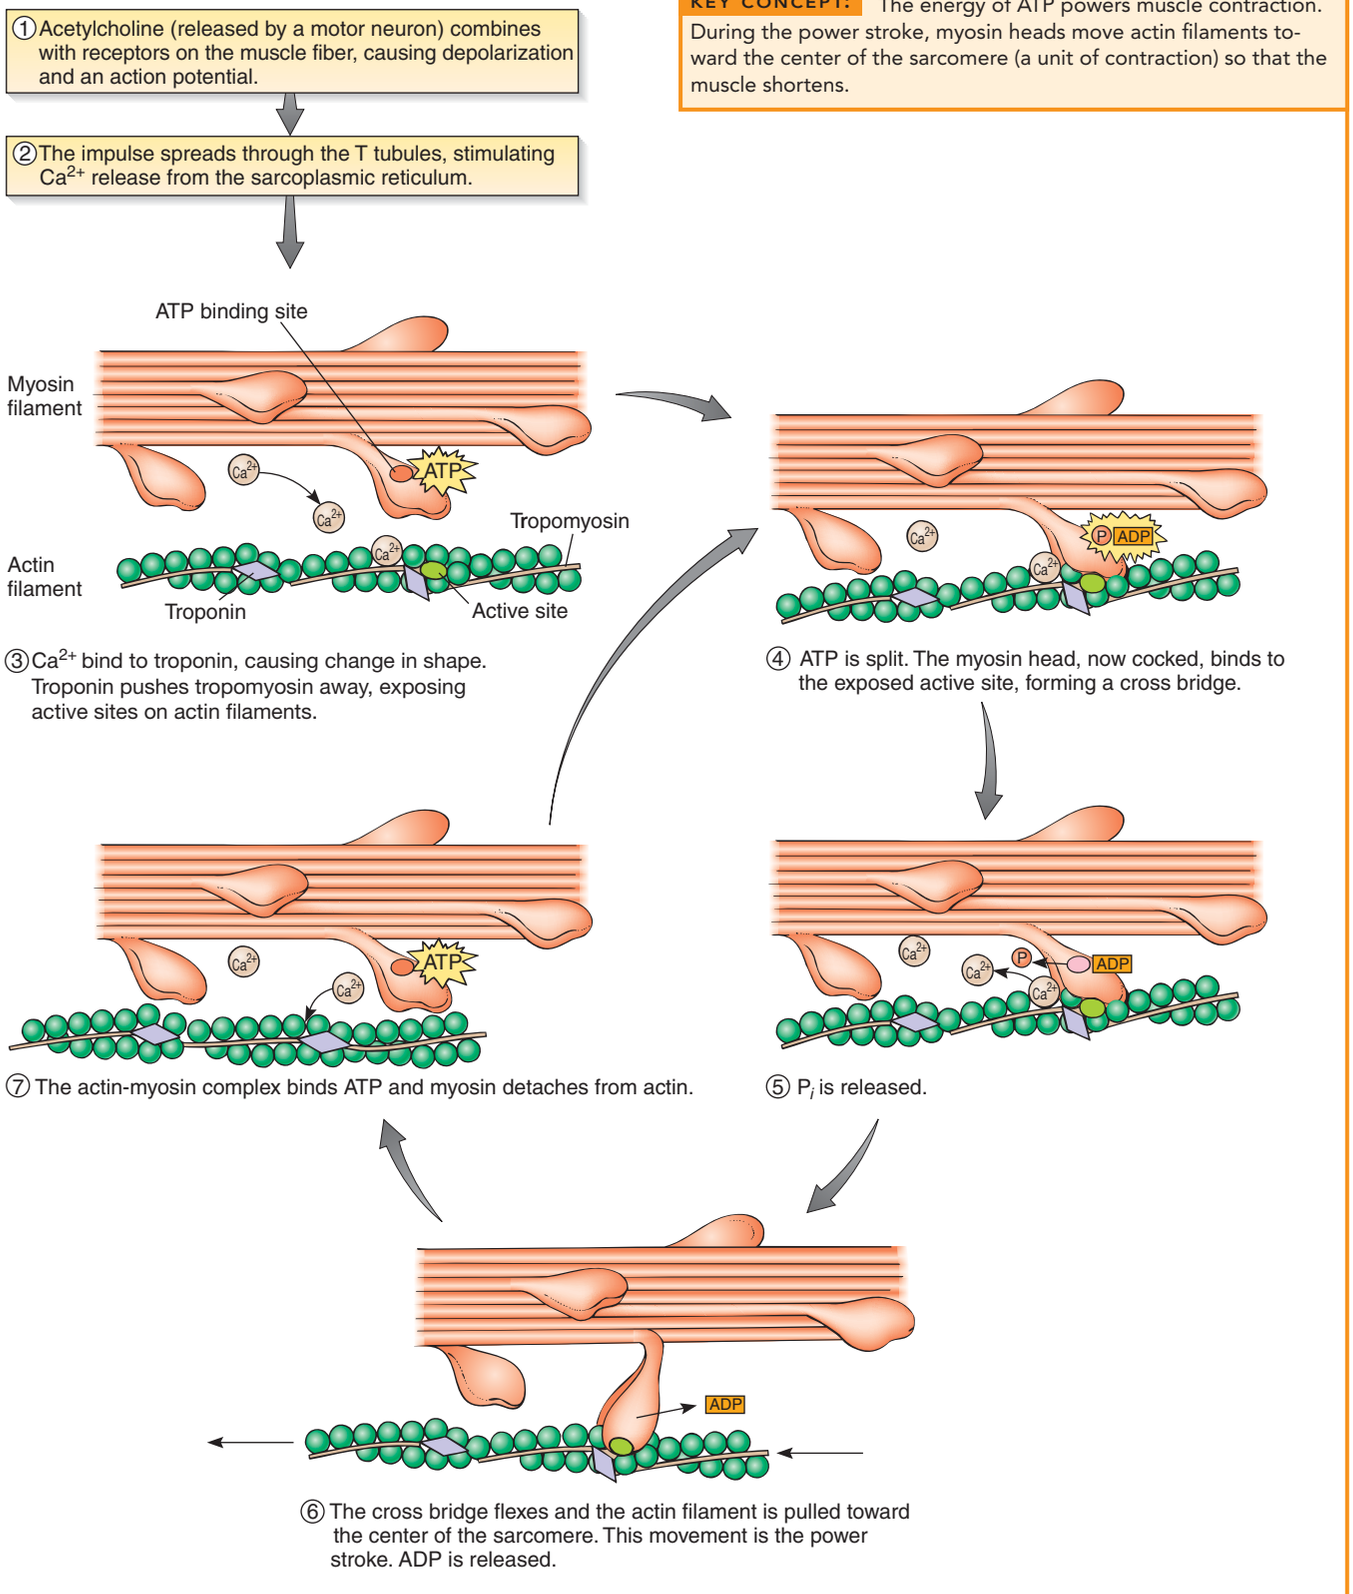
ent, the cycle begins anew. Energized once again, myosin heads contact a second set of active sites on the actin filament; this next set is further down the molecule, closer to the end of the sarcomere. The process repeats with a third set, and so on. This series of stepping motions pulls the actin filaments toward the center of the sarcomere.

Each time the myosin heads attach, move 45 degrees, detach, and then reattach farther along the actin filament, the muscle shortens. One way to visualize this process is to imagine the myosin heads engaging "hand-over-hand" with the actin filaments. When many sarcomeres contract simultaneously,

FIGURE 38-9 A motor unit.

A motor unit consists of a motor nerve fiber and muscle fibers that it innervates. A motor unit typically includes about 150 muscle fibers, but some units have less than a dozen fibers, whereas others have several hundred. **(a)** The motor unit illustrated here shows only a single motor nerve fiber. **(b)** SEM of some of the fibers in a motor unit. Note how the neuron branches to innervate all muscle fibers in the motor unit.

KEY CONCEPT: The energy of ATP powers muscle contraction. During the power stroke, myosin heads move actin filaments toward the center of the sarcomere (a unit of contraction) so that the muscle shortens.



ACTIVE FIGURE **38-10** **Model of muscle contraction.**

Contraction results when actin filaments slide toward the center of individual sarcomeres of a myofibril. After Step ⑦, the cycle repeats from step ④.

BiologyNow™ Watch **the steps of muscle contraction** by clicking on this figure on your BiologyNow CD-ROM.

they contract the muscle as a whole. The sequence of events in muscle contraction can be summarized as follows (circled numbers correspond to steps in Fig. 38-10):

① Acetylcholine (released from motor neuron) combines with receptors on muscle fiber causing depolarization and an action potential
② the action potential spreads through T tubules, triggering Ca^{2+} release from sarcoplasmic reticulum
③ When troponin binds Ca^{2+} it undergoes a conformational change that causes active sites on actin filaments to be exposed
④ ATP (attached to myosin) is split and the energized myosin head is cocked; it binds to active site on actin filament, forming a cross bridge
⑤ P_i is released from myosin head, triggering the power stroke
⑥ the power stroke occurs as the actin filament is pulled toward center of sarcomere; and ADP is released
⑦ the myosin head binds ATP and detaches from actin If sufficient Ca^{2+} is present, the sequence repeats from step ④.

When impulses from the motor neuron cease, muscle fibers return to their resting state. The enzyme acetylcholinesterase in the synaptic cleft inactivates acetylcholine. Calcium ions are pumped back into the sarcoplasmic reticulum by active transport, a process that requires ATP. Without calcium ions, the tropomyosin-troponin complex once again covers active sites on the actin filaments. The actin filaments slide back to their original position, and the muscle relaxes. This entire series of events happens in milliseconds.

Even when you are not moving, your muscles are in a state of partial contraction known as **muscle tone.** At any given moment some muscle fibers are contracted, stimulated by messages from motor neurons. Muscle tone is an unconscious process that keeps muscles prepared for action. When the motor nerve to a muscle is cut, the muscle becomes limp (completely relaxed, or flaccid) and eventually atrophies (decreases in size).

ATP powers muscle contraction

Muscle cells often perform strenuously and need large amounts of energy. As noted, the immediate source of energy for muscle contraction is ATP. Energy stored in ATP molecules powers the repeated cocking, attachment of the myosin heads to the actin filaments, flexion, and release of the myosin heads. Note that energy is needed not only for the pull exerted by the cross bridges but also for their release from each active site. *Rigor mortis,* the temporary but very marked muscular rigidity that appears after death, results from ATP depletion following the end of cellular respiration. Rigor mortis does not persist indefinitely, because the entire contractile apparatus of the muscles eventually decomposes, restoring pliability. The phenomenon is temperature dependent, so, given the prevailing temperature, a medical examiner can estimate the time of death of a cadaver from its degree of rigor mortis.

ATP molecules can provide energy for only a few seconds of strenuous activity. Fortunately, muscle cells have a backup energy storage compound, called **creatine phosphate,** that can be stockpiled. The energy stored in creatine phosphate is transferred to ATP as needed. But during vigorous exercise the supply of creatine phosphate is quickly depleted. Muscle cells must replenish their supplies of these energy-rich compounds.

Chemical energy is stored in muscle fibers in **glycogen,** a large polysaccharide formed from hundreds of glucose molecules. Glycogen is degraded, yielding glucose, which then breaks down in cellular respiration. When sufficient oxygen is available, enough energy is captured from glucose to produce needed quantities of ATP and creatine phosphate.

During a burst of strenuous exercise, the circulatory system cannot deliver enough oxygen to keep up with the demand of the rapidly metabolizing muscle cells. This results in an **oxygen debt.** Under these conditions, muscle cells break down fuel molecules anaerobically (without oxygen) for short periods. Lactic acid fermentation is a method of generating ATP anaerobically, but not in great quantity (see Fig. 7-3). ATP depletion results in weaker contractions and muscle fatigue. Accumulation of the waste product **lactic acid** also contributes to muscle fatigue. Well-conditioned athletes develop the ability to tolerate the high levels of lactic acid generated during high-performance activity. The period of rapid breathing that generally follows strenuous exercise pays back the oxygen debt by consuming lactic acid.

Skeletal muscle action depends on muscle pairs that work antagonistically

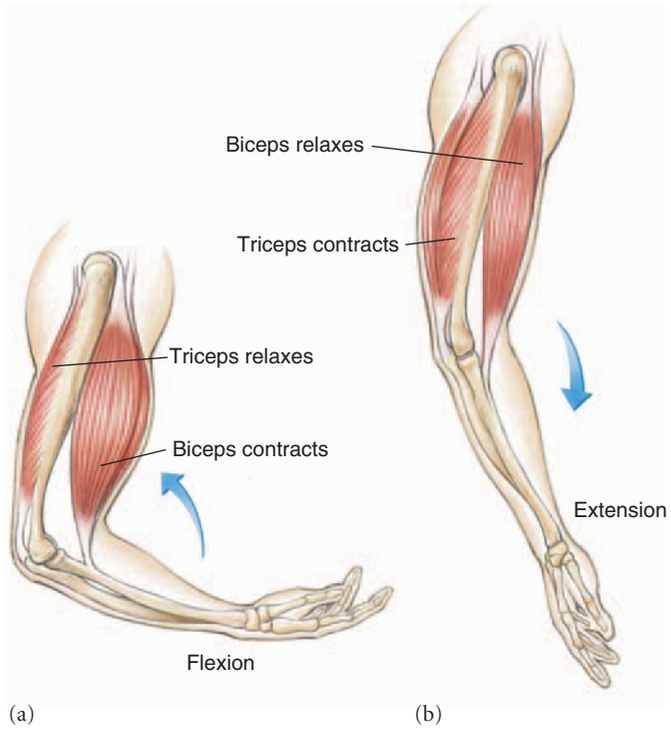
Skeletal muscles produce movements by pulling on **tendons,** tough cords of connective tissue that anchor muscles to bone. Tendons then pull on bones. Skeletal muscles, or their tendons, pass across a joint and are attached to the bones on each side of the joint. When the muscle contracts, it pulls one bone toward or away from the bone with which it articulates.

Because muscles can only contract, they can only pull; they cannot push. Muscles act **antagonistically** to one another, which means that the movement produced by one can be reversed by another. The biceps muscle, for example, flexes (bends) your arm, whereas contraction of the triceps muscle extends it once again (Fig. 38-11). Thus the biceps and triceps work antagonistically.

The muscle that contracts to produce a particular action is known as the **agonist.** The muscle that produces the opposite movement is the **antagonist.** When the agonist is contracting, the antagonist is relaxed. Generally, movements are accomplished by groups of muscles working together, so several agonists and several antagonists may take part in any action. Note that muscles that are agonists in one movement may serve as antagonists in another. The superficial skeletal muscles of the human body are shown in Figure 38-12.

Muscle fibers may be specialized for slow or quick responses.

One component of myosin, the heavy chain, exists in three different forms: Types I, IIa, and IIx. The three types of myosin



ACTIVE FIGURE **38-11** **Muscle action.**

The biceps and triceps muscles function antagonistically.

BiologyNow™ Watch **a muscle in action** by clicking on this figure on your BiologyNow CD-ROM.

apparently evolved early and have been conserved throughout the animal kingdom. Muscle fibers that contain mainly Type I myosin are called Type I fibers, or **slow fibers.** These fibers are specialized for endurance activities such as swimming, long-distance running, or maintaining posture. Slow fibers require a steady supply of oxygen. They derive most of their energy from aerobic metabolism and are rich in mitochondria and capillaries. Slow fibers are also called **red fibers,** because they are rich in **myoglobin,** a red pigment similar to hemoglobin in red blood cells. Myoglobin, like hemoglobin, stores oxygen. Myoglobin enhances rapid diffusion of oxygen from blood into muscles during strenuous muscle exertion.

Muscle fibers that contain Type IIa and IIx myosin are known as **fast fibers,** or **white fibers.** (Type IIx fibers are the fastest.) White fibers generate a great deal of power and carry out rapid movements but can sustain that activity for only a short time. They are important in activities such as sprinting and weight lifting. White fibers have few mitochondria and must obtain most of their energy from glycolysis. When their glycogen supply is depleted, they fatigue rapidly. People who are sedentary have higher numbers of Type IIx fibers than do physically fit individuals. With physical training, Type IIx fibers change to Type IIa fibers.

Entire muscles may be specialized for quick or slow responses. In chickens, for instance, the white breast muscles are efficient for quick responses, perhaps because a short flight is an escape mechanism for chickens. However, they walk about on the ground all day; the dark (red) meat of the leg and thigh is muscle specialized for more sustained activity. Birds that fly have red breast muscles specialized to support sustained activity.

The proportions of slow and fast fibers vary from person to person and from muscle to muscle in the same person. Although the relative proportions of the two types of fibers appear genetically influenced, appropriate training can change the proportions. Someone whose leg and thigh muscles contain a high proportion of fast fibers can, with proper training, become a good sprinter. An athlete with a greater proportion of slow fibers may be better suited to marathon activities.

Smooth, cardiac, and skeletal muscle respond in specific ways

The three types of vertebrate muscle—skeletal, smooth, and cardiac—are compared in Chapter 37, Table 37-3. Each type of muscle is specialized for particular types of responses. **Smooth muscle** is not attached to bones but instead forms tubes that squeeze like the muscle tissue in the body wall of the earthworm. Smooth muscle often contracts in response to simple stretching, and its contraction tends to be sustained. It is well adapted to performing such tasks as regulating blood pressure by sustained contraction of the walls of the arterioles. Although smooth muscle contracts slowly, it shortens much more than striated muscle does; it squeezes superlatively.

Smooth muscle is not striated because its actin and myosin filaments are not organized into myofibrils or into sarcomeres. The fibers of smooth muscle tissue function as a unit because they are connected by *gap junctions* (see Chapter 5). Gap junctions permit electrical signals to pass rapidly from fiber to fiber. Although smooth muscle contraction is basically similar to contraction of skeletal muscle (occurring by a sliding filament mechanism), the cross bridges in smooth muscle remain in the attached state longer. This translates into less ATP being required to maintain a high level of force.

Cardiac muscle contracts and relaxes in alternating rhythm, propelling blood with each contraction. Sustained contraction of cardiac muscle would be disastrous! Like smooth muscle fibers, cardiac muscle fibers are electrically coupled by gap junctions (the intercalated discs). Cardiac muscle produces its own signals for contraction (discussed in Chapter 42).

Skeletal muscle, when stimulated by a single brief electrical stimulus, contracts with a single quick contraction called a **simple twitch.** Typically, skeletal muscle receives a series of separate stimuli timed very close together. These do not produce a series of simple twitches, however, but a single, smooth, sustained contraction called **tetanus.** Depending on the identity and number of our muscle cells tetanically contracting, we might thread a needle, rock a baby, or run a mile.

Review

- Describe a skeletal muscle fiber. What are its two types of filaments?
- What events occur when a muscle fiber contracts (begin with release of acetylcholine and include cross-bridge action)?

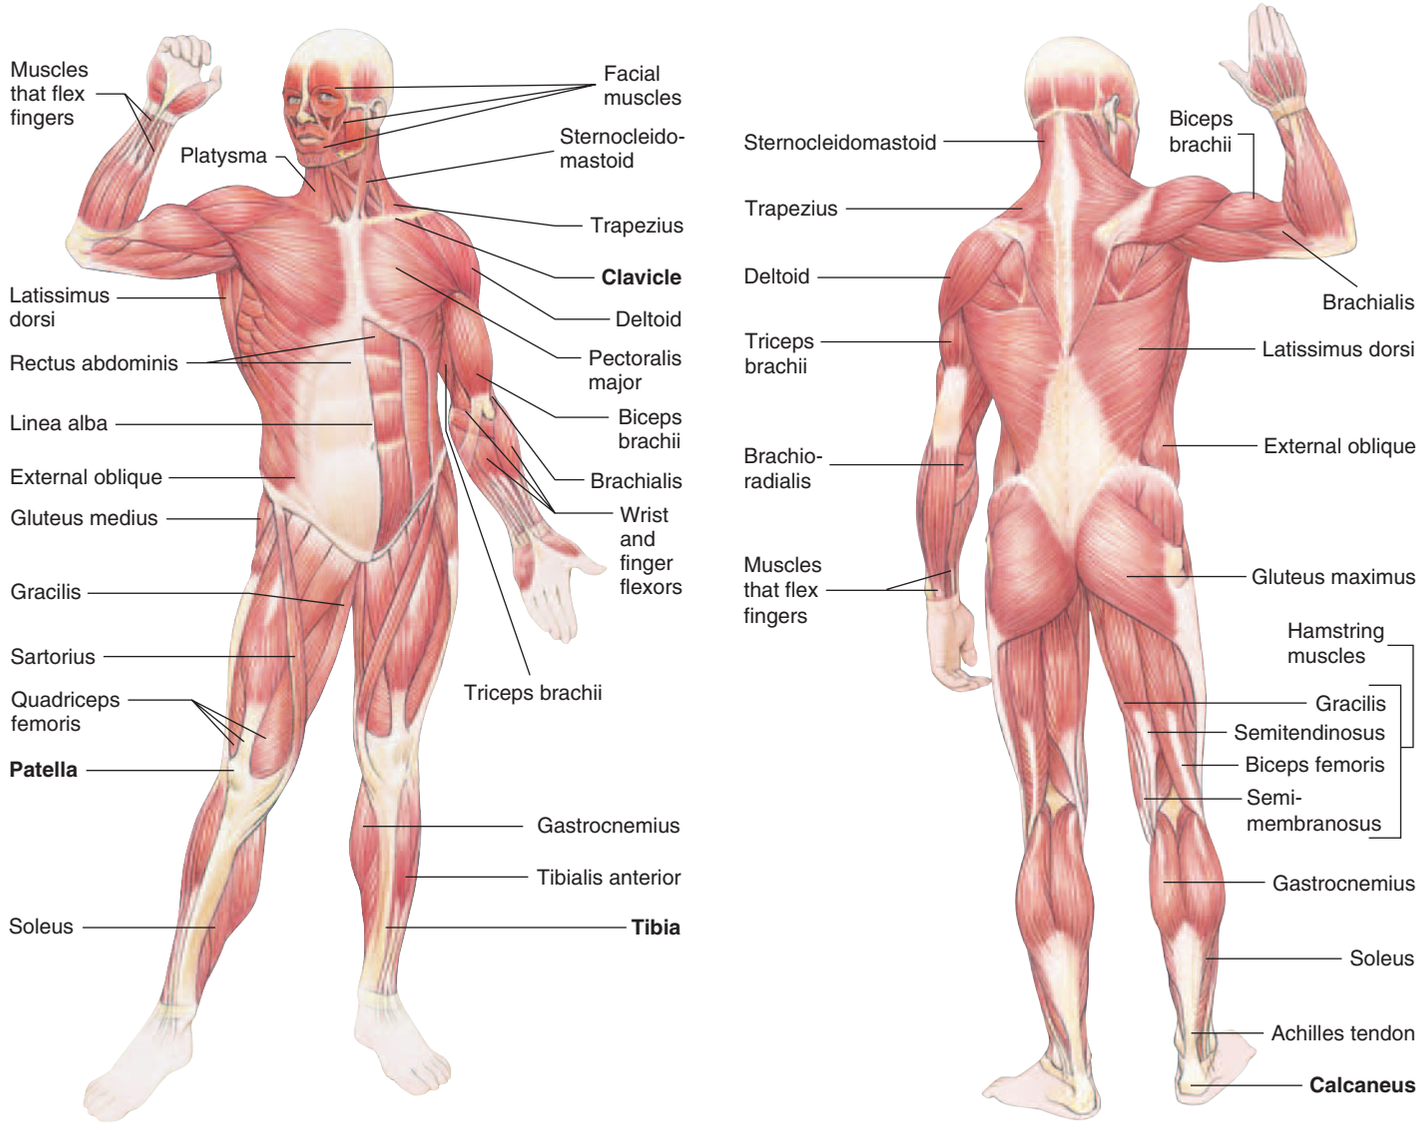


FIGURE **38-12** **Some superficial muscles of the human body.**
(a) Anterior view. **(b)** Posterior view. The labels in boldface are bones.

- What is the role of ATP in muscle contraction? What are the functions of creatine phosphate and glycogen?

BiologyNow™ Assess your understanding of **muscle contraction** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Compare the structure and functions of the external epithelium of invertebrates and vertebrates.

- **Epithelial coverings** in both invertebrates and vertebrates protect underlying tissues, and may be specialized for sensory or respiratory functions. The outer epithelium may be specialized to secrete lubricants or adhesives, or odorous or poisonous substances.
- In many invertebrates, the outer epithelium is specialized to secrete a protective **cuticle** or shell.
- The **integumentary system** of vertebrates includes the skin and structures that develop from it. Mammalian skin includes hair, claws or nails, sweat glands, oil glands, and sensory receptors.

2 Relate the structure of vertebrate skin to its functions.

- The feathers of birds and the hair of mammals help maintain a constant body temperature.
- Mammalian skin is well adapted to protect the body from the wear and tear that occurs as it interacts with the outer environ-

ment. **Stratum corneum,** the most superficial layer of the epidermis, consists of dead cells. These cells are filled with **keratin,** which gives mechanical strength to the skin and reduces water loss. Cells in **stratum basale** of the **epidermis** divide and are pushed upward toward the skin surface. These cells mature, flatten, produce keratin, and eventually die and slough off.

- The **dermis** consists of dense, fibrous connective tissue. In birds and mammals, the dermis rests on a layer of **subcutaneous tissue** composed largely of insulating fat.

3 Compare the different types of skeletal systems, including the hydrostatic skeleton, exoskeleton, and endoskeleton.

- The **skeletal system** supports and protects the body, and transmits mechanical forces generated by muscles.
- Many soft-bodied invertebrates, including cnidarians, flatworms, and annelids, have a **hydrostatic skeleton** in which fluid in a closed body compartment is used to transmit forces generated by contractile cells or muscle.
- **Exoskeletons** are characteristic of mollusks and arthropods. The arthropod skeleton, composed partly of **chitin,** is jointed for flexibility, and adapted for many lifestyles. This nonliving skeleton does not grow, making it necessary for arthropods to **molt** periodically.
- The **endoskeletons** of echinoderms and chordates consist of living tissue and therefore can grow.

4 Describe the main divisions of the vertebrate skeleton and the bones that make up each division.

- The vertebrate skeleton consists of an **axial skeleton** and an **appendicular skeleton.**
- The axial skeleton consists of **skull, vertebral column, ribs,** and **sternum.**
- The appendicular skeleton consists of bones of the limbs, **pectoral girdle,** and **pelvic girdle.**

5 Describe the structure of a typical long bone, and differentiate between endochondral and intramembranous bone development.

- A typical long bone consists of a thin outer shell of **compact bone** surrounding the inner **spongy bone** and a central cavity that contains **bone marrow.**
- Long bones develop from cartilage templates during **endochondral bone formation.** Other bones, such as the flat bones of the skull, develop from a noncartilage connective tissue model by **intramembranous bone development.**
- **Osteoblasts,** cells that produce bone, and **osteoclasts,** cells that break down bone, work together to shape and remodel bone.

6 Compare the main types of vertebrate joints.

- **Joints** are junctions of two or more bones. **Ligaments** are connective tissue bands that connect bones and limit movement at the joint.
- The sutures of the skull are **immovable joints.** Joints between vertebrae are **slightly movable joints.**
- A **freely movable joint** is enclosed by a joint capsule lined with a membrane that secretes **synovial fluid.**

7 Relate the structure and function of insect flight muscles.

- Large numbers of mitochondria and tracheae (air tubes) present in insect flight muscles support the high metabolic rate required for flight.

8 Describe the macroscopic and microscopic structures of skeletal muscle.

- A **muscular system** is found in most invertebrate phyla and in vertebrates. As muscle tissue contracts (shortens), it moves body parts by pulling on them. Three types of muscle are **skeletal, smooth,** and **cardiac muscle.**
- A skeletal muscle such as the biceps is an organ made up of hundreds of **muscle fibers.** Each fiber consists of threadlike **myofibrils** composed of smaller **myofilaments,** or simply **filaments.**
- The striations of skeletal muscle fibers reflect the overlapping of their **actin filaments** and **myosin filaments.** A **sarcomere** is a contractile unit of actin (thin) and myosin (thick) filaments.

9 List, in sequence, the events that take place during muscle contraction.

- **Acetylcholine** released by a motor neuron combines with receptors on the surface of a muscle fiber. This may cause **depolarization** of the sarcolemma and transmission of an **action potential.**
- The action potential spreads through the **T tubules,** releasing calcium ions from the **sarcoplasmic reticulum.**
- Calcium ions bind to **troponin** in the actin filaments, causing the troponin to change shape. Troponin pushes **tropomyosin** away from the active sites on the actin filaments.
- ATP binds to myosin; ATP is split, putting the myosin head in a high-energy state (it is "cocked"). Energized myosin heads bind to the exposed active sites on the actin filaments, forming **cross bridges** linking the myosin and actin filaments.
- After myosin attaches to the actin filament, phosphate is released, flexing the cross bridge. The actin filament is pulled toward the center of the sarcomere. This is the power stroke. ADP is released.
- The myosin head binds a new ATP, which lets the myosin head detach from the actin. As long as the calcium ion concentration remains elevated, the new ATP is split, and the sequence repeats. The myosin reattaches to new active sites so that the filaments are pulled past one another, and the muscle continues to shorten.

10 Compare the roles of glycogen, creatine phosphate, and ATP in providing energy for muscle contraction.

- During muscle contraction, the myosin filaments pull the actin filaments toward the center of the myofibril. This movement requires energy.
- ATP is the immediate source of energy for muscle contraction. The energy from ATP hydrolysis provides the energy to "cock" the myosin.
- Muscle tissue has an intermediate energy storage compound, **creatine phosphate.**
- **Glycogen** is the fuel stored in muscle fibers.

11 Describe how muscles work, including the antagonistic action of skeletal muscles.

- Muscles pull on **tendons,** connective tissue cords that attach muscles to bones. When a muscle contracts, it pulls a bone toward or away from the bone with which it articulates. **Muscle tone** is the state of partial contraction characteristic of muscles.
- Muscles act **antagonistically** to one another. The muscle that produces a particular action is the **agonist;** the **antagonist** produces the opposite movement.
- When activated by a brief electrical stimulus, skeletal muscle responds with a **simple twitch.** Typically skeletal muscle is stim-

SUMMARY WITH KEY TERMS *(continued)*

ulated with a series of separate stimuli timed close together and responds with a smooth, sustained contraction called **tetanus.**

12 Compare the structures and functions of slow and fast muscle fibers.

- **Slow fibers,** or **red fibers,** are rich in mitochondria and **myoglobin.** They are specialized for endurance activities.
- **Fast fibers,** or **white fibers,** are specialized for rapid response. Using ATP from glycolysis, they can generate a great deal of power for a brief period.

POST-TEST

1. The vertebrate skin consists of (a) outer epidermis, inner hypodermis (b) outer epidermis, inner endoskeleton (c) outer endodermis, inner epidermis (d) outer epidermis, inner dermis (e) outer subcutaneous layer, inner dermis
2. Cells actively divide in (a) stratum basale (b) stratum corneum (c) stratum dermis (d) the layer with cells that contain keratin (e) two of the preceding answers are correct
3. An endoskeleton (a) is typically composed of dead tissue (b) is characterized by fluid in a closed compartment (c) is typical of echinoderms (d) is typical of arthropods (e) requires the animal to molt
4. Which of the following is *not* part of the axial skeleton? (a) skull (b) vertebral column (c) pelvic girdle (d) rib cage (e) sternum
5. The thin outer shell of a long bone is made of (a) compact bone (b) spongy bone (c) epiphyses (d) cancellous bone (e) mainly chondrocytes
6. Which of the following connects bones to one another? (a) tendons (b) ligaments (c) osteoclasts (d) synovial membranes (e) smooth fibers
7. In endochondral bone formation (a) osteoclasts produce bone (b) joints connect fibers (c) the skeleton consists of cartilage (d) bones develop from cartilage templates (e) bones form in noncartilage connective tissue
8. All animals have (a) muscles (b) actin (c) bones (d) endoskeleton or exoskeleton (e) dermis
9. An energy storage compound that can be stockpiled in muscle cells for short-term use is (a) creatine phosphate (b) ADP (c) troponin (d) myosin (e) myoglobin
10. Myosin binds to actin, forming a cross bridge. What happens next? (a) acetylcholine is released (b) calcium ions stimulate process that leads to exposure of active sites (c) filaments slide past each other, and the muscle fiber shortens (d) myosin is activated (e) P_i is released, and the cross bridge flexes
11. Calcium ions are released from the sarcoplasmic reticulum. What happens next? (a) acetylcholine is released (b) active sites on the actin filaments are exposed (c) filaments slide past each other, and the muscle fiber shortens (d) myosin is activated (e) P_i is released, and the cross bridge flexes
12. When skeletal muscle is stimulated by a series of closely timed separate stimuli (a) it responds with a smooth, sustained contraction called *tetanus* (b) a simple twitch occurs (c) white fibers respond (d) red fibers respond (e) muscle tone occurs
13. Glycogen is (a) produced by actin (b) depleted within 1 second of strenuous activity (c) a form of long-term energy storage (d) synthesized when cross bridges form (e) depleted before creatine phosphate reserves are used
14. Slow fibers (a) are also called *white fibers* (b) do not depend on ATP (c) have few mitochondria (d) obtain most of their energy from glycolysis (e) are rich in myoglobin
15. Insect flight muscles (a) work best at low temperature (b) have a very high metabolic rate (c) do not create much lift (d) evolved after bird wings (e) are always attached directly to the wing and make up the bulk of the wing
16. Which of the following pairs of systems function together most closely? (a) integumentary and skeletal (b) integumentary and digestive (c) muscular and epithelial (d) skeletal and muscular (e) epithelial and muscular

CRITICAL THINKING

1. Compare the arthropod exoskeleton with the vertebrate endoskeleton. What are some advantages and some disadvantages of each type of skeleton?
2. What are some examples of hydrostatic support in plants?
3. Why is it important that a muscle be able to shift functions, sometimes acting as an agonist and at other times acting as an antagonist?
4. Summarize the functional relationship between skeletal and muscle tissues.

CHAPTER OUTLINE

- Information Flow Through the Nervous System
- Neurons and Glial Cells
- Transmitting Information Along the Neuron
- Neural Signaling Across Synapses
- Neural Integration
- Neural Circuits

An organism's ability to survive and to maintain homeostasis depends largely on how effectively it detects and responds to **stimuli**—changes in the environment. Stimuli within the body include internal signals such as hunger or lowered blood pressure. Stimuli from the outside world include changes in temperature, or light, an odor, or movement that may indicate the presence of a predator or of prey. In all animals except the sponges, responses to stimuli depend on *cell signaling* by networks of nerve cells, or **neurons.** These cells are specialized for transmitting **neural signals,** which are electrical signals and chemical messages.

In most animals, neurons and supporting cells are organized as a **nervous system** that, like a computer, takes in information, integrates it, and responds. Just how animals respond to stimuli depends on how their neurons are organized and connected to one another. A single neuron in the vertebrate brain may be functionally connected to thousands of other neurons. The endocrine system works with the nervous system to regulate many behaviors and physiological processes. The endocrine system generally provides relatively slow and long-lasting regulation, whereas the nervous system typically permits more rapid, but brief, responses.

Neurobiology is one of the most exciting areas of biological research. Many investigators are studying *neurotransmitters,* the chemical messengers used by neurons to signal other neurons, and the *receptors* that bind with the neurotransmitters. Another active area of research is the role of *glial cells* in the nervous system. These cells support and protect the neurons and have many regulatory functions. The glial cells shown in the micrograph are *astrocytes.* These glial cells provide glucose for neurons and also help regulate the composition of the extracellular fluid in the brain and spinal cord. Neurobiologists recently demonstrated that astrocytes induce and stabilize synapses (connections between neurons) in the brain. Although astrocytes can generate weak electrical signals, they communicate with one another and with neurons mainly with chemical sig-

nals. Based on recent findings, some researchers hypothesize that astrocytes may participate in information signaling in the brain by coordinating activity among neurons.

Astrocytes play a role in development by guiding neurons to appropriate locations in the body. Neurobiologists have shown that certain populations of astrocytes function as stem cells in the brain and spinal cord. These cells can give rise to neurons, additional astrocytes, and certain other glial cells. Taken out of their normal environment in the adult mouse brain, astrocytes can give rise to cells of all germ layers (that is, the embryonic tissue layers: ectoderm, mesoderm, and endoderm). Human astrocytes may some day be used to produce specific types of cells needed for treating various medical conditions. ■

INFORMATION FLOW THROUGH THE NERVOUS SYSTEM

Learning Objective

1 Trace the flow of information through the nervous system and describe the four processes involved in neural signaling: reception, transmission, integration, and action by effectors.

Thousands of stimuli constantly bombard an animal, and its survival depends on identifying these stimuli and responding appropriately. Appropriate response to a stimulus depends on communication by neurons, or **neural signaling.** In most animals, neural signaling involves four processes: reception, transmission, integration, and action by effectors (muscles or glands). **Reception,** the process of detecting a stimulus, is the job of the neurons and of specialized sensory receptors such as those in the skin, eyes, and ears. **Transmission** is the process of sending messages along a neuron, from one neuron to another or from a neuron to a muscle or gland. In vertebrates, a neural message is transmitted from a receptor to the **central nervous system (CNS),** which consists of the brain and spinal cord. Neurons that transmit information to the CNS are called **afferent** (meaning "to carry toward") **neurons,** or **sensory neurons.**

Afferent neurons generally transmit information to **interneurons,** or association neurons, in the CNS. Most neurons, perhaps 99%, are interneurons. Their function is to integrate input and output. **Integration** involves sorting and interpreting incoming sensory information and determining the appropriate response. Neural messages are transmitted from the CNS by **efferent** (meaning "to carry away") **neurons,** or **motor neurons,** to **effectors** (muscles and glands). The **action by effectors** is the actual response to the stimulus (Fig. 39-1). Sensory receptors and afferent and efferent neurons are part of the **peripheral nervous system (PNS).** In summary, information flows through the nervous system in the following sequence:

Reception by sensory receptor ⟶ transmission by afferent neuron ⟶ integration by interneurons in CNS ⟶ transmission by efferent neuron ⟶ action by effectors

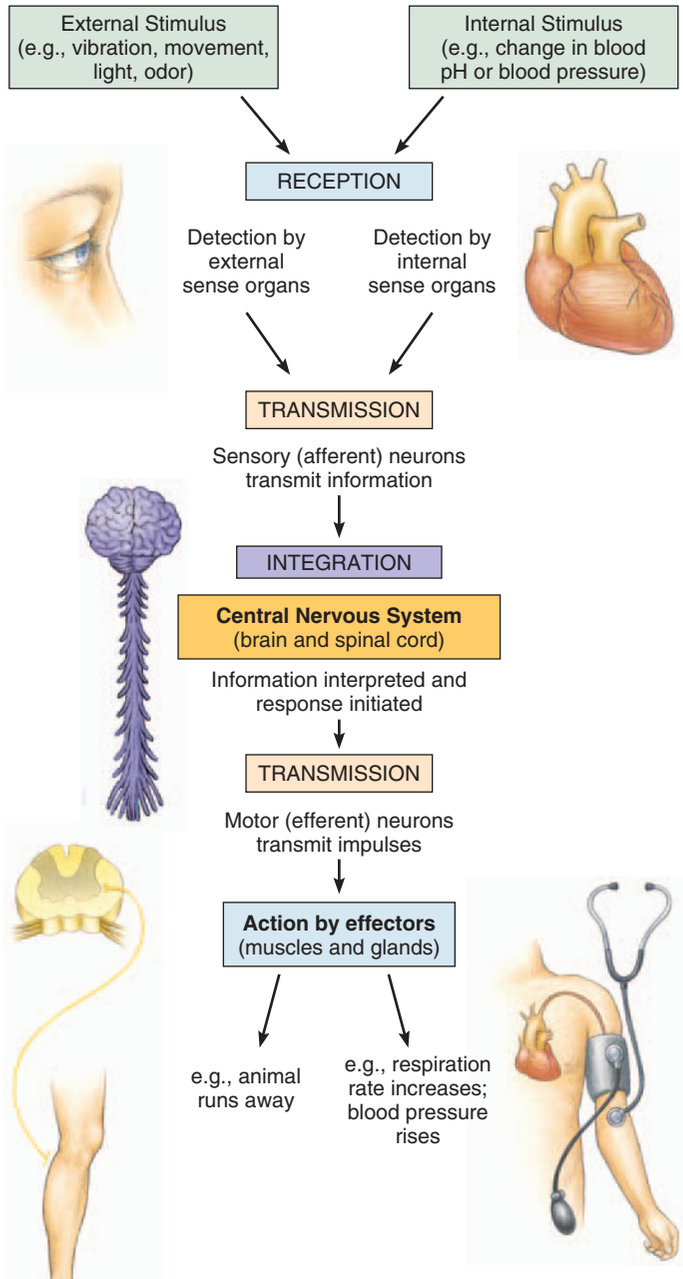

FIGURE **39-1** **Response to a stimulus.**
Whether a stimulus originates in the outside world or inside the body, information must be received, transmitted to the central nervous system, integrated, then transmitted to effectors, muscles or glands that carry out some action.

Review

- Imagine you are swimming and you suddenly spot a shark fin moving in your direction. What processes must take place within your nervous system before you can make your escape?
- What happens after neural signals are integrated in the CNS?

NEURONS AND GLIAL CELLS

Learning Objectives

2 Describe the functions of each type of vertebrate glial cell.

3 Describe the structure of a typical neuron, and give the function of each of its parts.

Two types of cells unique to the nervous system are neurons and glial cells. Neurons are specialized to receive and send information. Glial cells support and protect the neurons.

Glial cells provide metabolic and structural support

Glial cells collectively make up the **neuroglia** (literally, "nerve glue"). The human brain has 10 times as many glial cells as neurons. Vertebrates have three main types of glial cells in the CNS: microglia, astrocytes, and oligodendrocytes. **Microglia** are phagocytic cells that remove cell debris. They are found near blood vessels in the nervous system. Recent findings suggest that microglia can respond to signals from neurons and may be important in mediating responses in injury or disease.

Astrocytes are star-shaped glial cells that provide neurons with glucose (see chapter opening photograph). Astrocytes help regulate the composition of the extracellular fluid in the CNS by removing potassium ions and excess neurotransmitters. Some astrocytes position the ends of their long **processes** (cytoplasmic extensions) on blood vessels in the brain. In response, endothelial cells lining the blood vessels form *tight junctions* (Chapter 5) that prevent many substances in the blood from entering the brain tissue. This protective wall is the *blood–brain barrier.* Neurobiologists have recently shown that astrocytes are functionally connected throughout the brain and they communicate through gap junctions and with signaling molecules.

Oligodendrocytes are glial cells that envelop neurons in the CNS, forming insulating sheaths around them. This covering consists of **myelin,** a white, fatty substance found in the plasma membrane of the glial cell. Because it is an excellent electrical insulator, its presence speeds transmission of neural impulses. In the neurological disease **multiple sclerosis,** which affects more than 400,000 people in North America alone, patches of myelin deteriorate at irregular intervals along axons in the CNS and are replaced by scar tissue. This damage interferes with conduction of neural impulses, and the victim suffers loss of coordination, tremor, and partial or complete paralysis of parts of the body. Evidence suggests that multiple sclerosis is an *autoimmune disease,* in which the body attacks its own tissue, in this case glial cells (see Chapter 43 for a discussion of autoimmune diseases).

In vertebrates, **Schwann cells,** another type of glial cell, are located outside the CNS. Schwann cells form myelin sheaths around some axons (discussed later).

A typical neuron consists of a cell body, dendrites, and an axon

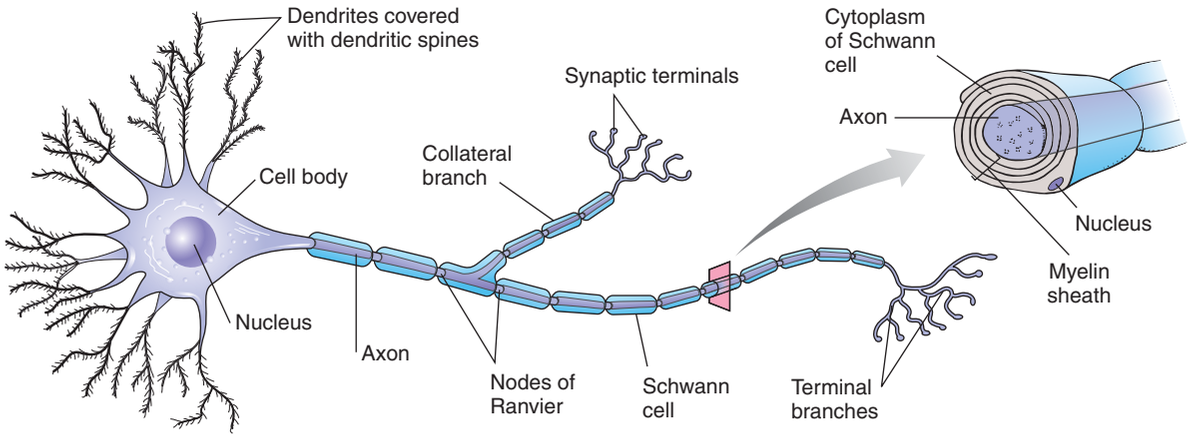
The **neuron** is highly specialized to receive stimuli and to produce and transmit electrical signals called **nerve impulses,** or **action potentials.** The neuron is distinguished from all other cells by its long processes. Examine the structure of a common type of neuron, the multipolar neuron in Figure 39-2.

The largest portion of the neuron, the **cell body,** contains the nucleus, the bulk of the cytoplasm, and most of the organelles. Typically, two types of cytoplasmic extensions project from the cell body of a multipolar neuron. Numerous dendrites extend from one end, and a long, single axon projects from the opposite end. **Dendrites** are typically short, highly branched processes specialized to receive stimuli and send signals to the cell body. The cell body integrates incoming signals.

Although microscopic in diameter, an **axon** may be 1 m (over 1 yd) or more in length and may divide, forming branches called **axon collaterals.** The axon conducts nerve impulses away from the cell body to another neuron, or to a muscle or gland. At its

FIGURE **39-2** **Structure of a multipolar neuron.**

The cell body contains most of the organelles. Many dendrites and a single axon extend from the cell body. Schwann cells form a myelin sheath around the axon.



end the axon divides, forming many **terminal branches** that end in **synaptic terminals.** The synaptic terminals release **neurotransmitters,** chemicals that transmit signals from one neuron to another, or from neuron to effector. The junction between a synaptic terminal and another neuron (or effector) is called a **synapse.** Typically, a small space exists between the membranes of these two cells.

In vertebrates, the axons of many neurons outside the CNS are surrounded by a series of Schwann cells that form an insulating covering, the **myelin sheath.** Gaps in the myelin sheath, called **nodes of Ranvier,** occur between successive Schwann cells. At these points the axon is not insulated with myelin. Axons more than 2 µm in diameter have myelin sheaths and are described as *myelinated.* Those of smaller diameter are generally unmyelinated.

A **nerve** consists of hundreds or even thousands of axons wrapped together in connective tissue (Fig. 39-3). We can compare a nerve to a telephone cable. The individual axons correspond to the wires that run through the cable, and the sheaths and connective tissue coverings correspond to the insulation. Within the CNS, bundles of axons are called **tracts** or **pathways** rather than nerves. Outside the CNS, the cell bodies of neurons are usually grouped together in masses called **ganglia** (sing., *ganglion*). Inside the CNS, collections of cell bodies are generally called *nuclei* rather than *ganglia.*

Review

- What are the functions of (a) astrocytes and (b) microglia?
- What are the functions of (a) dendrites (b) synaptic terminals (c) the myelin sheath?
- How is a neuron different from a nerve?

TRANSMITTING INFORMATION ALONG THE NEURON

Learning Objectives

4 Explain how the neuron develops and maintains a resting potential.
5 Compare a graded potential with an action potential, describing the production and transmission of each.
6 Contrast continuous conduction with saltatory conduction.

Most animal cells have a difference in electrical charge across the plasma membrane—a more negative electrical charge inside the cell compared with the electrical charge of the extracellular fluid outside. The plasma membrane is said to be electrically **polarized,** meaning that one side, or pole, has a different charge from the other side. When electrical charges are separated in this way, a potential energy difference exists across the membrane. This difference in electrical charge across the plasma membrane gives rise to an electrical voltage gradient. The voltage measured across the plasma membrane is called the **membrane potential.** If the charges are permitted to come together, they have the ability to do work. Thus the cell can be thought of as a biological battery. In excitable cells, such as neurons and muscle cells, the membrane potential can change rapidly, and such changes can transmit signals to other cells.

The neuron membrane has a resting potential

The membrane potential in a resting (not excited) neuron or muscle cell is its **resting potential.** The resting potential is generally expressed in units called *millivolts* (mV). (A millivolt equals one thousandth of a volt.) Voltage is the force that causes charged particles to flow between two points. Like other cells that can produce electrical signals, the neuron has a resting potential of

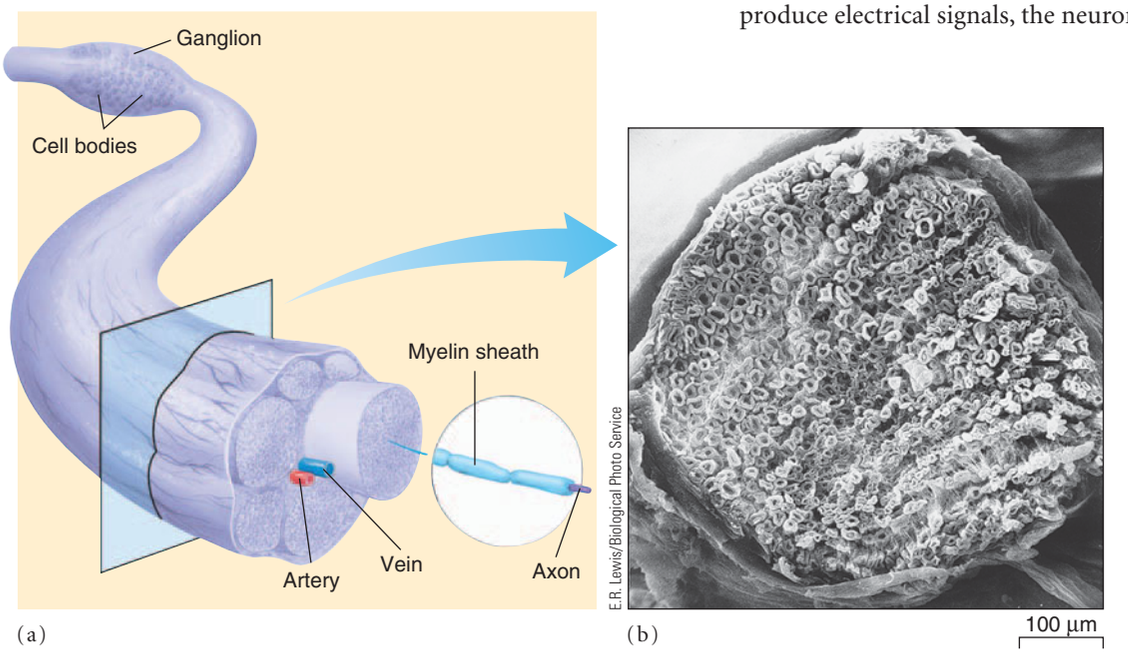

FIGURE **39-3**

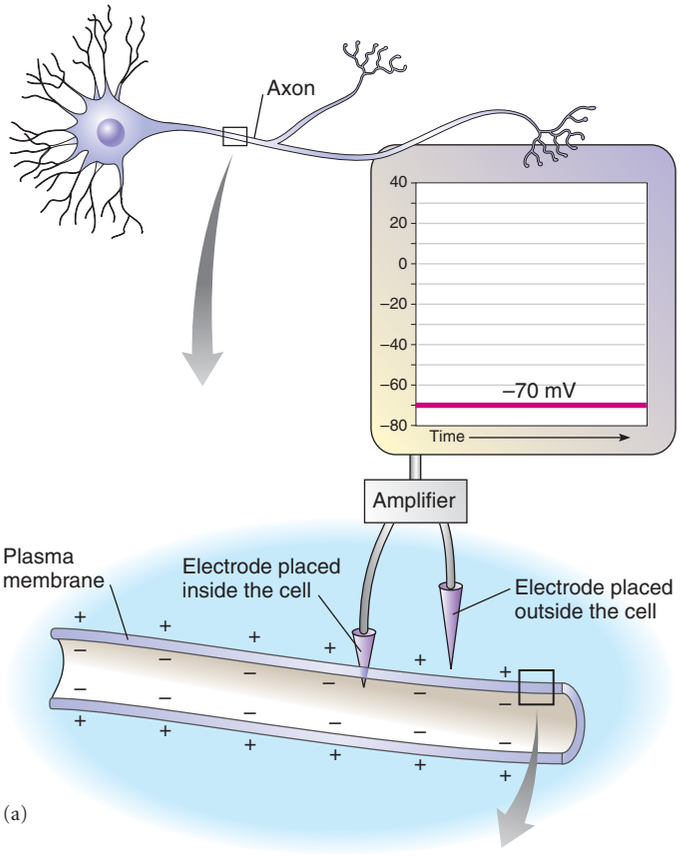
Structure of a nerve.

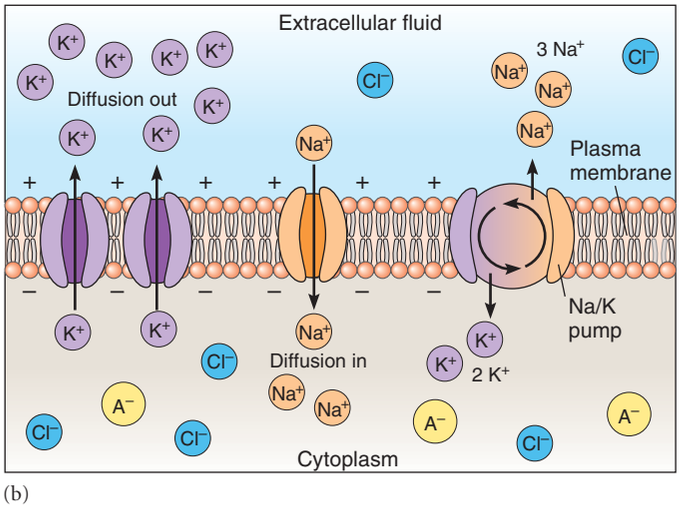
(a) A nerve consists of bundles of axons held together by connective tissue. The cell bodies belonging to the axons of a nerve are grouped together in a ganglion. **(b)** SEM showing a cross section through a myelinated afferent nerve of a bullfrog.

about 70 mV. By convention this is expressed as −70 mV because the cytosol close to the plasma membrane is negatively charged relative to the extracellular fluid (Fig. 39-4).

Biologists can measure the potential across the membrane by placing one electrode inside the cell and a second electrode outside the cell, and connecting them through a very sensitive voltmeter or oscilloscope. If you place both electrodes on the outside surface of the neuron, no potential difference between them is registered. (All points on the same side of the membrane have the same charge.) However, once one of the electrodes penetrates the cell, the voltage changes from zero to approximately −70 mV.



(a)



(b)

Two main factors determine the magnitude of the membrane potential: (1) differences in the concentrations of specific ions inside the cell compared with the extracellular fluid, and (2) selective permeability of the plasma membrane to these ions. The distribution of ions inside neurons and in the extracellular fluid surrounding them is like that of most other cells in the body. The potassium ion (K^+) concentration is about 10 times greater inside than outside the cell. In contrast, the sodium ion (Na^+) concentration is about 10 times greater outside than inside. This asymmetric distribution of ions across the plasma membrane at rest is brought about by the action of selective ion channels and ion pumps. In vertebrate neurons (and skeletal muscle fibers), the resting membrane potential depends mainly on the diffusion of ions down their concentration gradients.

Ions cross the plasma membrane by diffusion through ion channels that are formed by membrane proteins. Net movement of ions occurs from an area of higher concentration of that ion to one of lower concentration (see discussion of diffusion in Chapter 5). Typically, these channels allow only specific types of ions to pass. Neurons have three types of ion channels: *passive ion channels, voltage-activated channels,* and *chemically activated ion channels.* **Passive ion channels** permit the passage of specific ions such as Na^+, K^+, Cl^-, and Ca^{2+} (see Fig. 39-4). Unlike voltage-activated and chemically activated ion channels, passive ion channels are not controlled by gates.

Potassium channels are the most common type of passive ion channel in the plasma membrane, and cells are more permeable to potassium than to other ions. In fact, in the resting neuron, the plasma membrane is up to 100 times more permeable to K^+ than to Na^+. Sodium ions pumped out of the neuron cannot easily pass back into the cell, but K^+ pumped into the neuron easily diffuse out.

Potassium ions leak out through passive ion channels following their concentration gradient. As these positively charged ions diffuse out of the neuron, they increase the positive charge in the extracellular fluid outside the cell relative to the charge inside the cell. The resulting change in the electrical gradient across the membrane influences the flow of ions. This electrical gradient forces some of the positively charged potassium ions back into the cell.

FIGURE **39-4** **Resting potential.**

(a) As shown in this segment of an axon of a resting (nonconducting) neuron, the axon is negatively charged compared with the surrounding extracellular fluid. The difference in electrical charge across the plasma membrane is measured by placing an electrode just inside the neuron and a second electrode in the extracellular fluid just outside the plasma membrane. **(b)** The membrane is less permeable to sodium ions than to potassium ions. Potassium ions diffuse out along their concentration gradient and are largely responsible for the voltage across the membrane. Sodium-potassium pumps in the plasma membrane actively pump sodium ions out of the cell and pump potassium ions in. The plasma membrane is permeable to negatively charged chloride ions, and they contribute slightly to the negative charge. Large anions (A^-) such as proteins also contribute to the negative charge.

The membrane potential at which the flux (flow) of K^+ inward (due to the electrical gradient) equals the flux of K^+ outward (because of the concentration gradient) is the **equilibrium potential** for K^+. The equilibrium potential for any particular ion is a steady state in which opposing chemical and electrical fluxes are equal and there is no net movement of the ion. The equilibrium potential for K^+ in the typical neuron is -80 mV. The equilibrium potential for Na^+ is $+40$ mV; it differs from the equilibrium potential of K^+ because of the difference in concentration of Na^+ across the membrane (concentration is high outside and low inside the cell). Because the membrane is much more permeable to K^+ than to Na^+, the resting potential of the neuron is closer to the potassium equilibrium potential than to the equilibrium potential of sodium. (Remember, the resting potential of the neuron is about -70 mV.)

Although the resting potential is primarily established by K^+, and less so by Na^+, chloride ions also contribute slightly because the plasma membrane is permeable to negatively charged chloride ions. These ions accumulate in the cytosol close to the plasma membrane. Also contributing to the negative charge in the cytosol are negative charges on large molecules such as proteins. These large anions cannot cross the plasma membrane.

Ion pumping maintains the gradients that determine the resting potential. The neuron plasma membrane has very efficient **sodium-potassium pumps** that actively transport sodium ions out of the cell and potassium ions into the cell (see Fig. 5-15). Both sodium and potassium ions are pumped against their concentration and electrical gradients, and these pumps require ATP. For every three sodium ions pumped out of the cell, two potassium ions are pumped in. Thus, more positive ions are pumped out than in. The sodium-potassium pumps maintain a higher concentration of K^+ inside the cell than outside, and a higher concentration of Na^+ outside than inside.

In summary, the development of the resting potential depends mainly on the diffusion of K^+ out of the cell. However, once the neuron reaches a steady state, Na^+ diffusion into the cell is greater than K^+ diffusion out of the cell. This situation is offset by the sodium-potassium pumps that pump three Na^+ out of the cell for every two K^+ pumped in.

Graded local signals vary in magnitude

Neurons are excitable cells. They can respond to stimuli and convert stimuli into nerve impulses. An electrical, chemical, or mechanical stimulus may alter the resting potential by increasing the membrane's permeability to sodium ions.

When a stimulus causes the membrane potential to become less negative (closer to zero) than the resting potential, the membrane is **depolarized.** Because depolarization brings a neuron closer to transmitting a neural impulse, it is described as *excitatory.* In contrast, when the membrane potential becomes more negative than the resting potential, the membrane is **hyperpolarized.** Hyperpolarization is *inhibitory;* it decreases the ability of the neuron to generate a neural impulse.

A stimulus may change the potential in a relatively small region of the plasma membrane. Such a **graded potential** is a local response that functions as a signal only over a very short distance, because it fades out within a few millimeters of its point of origin. A graded potential varies in magnitude; that is, the potential charge varies depending on the strength of the stimulus applied.

An action potential is generated by an influx of Na^+ and an efflux of K^+

If a stimulus is strong enough, a neuron fires a nerve impulse, or **action potential.** An action potential is an electrical excitation that travels rapidly down the axon into the synaptic terminals. All cells can generate graded potentials, but only neurons, muscle cells, and a few other cell types (certain cells of the endocrine and immune systems) can generate action potentials.

In a series of experiments in the 1940s, pioneering English researchers Alan Hodgkin and Andrew Huxley inserted electrodes into large axons found in squids. By measuring voltage changes as they varied ion concentrations, they showed that passage of Na^+ ions into the neuron and K^+ ions out of the neuron resulted in an action potential. In 1963 Hodgkin and Huxley received the Nobel Prize in Medicine for this research.

We now know that specific **voltage-activated ion channels** (also called **voltage-gated ion channels**) in the plasma membrane of the axon and cell body are regulated by changes in voltage. These channels have been studied using the **patch clamp technique** (see Fig. 5-16). Using this technique, biologists can measure currents across a very small segment of the plasma membrane rather than across the entire membrane. The patch of membrane measured is so small that it may contain a single channel.

In investigating membrane channels and how they function, biologists have used certain toxins that affect the nervous system. For example, the poison tetrodotoxin (TTX) binds to voltage-activated sodium channels, blocking the passage of Na^+. Using TTX and other toxins, researchers were able to identify the channel protein. TTX was first isolated from the Japanese pufferfish, which is eaten as a delicacy (Fig. 39-5). In small amounts TTX tingles the taste buds, but in a larger dose it can

FIGURE **39-5** **Japanese pufferfish.**
A poison, tetrodotoxin, isolated from this fish (*Fugu rubripes*) binds to voltage-activated sodium ion channels, allowing neurobiologists to study them.

Jeffrey L. Rotman/Peter Arnold, Inc.

prevent breathing. (The Japanese government operates a certification program for pufferfish chefs!)

Investigators have established that voltage-activated ion channels have charged regions that act as gates. Voltage-activated Na^+ channels have two gates—an *activation gate* and an *inactivation gate* (see Fig. 39-6a). Voltage-activated K^+ channels have a single gate (see Fig. 39-6b).

An action potential is generated when the voltage reaches a certain critical point known as the **threshold level.** The membrane of most neurons can depolarize by about 15 mV, that is, to a potential of about −55 mV, without initiating an action potential. However, when depolarization is greater than −55 mV, the threshold level is reached, and an action potential is generated. The neuron membrane quickly reaches zero potential and even **overshoots** to +35 mV or more as a momentary reversal in polarity takes place. The sharp rise and fall of the action potential is called a *spike.* Figure 39-7 illustrates an action potential recorded by placing one electrode inside an axon and one just outside.

At resting potentials, Na^+ activation gates are closed, and Na^+ cannot pass through them into the neuron (Fig. 39-7b). When the voltage reaches the threshold level, the protein making up the channel changes shape, opening the activation gate. When the gate opens, Na^+ flow through the channel and the inside of the neuron becomes positively charged relative to the extracellular fluid outside the plasma membrane; an action potential may be generated. Inactivation gates that are open in the resting neuron close slowly in response to depolarization. Sodium ions can pass through the channel only during the brief period when both activation and inactivation gates are open.

The generation of an action potential depends on a **positive feedback mechanism.** (Recall from Chapter 37 that in a positive feedback mechanism, a change in some condition triggers a response that intensifies the change.) As just discussed, when a neuron is depolarized, voltage-activated sodium channels open, increasing the membrane permeability to Na^+. Sodium ions diffuse into the cell, moving from an area of higher concentration to an area of lower concentration. As Na^+ flows into the cell, the cytosol becomes positively charged relative to the extracellular fluid. This charge further depolarizes the neuron so that more voltage-gated sodium channels open, further increasing membrane permeability to sodium.

When, after a certain period, inactivation sodium gates close, the membrane again becomes impermeable to sodium. This inactivation begins the process of **repolarization,** during which the membrane potential returns to its resting level. Voltage-gated potassium ion channels slowly open in response to depolarization. When potassium ion channels open, potassium leaks out of the neuron (Fig. 39-7b, ③). This decrease in intracellular K^+ returns the interior of the membrane to its relatively negative state, repolarizing the membrane. Potassium channels remain open until the resting potential has been restored (Fig. 39-7b, ④). As a wave of depolarization moves down the membrane of the neuron, the normal polarized state is quickly re-established behind it. The entire process—depolarization and then repolarization—can take place in less than 1 millisecond.

During the millisecond or so in which it is depolarized, the axon membrane is in an **absolute refractory period:** It cannot transmit another action potential no matter how great a stimulus is applied. This is because the voltage-activated Na^+ channels are inactivated. Until their gates are reset, they cannot be reopened. When enough Na^+ channel gates have been reset, the neuron enters a **relative refractory period** that lasts for a few more milliseconds. During this period, the axon can transmit impulses, but the threshold is higher (more negative). Even with the limits imposed by their refractory periods, most neurons can transmit several hundred impulses per second.

In summary, neural action proceeds as follows:

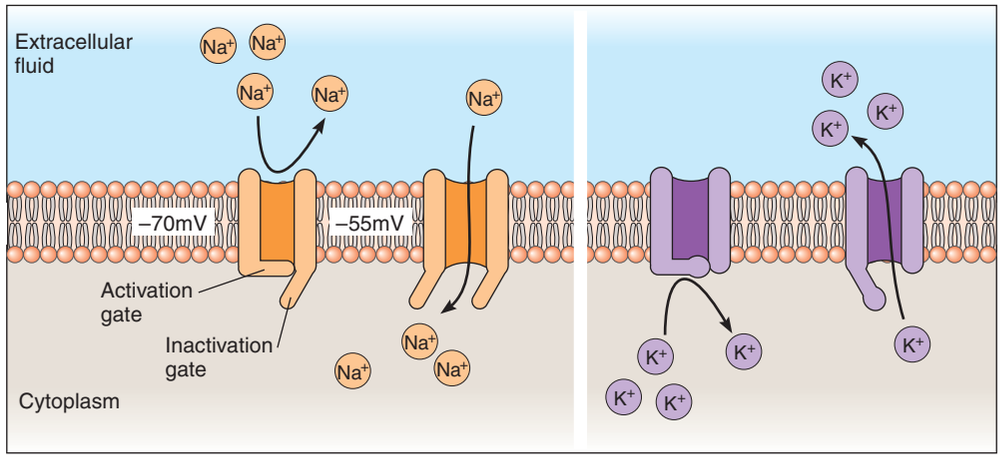
Resting state ⟶ stimulus causes depolarization ⟶ action potential ⟶ repolarization and return to resting state

Local anesthetics such as procaine (novocaine), lidocaine (Xylocaine), and also cocaine, bind to voltage-activated sodium ion channels and block them. The channels are not able to open in response to depolarization, and the neuron cannot transmit an impulse through the anesthetized region. Signals do not reach the brain, so pain is not experienced.

FIGURE **39-6**

Voltage-activated ion channels.

(a) In the resting state, voltage-activated Na^+ channels are closed. When the voltage reaches threshold level, activation gates open, allowing Na^+ to pass into the cell. After a certain amount of time elapses, activation gates close, blocking the channels. Inactivation gates are open when a neuron is in the resting state; they close slowly in response to depolarization. The ion channel is open only during the brief period when both activation and inactivation gates are open. **(b)** Potassium channels have activation gates that open slowly in response to depolarization. These channels have no inactivation gates.



(a) Sodium channels (b) Potassium channels

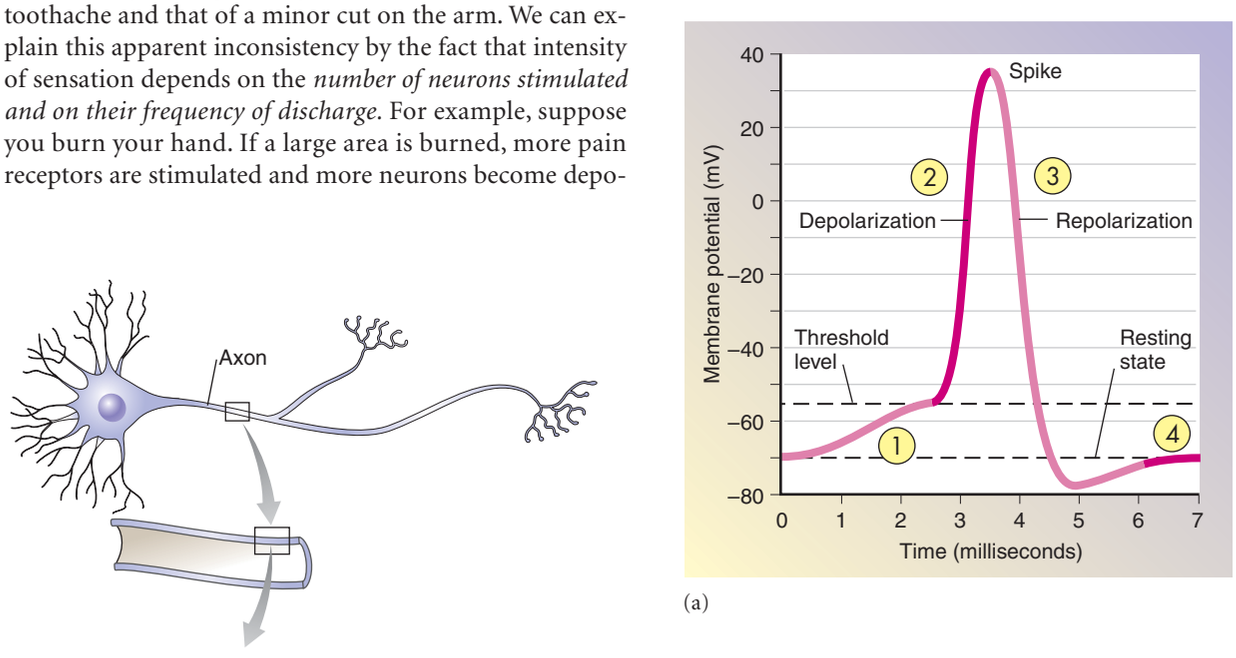
The action potential is an all-or-none response

Any stimulus too weak to depolarize the plasma membrane to threshold level cannot fire the neuron. It merely sets up a local signal that fades and dies within a few millimeters from the point of stimulus. Only a stimulus strong enough to depolarize the membrane to its critical threshold level results in transmission of an impulse along the axon. An action potential is an **all-or-none response,** because either it occurs or it does not. No variation exists in the strength of a single impulse.

If the all-or-none law is valid, how can we explain differences in the levels of intensity of sensations? After all, we have no difficulty distinguishing between the pain of a severe toothache and that of a minor cut on the arm. We can explain this apparent inconsistency by the fact that intensity of sensation depends on the *number of neurons stimulated and on their frequency of discharge.* For example, suppose you burn your hand. If a large area is burned, more pain receptors are stimulated and more neurons become depolarized. Also, each neuron transmits more action potentials per unit of time.

An action potential is self-propagating

Once begun, the action potential is self-propagating. During depolarization, the affected area of the membrane is more positive relative to adjacent regions where the membrane is still at resting potential. The difference in potentials between active and resting membrane regions causes ions to flow between them (an electrical current). The flow of Na^+ into the adjacent region induces the opening of voltage-activated sodium channels in one



① Resting state. Voltage-activated Na^+ and K^+ channels are closed.

② Depolarization. Voltage-activated Na^+ channels open. Na^+ ions enter cell; inside of neuron becomes positive relative to outside.

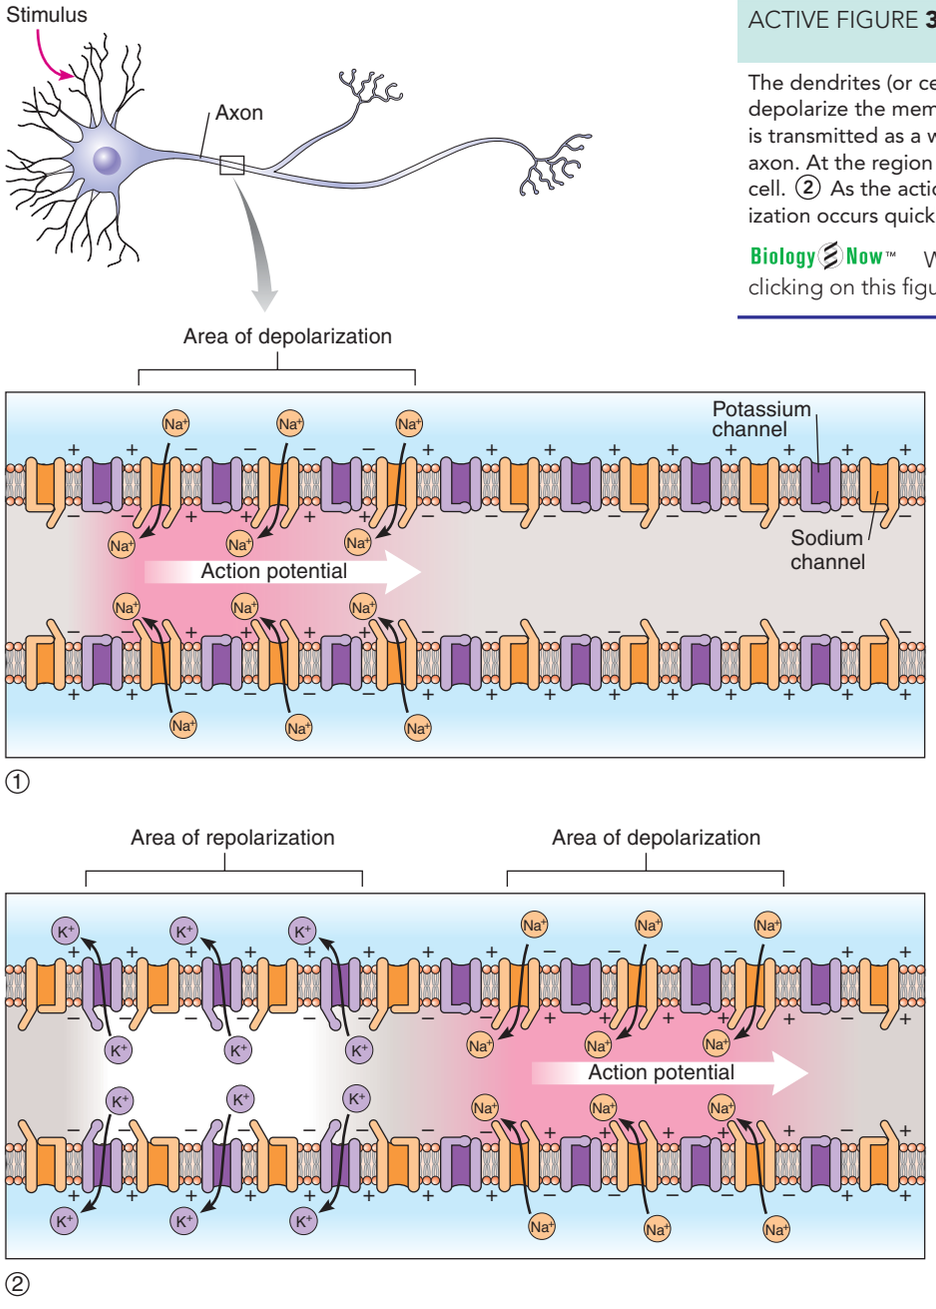
③ Repolarization. Voltage-activated Na^+ channels close; K^+ channels are open; K^+ moves out of cell, restoring negative charge to inside of cell.

④ Return to resting state. Voltage-activated Na^+ and K^+ channels close.

ACTIVE FIGURE **39-7** **Action of voltage-activated ion channels.**

(a) Action potential. When the axon depolarizes to about −55 mV, an action potential is generated. (The numerical values vary for different nerve cells.) **(b)** The state of ion channels in the plasma membrane determines the state of the neuron. ① Resting state. ② Depolarization. At threshold, voltage-activated Na^+ channels open and Na^+ enters the neuron, causing further depolarization. An action potential is generated. K^+ channels slowly begin to open. ③ Repolarization. ④ Resting conditions are restored.

BiologyNow™ Learn more about **the action potential** by clicking on this figure on your BiologyNow CD-ROM.



ACTIVE FIGURE **39-8** **Transmission of an action potential along the axon.**

The dendrites (or cell body) of a neuron are stimulated enough to depolarize the membrane to its firing level. ① An action potential is transmitted as a wave of depolarization that travels down the axon. At the region of depolarization, sodium ions diffuse into the cell. ② As the action potential progresses along the axon, repolarization occurs quickly behind it.

BiologyNow™ Watch **transmission of an action potential** by clicking on this figure on your BiologyNow CD-ROM.

area of the membrane (Fig. 39-8). This action causes the next adjacent voltage-activated ion channels to open, permitting sodium ions to enter in that area, and the process is repeated like a chain reaction until the end of the axon is reached. Thus an action potential is a **wave of depolarization** that travels down the length of the axon. It is self-propagating and moves at a velocity that is constant for each type of neuron. Conduction of a neural impulse is sometimes compared with burning a trail of gunpowder. Once the gunpowder is ignited at one end of the trail, the flame moves steadily to the other end by igniting the powder particles ahead of it.

Compared with the flow of electrons in electrical wiring or the speed of light, a nerve impulse travels rather slowly. Most axons transmit impulses at about 1 to 10 m per second. The smooth, progressive impulse transmission just described, called **continuous conduction,** occurs in unmyelinated neurons. In unmyelinated axons, the speed of transmission is proportional to the diameter of the axon. Axons with larger diameters transmit faster than do those with smaller diameters, because an axon with a large diameter presents less internal resistance to the ions flowing along its length. Squids and certain other invertebrates have giant axons, up to 1 mm in diameter, that let them respond rapidly when escaping from predators.

Myelinated neurons transmit impulses rapidly

In vertebrates, another strategy has evolved that speeds transmission—myelinated neurons. Myelin acts as an effective electrical insulator around the axon except at the nodes of Ranvier, which are not myelinated. The axon plasma membrane makes direct contact with the surrounding extracellular fluid only at the nodes, and voltage-activated sodium and potassium ion channels are concentrated there. Ion movement across the membrane occurs only at the nodes. The ion activity at the active node results in diffusion of ions along the axon that depolarize the next node; the action potential appears to jump from one node of Ranvier to the next (Fig. 39-9). This type of impulse transmission is known as **saltatory conduction** (from the Latin word *saltus,* which means "to leap").

In myelinated neurons, the distance between successive nodes of Ranvier affects speed of transmission: When nodes are farther apart, less of the axon must depolarize, and the axon conducts the impulse faster. Using saltatory conduction, a myelinated axon can conduct an impulse up to 50 times faster than the fastest unmyelinated axon. Saltatory conduction has another advantage over continuous conduction: It requires less energy. Ions move across the plasma membrane only at the nodes, so fewer sodium and potassium ions are displaced. As a result, the

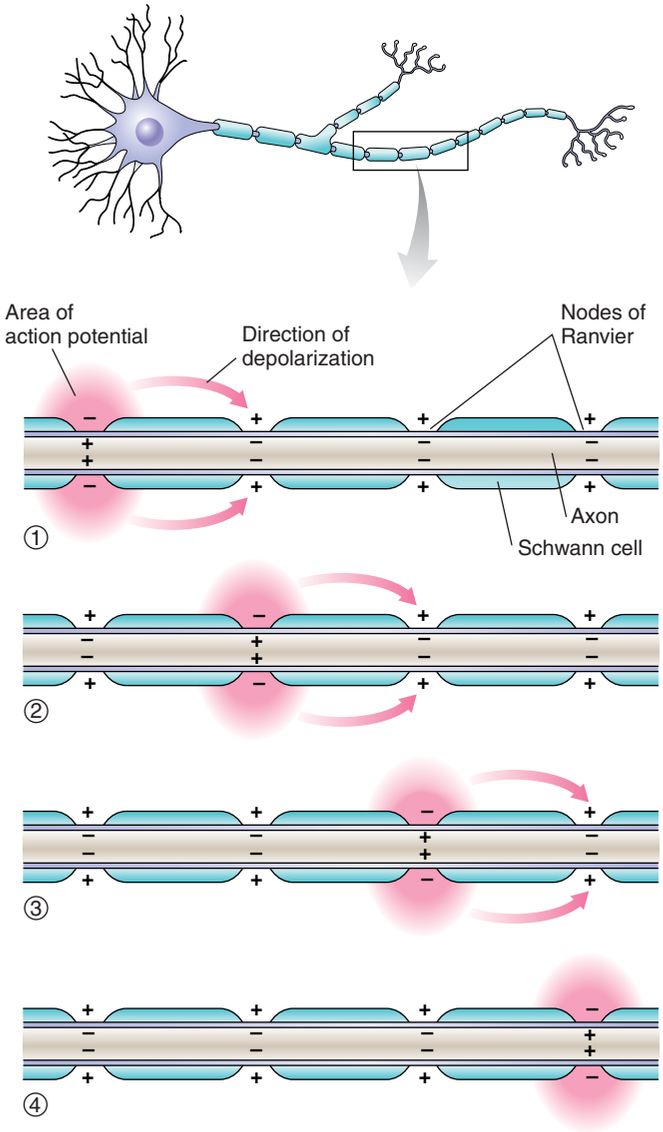


FIGURE **39-9** **Saltatory conduction.**
In a myelinated axon, action potentials leap from one node of Ranvier to the next.

sodium-potassium pumps do not expend as much ATP to re-establish resting conditions each time an impulse is conducted.

Review

- How do ion channels and sodium-potassium pumps contribute to the resting potential?
- What sequence of events occurs when threshold level is exceeded in a neuron?
- How do voltage-activated ion channels work?
- How does an action potential differ from a graded potential?
- What are the benefits of saltatory conduction compared with continuous conduction?

NEURAL SIGNALING ACROSS SYNAPSES

Learning Objectives

7 Describe the actions of the neurotransmitters identified in the chapter.
8 Trace the events that take place in synaptic transmission; draw diagrams to support your description.
9 Compare excitatory and inhibitory signals and their effects.

A **synapse** is a junction between two neurons or between a neuron and an effector, such as between a neuron and a muscle cell. A neuron that *terminates* at a specific synapse is called a **presynaptic neuron,** whereas a neuron that *begins* at that synapse is a **postsynaptic neuron.** Note that these terms are relative to a specific synapse. A neuron that is postsynaptic with respect to one synapse may be presynaptic to the next synapse in the sequence.

Signals across synapses can be electrical or chemical

Based on how presynaptic and postsynaptic neurons communicate, two types of synapses have been identified: electrical synapses and chemical synapses. In **electrical synapses,** the presynaptic and postsynaptic neurons occur very close together (within 2 nm of one another) and form *gap junctions* (see Chapter 5). The interiors of the two cells are physically connected by a protein channel. Electrical synapses let ions pass from one cell to another, permitting an impulse to be directly and rapidly transmitted from a presynaptic to a postsynaptic neuron. The escape responses of many animals involve electrical synapses. For example, the "tail-flick" escape response of the crayfish involves giant neurons in the nerve cord that form electrical synapses with large motor neurons. The motor neurons signal muscles in the abdomen to contract.

The majority of synapses are **chemical synapses.** Presynaptic and postsynaptic neurons are separated by a space, the **synaptic cleft,** about 20 nm wide (less than one millionth of an inch). Because depolarization is a property of the plasma membrane, when an action potential reaches the end of the axon it cannot jump the gap. The electrical signal must be converted into a chemical one. Neurotransmitters are the chemical messengers that conduct the neural signal across the synapse and bind to chemically activated ion channels in the membrane of the postsynaptic neuron. When a postsynaptic neuron reaches threshold depolarization, it transmits an action potential.

Neurons use neurotransmitters to signal other cells

More than 60 different chemical compounds are now known or suspected to function as neurotransmitters, chemical messengers used by neurons to signal other neurons or to signal muscle or gland cells (Table 39-1).

TABLE **39-1** Selected Neurotransmitters

Substance	Source	Actions
Acetylcholine	Some neurons in the brain and certain neurons in the autonomic nervous system; motor neurons	Excitatory effect on skeletal muscle; inhibitory effect on cardiac muscle
Biogenic Amines		
Norepinephrine	Neurons in both the central and autonomic nervous systems	Excitatory or inhibitory effect; may be involved in dreaming during REM sleep; level in brain affects mood
Dopamine	Central nervous system (CNS)	Helps maintain balance between inhibition and excitation of neurons; important in motor functions; level in brain affects mood
Serotonin (5-hydroxytryptamine, 5-HT)	CNS	Excitatory effect on pathways that control muscle action; inhibitory effect on pathways involved in sensations; also functions in regulation of food intake and affects mood
Amino Acids		
Glutamate	Brain (major excitatory neurotransmitter in the brain)	Functions in memory and learning; *In vertebrates:* excitatory effect on pathways in the brain; *In invertebrates:* excitatory effect at neuromuscular junctions
Aspartate	CNS	Excitatory effect on CNS pathways; functions in memory and learning
Glycine	Inhibitory interneurons in CNS	Inhibitory effect on CNS pathways
Gamma-aminobutyric acid (GABA)	Inhibitory interneurons in CNS	*In vertebrates;* inhibitory effect on CNS pathways *In invertebrates;* inhibitory effect at neuromuscular junctions
Neuropeptides		
Endorphins (opioids)	Brain	Pain regulation
Enkephalins (opioids)	Brain	Pain regulation
Substance P	Sensory neurons	Pain regulation
Gaseous Neurotransmitter		
Nitric oxide (NO)	Most neurons?	Retrograde messenger; transmits signals in opposite direction from other neurotransmitters, i.e., from postsynaptic to presynaptic neuron

Acetylcholine is a low-molecular-weight neurotransmitter that is released from motor neurons and triggers muscle contraction. Acetylcholine is also released by some neurons in the brain and in the autonomic nervous system (Focus on Alzheimer's disease; also see Chapter 40). Cells that release this neurotransmitter are called **cholinergic neurons.**

Neurons that release **norepinephrine** are called **adrenergic neurons.** Norepinephrine and the neurotransmitter **dopamine** are **catecholamines.** The catecholamines and the neurotransmitter **serotonin** belong to a class of compounds called **biogenic amines.** Biogenic amines affect mood, and their imbalance has been linked to several disorders, including major depression, attention deficit disorder (ADD), and schizophrenia.

The major excitatory neurotransmitter in the brain is the amino acid **glutamate.** One type of glutamate receptor is the target of several mind-altering drugs, including phencyclidine ("angel dust").

The amino acid **glycine** and a modified amino acid, **gamma-aminobutyric acid (GABA),** are neurotransmitters that inhibit neurons in the brain and spinal cord. Drugs that reduce anxiety enhance the actions of GABA by permitting lower concentrations of GABA to open Cl^- channels. These drugs include benzodiazepines such as diazepam (Valium) and alprazolam (Xanax), and barbiturates, such as phenobarbital.

Opiate drugs, for example, morphine and codeine, are powerful analgesics, drugs that relieve pain without causing loss of consciousness. The body has its own endogenous opioids **enkephalin** and **endorphins,** such as **beta-endorphin.** These neuropeptides bind to opioid receptors (the same receptors to which opiate drugs bind) and block pain signals. Opioids modulate the effect of other neurotransmitters. (Chapter 41 discusses pain perception.)

Much recent research has focused on the signaling molecule **nitric oxide (NO).** NO is a gas that acts as a retrograde messenger at some synapses. It transmits information from the postsynaptic neuron to the presynaptic neuron, the opposite direction of other neurotransmitters.

Neurotransmitters bind with receptors on postsynaptic cells

Neurotransmitters are stored in the synaptic terminals within small membrane-bounded sacs called **synaptic vesicles** (Fig. 39-10a). Each time an action potential reaches a synaptic terminal, voltage-gated calcium channels open. Calcium ions from the extracellular fluid then flow into the synaptic terminal. The Ca^{2+} ions cause synaptic vesicles to fuse with the presynaptic membrane and release neurotransmitter molecules into the synaptic cleft by exocytosis (Fig. 39-10b).

Neurotransmitter molecules diffuse across the synaptic cleft and combine with specific receptors on the dendrites or cell bodies of postsynaptic neurons (or on the plasma membranes of

KEY CONCEPT: At most synapses the action potential cannot jump across the synaptic cleft between the two neurons. The problem is solved by chemical signaling across synapses.

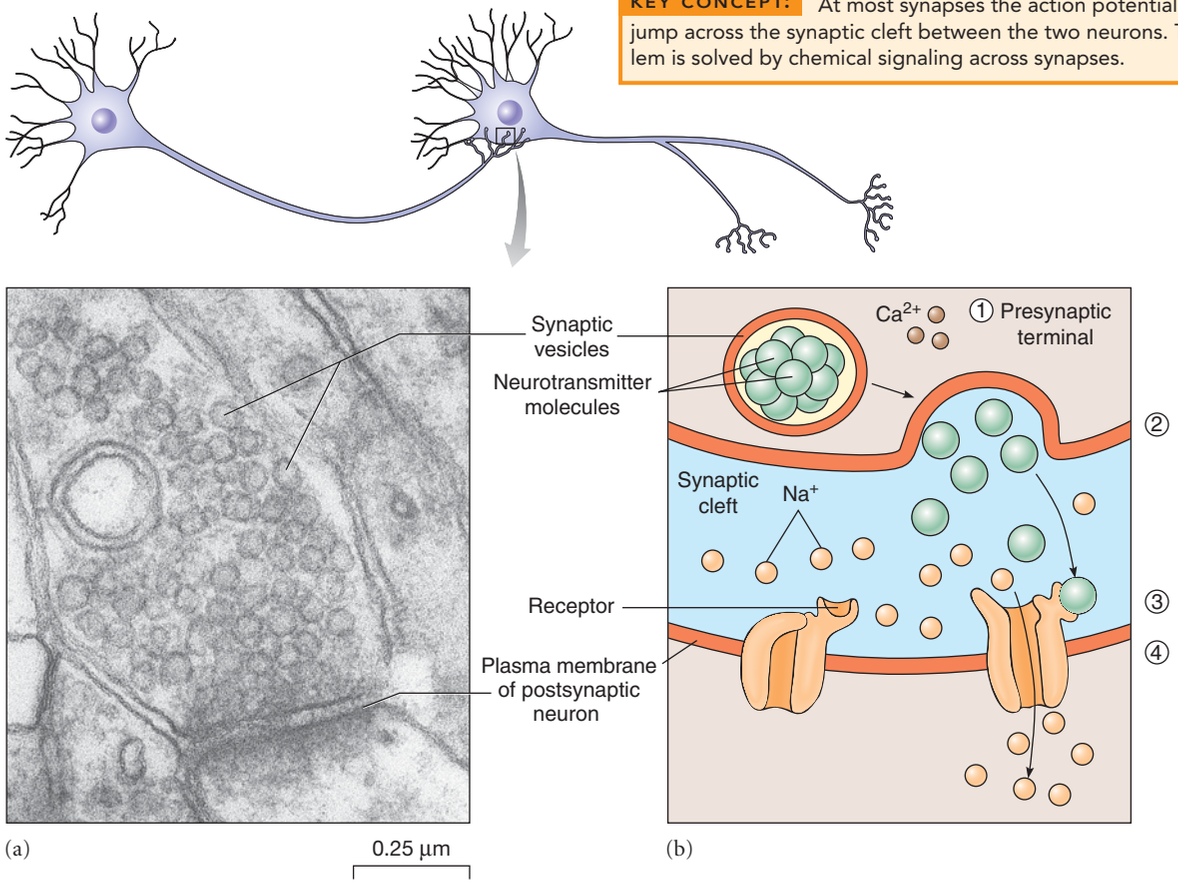

FIGURE **39-10** **Synaptic transmission.**

(a) The TEM shows synaptic terminals filled with synaptic vesicles. **(b)** How a neural impulse is transmitted across a synapse. ① When an action potential reaches the synaptic terminals at the end of a presynaptic neuron, calcium ions enter the synaptic terminal from the extracellular fluid. ② The calcium ions cause the synaptic vesicles to fuse with the plasma membrane and release a neurotransmitter into the synaptic cleft. ③ The neurotransmitter diffuses across the synaptic cleft and combines with receptors in the membrane of the postsynaptic neuron. ④ The receptors cause ion channels to open or close, resulting in either depolarization or hyperpolarization. When depolarization reaches threshold level, an action potential is generated in the postsynaptic neuron.

effector cells). Many neurotransmitter receptors are chemically activated ion channels known as **ligand-gated ion channels.** When the neurotransmitter, the **ligand,** binds with the receptor, the ion channel opens. The acetylcholine receptor, for example, is an ion channel that permits the passage of Na^+ and K^+.

Some neurotransmitters, such as serotonin, operate by a different mechanism. They work indirectly through a **second messenger.** Binding of the neurotransmitter with a receptor activates a **G protein.** The G protein then activates an enzyme, such as adenylyl cyclase, in the postsynaptic membrane. Adenylyl cyclase converts ATP to **cyclic AMP (cAMP),** which acts as a second messenger (see Fig. 3-25 and Chapters 5 and 47). Cyclic AMP activates a kinase that phosphorylates a protein, which then closes K^+ channels.

If a postsynaptic neuron is to repolarize quickly, any excess neurotransmitter in the synaptic cleft must be removed. Some neurotransmitters are inactivated by enzymes. For example, excess acetylcholine is degraded into its chemical components, choline and acetate, by the enzyme acetylcholinesterase. Other neurotransmitters, such as the biogenic amines, are actively transported back into the synaptic terminals, a process known as **reuptake.** These neurotransmitters are repackaged in vesicles and recycled.

Many drugs inhibit the reuptake of neurotransmitters. For example, some antidepressants are selective serotonin reuptake inhibitors, or SSRIs (such as fluoxetine [Prozac]) that selectively inhibit the reuptake of serotonin in the brain. This action concentrates serotonin in the synaptic cleft, elevating mood. Some antidepressants (and cocaine) also inhibit the reuptake of dopamine.

Neurotransmitters and their receptors can send excitatory or inhibitory signals

A postsynaptic neuron may have receptors for several types of neurotransmitters. Some of its receptors may be excitatory, and others may be inhibitory. Depending on the type of postsynap-

Focus On Alzheimer's Disease

In **Alzheimer's disease (AD),** a progressive, degenerative brain disorder, neural signaling is disrupted and neurons are damaged and die prematurely. Alzheimer's disease is the leading cause of senile dementia, which is the loss of memory, judgment, and the ability to reason that may be associated with aging. This disease afflicts more than 4 million people in the United States alone.

The development of AD may be a lifelong process. One startling study demonstrated that a person's writing early in life can predict the disease. Young adults whose writings had a lower density of ideas were more likely to develop the disease. One approach to detecting development of AD is the use of positron emission tomography (PET) scans to study glucose uptake in the brain. Low glucose uptake in certain areas of the brain indicates that neurons in these areas may be damaged.

In AD, neurons are damaged in certain parts of the brain, including the cerebral cortex and hippocampus, areas that are important in thinking and remembering. Neurons that secrete the neurotransmitter acetylcholine are especially affected. Investigators have demonstrated that two of the abnormalities that develop in brain tissue as we age, amyloid plaques and neurofibrillary tangles, are especially characteristic of AD. Understanding the biochemistry and genetic basis of both plaques and tangles may provide clues to the causes and cures of AD.

Amyloid plaques were first identified in autopsied brains in 1906 by the German physician Alois Alzheimer. These plaques are extracellular deposits of a peptide called β-amyloid. Neurons near these plaques appear swollen and misshapen. Microglia are typically present, suggesting an attempt to remove the damaged cells or the plaques themselves.

Researchers have found that β-amyloid is cut from a protein called β-amyloid precursor protein, or β-APP, a large transmembrane protein coded by a gene on chromosome 21. Normal β-amyloid molecules have 40 amino acids. However, about 10% of the peptides produced have two additional amino acids. This longer peptide appears to form the plaques. Investigators have identified mutations in specific genes that result in the production of abnormal β-amyloid.

Just how the longer β-amyloid leads to AD is not known. The abnormal peptide appears to disrupt calcium regulation, killing neurons in the brain. The peptide may also damage mitochondria, releasing harmful free radicals. In 2002 Dennis Selkoe, of Harvard Medical School, reported that AD begins with subtle changes in synaptic function in the hippocampus, a part of the brain important in memory. An early symptom is the loss of the ability to encode new memories. Selkoe hypothesizes that the

tic receptor with which it combines, the same neurotransmitter can have different effects. For example, acetylcholine has an excitatory effect on skeletal muscle and an inhibitory effect on cardiac muscle.

When neurotransmitter molecules bind to receptors, they directly or indirectly cause ion channels to open or close, thus changing the permeability of the postsynaptic membrane to certain ions. The resulting redistribution of ions changes the electrical potential of the membrane, and the membrane may depolarize. If sufficiently intense, a local depolarization can set off an action potential. For example, when neurotransmitter molecules combine with receptors that open sodium channels, the resulting influx of sodium ions partially depolarizes the membrane. A change in membrane potential that brings the neuron closer to firing is called an **excitatory postsynaptic potential (EPSP)**. Imagine that sufficient sodium ions enter to change the membrane potential, from −70 mV to −60 mV. The membrane would be only −5 mV away from threshold. Under such conditions, an additional relatively weak stimulus, causing a small influx of Na^+, can cause the neuron to fire.

Some neurotransmitter-receptor combinations hyperpolarize the postsynaptic membrane. The membrane potential becomes more negative. Because such an action takes the neuron farther away from the firing level, a potential change in this direction is called an **inhibitory postsynaptic potential (IPSP).** For example, if the membrane potential changes from −70 mV to −80 mV, the membrane is farther away from threshold, and a stronger stimulus is required to fire the neuron.

Like an EPSP, an IPSP can be produced in several ways. Two types of GABA receptors are known to produce IPSPs. Binding of GABA to a $GABA_B$ receptor opens K^+ channels. As K^+ diffuses out, the neuron becomes more negative, hyperpolarizing the membrane. Activated $GABA_A$ receptors produce IPSPs by opening Cl^- channels. In this case, the influx of negative ions hyperpolarizes the membrane. Although the mechanisms are different, the inhibiting effect of GABA is the same in both cases.

In summary, when an action potential reaches the synaptic terminals at the end of a presynaptic neuron, the following sequence of events takes place:

Calcium ions enter synaptic terminal ⟶ synaptic vesicles release neurotransmitter into the synaptic cleft ⟶ neurotransmitter diffuses across synaptic cleft and combines with receptors in membrane of the postsynaptic neuron ⟶ ion channels open or close ⟶ depolarization or hyperpolarization of postsynaptic membrane

Review

- What are some functions of biogenic amines?
- What are the functions and mechanisms of action of the following substances: (a) acetylcholine (b) acetylcholinesterase; (c) norepinephrine (d) GABA?
- How are EPSPs produced? IPSPs?

BiologyNow™ Assess your understanding of **neural signaling across synapses** by taking the pretest on your BiologyNow CD-ROM.

loss of synaptic function is caused by abnormal β-amyloid.

Another piece of the AD puzzle may be **neurofibrillary tangles,** which form in the neuron cytoplasm. A cytoskeletal protein called **tau** normally associates with the protein tubulin, which forms microtubules. Mutations in the *tau* gene may interfere with the way the tau protein binds to microtubules, resulting in abnormal microtubules that cannot effectively transport materials through the axons. Abnormal tau proteins accumulate in the cytoplasm, forming fibrous deposits that make up the neurofibrillary tangles. These tangles interfere with neural signaling.

Recent findings indicate that the mechanisms that cause amyloid plaques and neurofibrillary tangles are connected. In 2001 two groups of investigators working with transgenic mice independently demonstrated that β-amyloid deposits in the brain are responsible for the formation of neurofibrillary tangles in areas of the brain known to be affected in Alzheimer's disease.

Several drugs designed to slow the progress of Alzheimer's disease are now in clinical trials. One of the challenges of developing a drug has been getting the medication through the blood–brain barrier (see Chapter 40). Two approaches to developing a treatment for AD are blocking formation of β-amyloid and dissolving the abnormal β-amyloid deposits that are already present.

A promising strategy is to stimulate the immune system to destroy β-amyloid deposits. In 2000 Dale Schenk and his colleagues at Elan Pharmaceuticals demonstrated that when they immunized genetically engineered mice with a vaccine made of β-amyloid, the mice developed antibodies against the protein and destroyed the β-amyloid plaques. In 2001 investigators demonstrated that this vaccine also reduces memory loss and enhances learning in aging mice. Vaccinated mice developed fewer plaques and performed significantly better on memory tests. Researchers were optimistic when human clinical trials began. Unfortunately, these trials were halted when about 5% of the patients developed a dangerous brain inflammation. Studies are currently underway to develop a safer vaccine.

People with high cholesterol levels are at greater risk for developing AD because cholesterol apparently promotes β-amyloid production. Clinical trials are in progress to test the use of statins, drugs that lower cholesterol levels in the blood. Other approaches include the use of anti-inflammatory drugs and of antioxidants (such as vitamin C or E). The drug memantine, used to treat AD in Germany, is in clinical trials in the United States. Memantine blocks the action of the neurotransmitter glutamate, which appears to be overproduced in the brains of AD patients.

NEURAL INTEGRATION

Learning Objective

10 Describe how a postsynaptic neuron integrates incoming stimuli and "decides" whether or not to fire.

Each EPSP or IPSP is a graded potential that varies in magnitude depending on the strength of the stimulus applied. One EPSP is usually too weak to trigger an action potential by itself. Its effect is below threshold level. Even though subthreshold EPSPs do not produce an action potential, they do affect the membrane potential. EPSPs may add together in a process known as **summation.**

Temporal summation occurs when repeated stimuli cause new EPSPs to develop before previous EPSPs have decayed. The summation of several EPSPs may bring the neuron to the critical firing level. Spatial summation can also bring the postsynaptic neuron to the threshold level. **Spatial summation** occurs when several closely spaced synaptic terminals release neurotransmitter simultaneously. The postsynaptic neuron is stimulated at several places at once.

Neural integration is the process of summing, or integrating, incoming signals. Each neuron may synapse with hundreds of other neurons. Indeed, thousands of synaptic terminals of presynaptic neurons may cover as much as 40% of a postsynaptic neuron's dendritic surface and cell body. It is the job of the dendrites and the cell body of every neuron to integrate the messages that continually bombard them.

EPSPs and IPSPs are produced continually in postsynaptic neurons, and IPSPs cancel the effects of some EPSPs. It is important to remember that each EPSP and IPSP is not an all-or-none response. Rather, each is a graded response that does not travel like an action potential but may be added to or subtracted from other EPSPs and IPSPs. As the postsynaptic neuron membrane continuously updates its molecular tabulations, the neuron may be inhibited or brought to threshold level. This mechanism integrates hundreds of signals (EPSPs and IPSPs) before an action potential is actually transmitted along the axon of a postsynaptic neuron. Local responses permit the neuron and the entire nervous system a far greater range of response than would be possible if every EPSP generated an action potential.

Where does neural integration take place? Every neuron sorts through (on a molecular level) the hundreds and thousands of bits of information simultaneously bombarding it. In vertebrates more than 90% of the neurons in the body are located in the CNS, so most neural integration takes place there, within the brain and spinal cord. These neurons are responsible for making most of the "decisions." In the next chapter, the brain and spinal cord are examined in some detail.

Review

- How do temporal and spatial summation differ?

(a) (b)

FIGURE **39-11** **Neural circuits.**

(a) Convergence of neural input permits one neuron to receive signals from many sources. Several presynaptic neurons synapse with one postsynaptic neuron. **(b)** Divergence of neural output allows one neuron to communicate with many others. A single presynaptic neuron synapses with many postsynaptic neurons.

NEURAL CIRCUITS

Learning Objective

11 Distinguish among convergence, divergence, and reverberation, and explain why each is important.

The CNS contains millions of neurons, but it is not just a tangled mass of nerve cells. Its neurons are organized into separate **neural networks,** and within each network the neurons are arranged in specific pathways, or **neural circuits.** Although each network has some special characteristics, the neural circuits in all the networks share many organizational features. For example, convergence and divergence are probably characteristic of them all.

In **convergence,** a single neuron is controlled by converging signals from two or more presynaptic neurons (Fig. 39-11a). An interneuron in the spinal cord, for instance, may receive converging information from sensory neurons entering the cord, from neurons bringing information from various parts of the brain, and from neurons coming from different levels of the spinal cord. Information from all these sources must be integrated before an action potential is transmitted and an appropriate motor neuron stimulated. Convergence is an important mechanism by which the CNS integrates the information that impinges on it from various sources.

In **divergence,** a single presynaptic neuron stimulates many postsynaptic neurons (Fig. 39-11b). Each presynaptic neuron may branch and synapse with thousands of different postsynaptic neurons. For example, a single neuron transmitting an impulse from the motor area of the brain may synapse with hundreds of interneurons in the spinal cord, and each of these may diverge in turn, so that hundreds of muscle fibers are stimulated.

Another important type of neural circuit is the **reverberating circuit,** a neural pathway arranged so that an axon collateral synapses with an interneuron (Fig. 39-12). The interneuron synapses with a neuron in a sequence that can send new impulses through the circuit. This is an example of positive feedback. New impulses can be generated again and again until the synapses fatigue (from depletion of neurotransmitter) or until stopped by some sort of inhibition. Researchers think reverberating circuits are important in rhythmic breathing, mental alertness, and short-term memory.

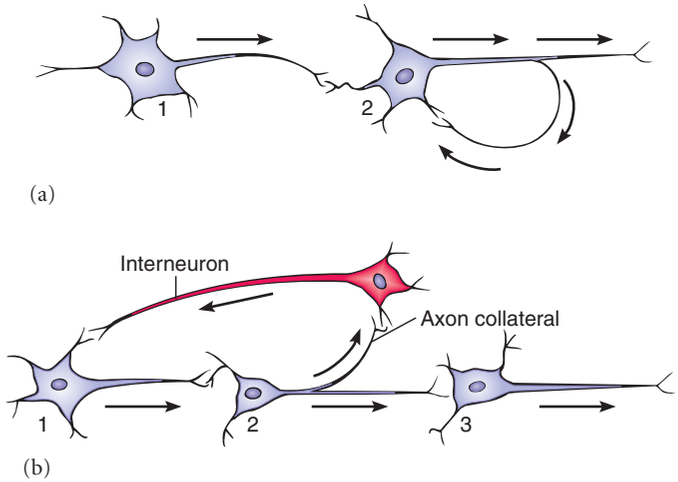

FIGURE **39-12** **Reverberating circuits.**

(a) A simple reverberating circuit in which an axon collateral of the second neuron turns back on its own dendrites, so the neuron continues to stimulate itself. **(b)** In this neural circuit an axon collateral of the second neuron synapses with an interneuron. The interneuron synapses with the first neuron in the sequence. New impulses are triggered again and again in the first neuron, causing reverberation.

Review

- How does convergence differ from divergence?
- What is the role of positive feedback in a reverberating circuit?

BiologyNow™ Assess your understanding of **neural circuits** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Trace the flow of information through the nervous system, and describe the processes involved in neural signaling: reception, transmission, integration, and action by effectors.

- Neural signaling involves (a) **reception** of information by a sensory receptor (b) **transmission** by an **afferent neuron** to the CNS (c) **integration** by interneurons in the **central nervous**

system (CNS) (d) transmission by an **efferent neuron** to other neurons or to an effector (e) action by **effectors,** the muscles and glands. Sensory receptors and neurons outside the CNS make up the **peripheral nervous system (PNS).**

2 Describe the functions of each type of vertebrate glial cell.

- **Glial cells** support and nourish neurons. **Microglia** are phagocytic cells. Some **astrocytes** are phagocytic, and others help regulate the composition of the extracellular fluid in the CNS. Astrocytes may also induce and stabilize synapses.
- **Oligodendrocytes** are glial cells that form myelin sheaths around axons in the CNS; **Schwann cells** form sheaths around axons in the PNS.

3 Describe the structure of a typical neuron, and give the function of each of its parts.

- **Neurons** are specialized to receive stimuli and transmit electrical signals. In a typical neuron a **cell body** contains the nucleus and most of the organelles. Many branched **dendrites** extend from the cell body; they are specialized to receive stimuli and send signals to the cell body.
- The single long **axon** extends from the cell body and forms branches called **axon collaterals.** The axon transmits signals into its **terminal branches** that end in **synaptic terminals.** Many axons are surrounded by an insulating **myelin sheath. Nodes of Ranvier** are gaps in the sheath between successive Schwann cells. A **nerve** consists of several hundred axons wrapped in connective tissue; a **ganglion** is a mass of neuron cell bodies.

4 Explain how the neuron develops and maintains a resting potential.

- Neurons use electrical signals to transmit information. In a resting neuron, one that is not transmitting an impulse, the inner surface of the plasma membrane is negatively charged compared with the outside; the membrane is **polarized.**
- The **resting potential** is the potential difference of about −70 mV that exists across the membrane. The magnitude of the resting potential is determined by (1) differences in concentrations of specific ions (mainly Na^+ and K^+) inside the cell relative to the extracellular fluid, and (2) selective permeability of the plasma membrane to these ions.
- Ions pass through specific **passive ion channels.** K^+ leaks out more readily than Na^+ can leak in. Cl^- ions accumulate along the inner surface of the plasma membrane. Large anions such as proteins that cannot cross the plasma membrane contribute negative charges.
- The gradients that determine the resting potential are maintained by ATP-requiring **sodium-potassium pumps** that continuously transport three sodium ions out of the neuron for every two potassium ions transported in.

5 Compare a graded potential with an action potential, describing the production and transmission of each.

- If a stimulus causes the membrane potential to become less negative, the membrane becomes **depolarized.** If the membrane potential becomes more negative than the resting potential, the membrane is **hyperpolarized.**
- A **graded potential** is a local response that varies in magnitude depending on the strength of the applied stimulus. A graded potential fades out within a few mm of its point of origin.
- If voltage across the membrane declines to a critical point, called the **threshold level,** the **voltage-activated ion channels** open, allowing Na^+ to flow into the neuron, and an **action potential** is generated. The action potential is a **wave of depolarization** that moves down the axon.
- The action potential conforms to an **all-or-none response,** no variation exists in the strength of a single impulse. The membrane potential either exceeds threshold level, leading to transmission of an action potential, or it does not. Once begun, an action potential is self-propagating.
- As the action potential moves down the axon, **repolarization** occurs behind it. During depolarization, the axon enters an **absolute refractory period,** a time when it cannot transmit another action potential. When enough gates controlling Na^+ channels have been reset, the neuron enters a **relative refractory period,** a time when the threshold is higher.

6 Contrast continuous conduction with saltatory conduction.

- **Continuous conduction** takes place in unmyelinated neurons; it involves the entire axon plasma membrane.
- **Saltatory conduction,** which is more rapid than continuous conduction, takes place in myelinated neurons. Depolarization skips along the axon from one **node of Ranvier** to the next—sites where the axon is not covered by myelin and where Na^+ channels are concentrated.

7 Describe the actions of the neurotransmitters identified in the chapter.

- The junction between two neurons or between a neuron and effector is a **synapse.** Although there are electrical synapses, most synapses are chemical. Synaptic transmission generally depends on release of a **neurotransmitter** from **synaptic vesicles** in the synaptic terminals of a **presynaptic neuron.**
- **Acetylcholine** triggers contraction of skeletal muscle.
- The **biogenic amines** include **norepinephrine, serotonin,** and **dopamine.** These neurotransmitters play important roles in regulating mood. Dopamine is also important in motor function.
- Several amino acids function as neurotransmitters including **glutamate,** the main excitatory neurotransmitter in the brain and **GABA ,** a widespread inhibitory neurotransmitter.
- The neuropeptides include the **endorphins** (for example, **beta-endorphin**) and the **enkephalins.** These neuropeptides are opioids.
- **Nitric oxide (NO)** is a gaseous neurotransmitter that transmits signals from the postsynaptic neuron to the presynaptic neuron, the opposite direction from other neurotransmitters.

8 Trace the events that take place in synaptic transmission; draw diagrams to support your description.

- Calcium ions cause synaptic vesicles to fuse with the presynaptic membrane and release neurotransmitter into the **synaptic cleft.** A neurotransmitter diffuses across the synaptic cleft and combines with specific receptors on a postsynaptic neuron.
- Many neurotransmitter receptors are proteins that form **ligand-gated ion channels.** Others work through a **second messenger** such as **cAMP.**

9 Compare excitatory and inhibitory signals and their effects.

- Binding of a neurotransmitter to a receptor can cause either an **excitatory postsynaptic potential (EPSP)** or an **inhibitory postsynaptic potential (IPSP),** depending on the type of receptor.
- EPSPs bring the neuron closer to firing. IPSPs move the neuron farther away from its firing level.

SUMMARY WITH KEY TERMS *(continued)*

10 Describe how a postsynaptic neuron integrates incoming stimuli and "decides" whether or not to fire.

- Each EPSP or IPSP is a graded potential that varies in magnitude depending on the strength of the stimulus applied.
- The mechanism of neural integration is **summation,** the process of adding and subtracting incoming signals. By summation of several EPSPs, the neuron may be brought to critical firing level.
- **Temporal summation** occurs when repeated stimuli cause new EPSPs to develop before previous EPSPs have decayed. **Spatial summation** occurs when several closely spaced synaptic terminals release neurotransmitter simultaneously, stimulating the postsynaptic neuron at several different places.

11 Distinguish among convergence, divergence, and reverberation, and explain why each is important.

- Complex **neural circuits** are possible because of associations such as convergence and divergence. In **convergence,** a single neuron is controlled by converging signals from two or more presynaptic neurons. Convergence permits the CNS to integrate incoming information from various sources. In **divergence,** a single presynaptic neuron stimulates many postsynaptic neurons, allowing widespread effect.
- **Reverberating circuits** depend on positive feedback. New impulses can be generated again and again until the synapses fatigue. Reverberating circuits are important in rhythmic breathing, mental alertness, and short-term memory.

POST-TEST

1 Summing incoming neural signals is part of (a) reception (b) transmission (c) integration (d) action by effectors (e) afferent neuron transmission

2. Which of the following are phagocytic cells that remove debris from tissue in the CNS? (a) Schwann cells (b) axons (c) oligodendrocytes (d) effectors (e) microglia

3. Most of the neuron cytoplasm is located in the (a) cell body (b) axon (c) dendrites (d) synaptic terminals (e) nodes

4. Action potentials are transmitted to synaptic terminals by the (a) ganglia (b) axon (c) dendrites (d) cell body (e) nodes

5. In responding to a stimulus, a motor neuron signals a(an) (a) efferent neuron (b) receptor (c) afferent neuron (d) interneuron (e) effector

6. The myelin sheath is produced around axons outside the CNS by the (a) axon (b) neuron cell body (c) dendrites (d) Schwann cells (e) synaptic terminals

7. Neurotransmitters are released by the (a) axon (b) neuron cell body (c) dendrites (d) astrocytes (e) synaptic terminals

8. Which of the following does *not* contribute to the resting potential of a neuron? (a) sodium-potassium pumps (b) ion channels (c) differences in concentration of ions across the membrane (d) differences in permeability to certain ions (e) graded potentials

9. Which of the following occurs first when voltage reaches the threshold level? (a) gates of certain voltage-activated ion channels open (b) K^+ channels close (c) the membrane hyperpolarizes (d) neurotransmitter is released (e) neurotransmitter reuptake takes place at the synapse

10. Saltatory conduction (a) requires more energy than continuous conduction (b) occurs in unmyelinated neurons (c) occurs when the action potential jumps from one node of Ranvier to the next (d) slows transmission of an impulse (e) depends on the presence of GABA

11. Acetylcholine (a) is a biogenic amine (b) is recycled (c) is released by motor neurons and by some neurons in the brain (d) is deactivated by G proteins (e) binds to opioid receptors

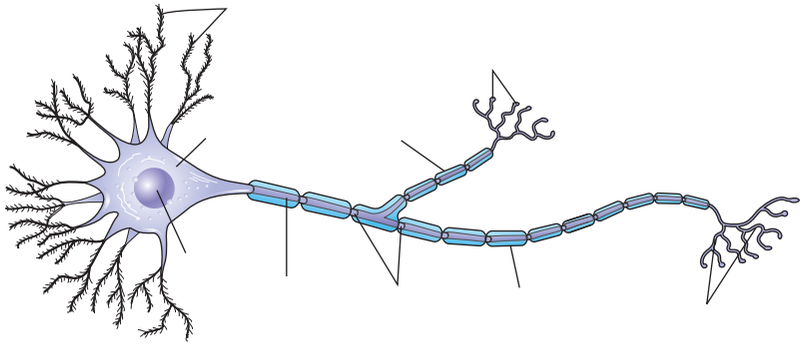
12. Neurotransmitter receptors often (a) are voltage-activated ion channels (b) permit influx of chloride ions, leading to depolarization of the membrane (c) work through a second messenger (d) inhibit reuptake of the neurotransmitter (e) are passive ion channels

13. IPSPs (a) excite presynaptic neurons (b) excite postsynaptic neurons (c) cancel the effects of some EPSPs (d) release large amounts of neurotransmitters (e) are released by postsynaptic cell bodies

14. A presynaptic neuron in the cerebrum synapses with hundreds of other neurons. This is an example of (a) convergence (b) divergence (c) summation (d) a reverberating circuit (e) a graded potential

15. During a relative refractory period (a) IPSPs are generated (b) opioid neurotransmitters are released (c) voltage-activated sodium channels are inactivated (d) an axon can transmit impulses but the threshold is higher (more negative) (e) an axon cannot transmit an action potential

16. Label the diagram. Use Figure 39-2 to check your answers.



CRITICAL THINKING

1. Discuss several specific ways in which the nervous system helps maintain homeostasis.
2. Stimulant drugs such as amphetamines increase the activity of the nervous system. Describe two mechanisms involving synaptic transmission that could explain the action of such drugs.
3. Develop a hypothesis to explain the fact that acetylcholine has an excitatory effect on skeletal muscle but an inhibitory effect on cardiac muscle.
4. Investigators have genetically engineered cells to produce acetylcholine, dopamine, GABA, and other neurotransmitters. In what ways might these cells be useful in neurobiological research? How might they be useful in clinical medicine?

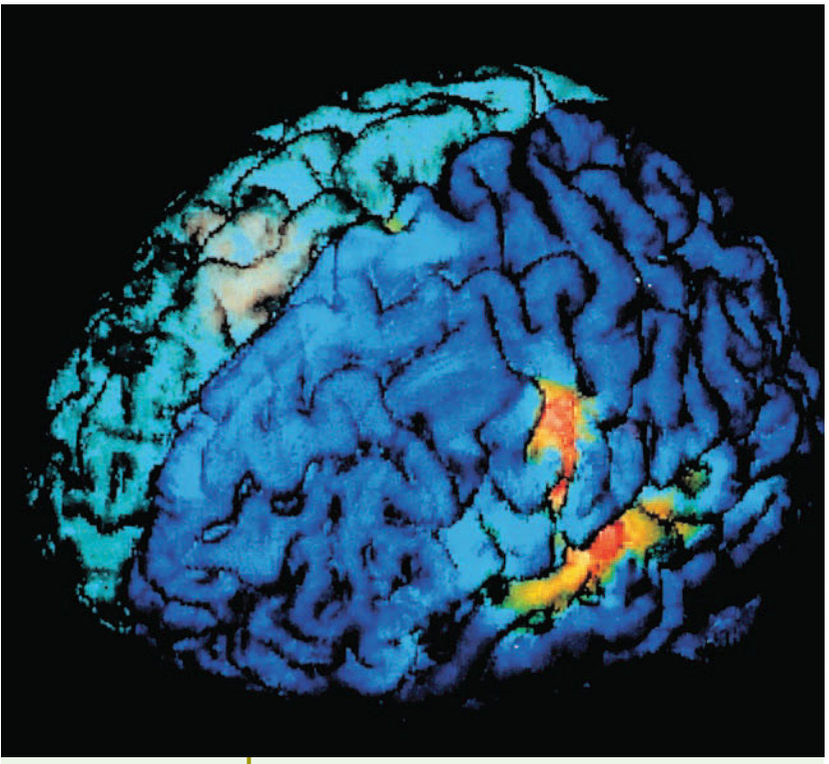
Neural Regulation



Volker Steger/Peter Arnold, Inc.

Functional magnetic resonance imaging (fMRI) of the brain. In this image, red indicates areas of greatest activation during speech; yellow indicates medium activation.

CHAPTER OUTLINE

- Invertebrate Nervous Systems
- Organization of the Vertebrate Nervous System
- Evolution of the Vertebrate Brain
- The Human Central Nervous System
- The Peripheral Nervous System
- Effects of Drugs on the Nervous System

A frog flicks out its tongue with lightning speed to capture a fly, a rabbit escapes from a predator, and you learn biology—perhaps not that quickly. In a complex nervous system, millions of neurons work together to produce effective responses to stimuli in the external environment. The nervous system also regulates heart rate, breathing, and hundreds of other internal activities Researchers have focused extensively on just how neurons interact, and we are only beginning to understand the mechanisms that permit the complex functions of the nervous system.

Neurobiologists have investigated two major aspects of neural function: hard-wiring of the nervous system and neural plasticity. The term **hard-wiring** refers to how neurons signal one another, how they connect, and how they carry out basic functions such as regulating heart rate, blood pressure, respiration, and sleep–wake cycles. Hard-wiring was the major focus of neurobiologists for decades.

Eventually, neurobiologists began to focus on their observation that even animals with very simple nervous systems can learn to repeat behaviors associated with reward and to avoid behaviors that cause pain. Such changes in behavior are possible because of **neural plasticity,** the ability of the nervous system to change in response to experience. Such change modifies structure and function. Many areas of the brain once thought hard-wired are now known to be flexible and capable of change. Familiar examples of neural plasticity in human motor skills include learning to walk, ride a bicycle, or catch a baseball. At first you were probably clumsy, but with practice your performance became smoother and more precise. Similarly, the ability to learn languages, solve problems, and perform scientific experiments depends on neural plasticity.

What are the mechanisms by which neurons signal one another to learn diverse activities such as skilled movement and studying biology? Canadian psychologist Donald O. Hebb proposed in 1949 that when two neurons connected by a *synapse* are active simultaneously, the synapse is somehow strengthened.

In 1973, British researchers T.V.P. Bliss and T.J. Lomo found experimental evidence for Hebb's hypothesis. Investigating rabbit brains, these researchers found that when neurons in the hippocampus (a region that converts information into memories) were stimulated by a series of high-frequency electrical stimuli, functional changes occurred at synapses.

Because neurons signal one another at synapses, these junctions between neurons are currently the focus of intense research. Neural plasticity may, in fact, be **synaptic plasticity,** because changes that occur during learning and remembering appear to take place at synapses. Working on a molecular level, neurobiologists are studying neurotransmitter action on membrane receptors. They are asking questions more quickly than they can find answers. How is synaptic activity depressed, and how is it enhanced? Do neurons change the contacts they make with one another? Do they make connections with new neurons? What mechanisms are activated by neurotransmitter-receptor binding? These mechanisms are known to include complex intracellular signaling systems that involve second messengers, gene activation, and protein synthesis.

Neurobiologists use a variety of methods to study the mechanisms of neural function. For example, improved imaging methods have revolutionized the study of the brain. Functional magnetic resonance imaging (fMRI) has provided investigators with a window through which to observe brain function. Functional MRI allows neurobiologists to study the responses of neural networks in the brain while an individual is actually performing a task, such as speaking (see figure). During the performance of the task, an area of the brain becomes active, and flow of oxygenated blood to that area increases. Functional MRI detects changes that take place in response to a very brief stimulus. For example, a visual stimulus lasting only 30 milliseconds stimulates brain activation that can be detected by fMRI.

In this chapter we compare various animal nervous systems. We then examine the structure and function of the vertebrate nervous system, with emphasis on the function of the human brain. We explore some of the frontiers of neurobiology such as the mechanisms involved in information processing. ■

INVERTEBRATE NERVOUS SYSTEMS

Learning Objectives

1. Contrast nerve nets and radial nervous systems with bilateral nervous systems.
2. Identify trends in the evolution of the invertebrate nervous system.

An animal's lifestyle is closely related to the organization and complexity of its nervous system. *Hydra* and other cnidarians have a **nerve net** consisting of interconnected neurons with no central control organ. Electrical signals are sent from neuron to neuron in more than one direction (Fig. 40-1). Responses may involve large parts of the body. An advantage of the nerve net is that the cnidarian responds effectively to predator or prey approaching from any direction. *Hydra* responds by discharging nematocysts (stinging structures) and coordinating the movements of its tentacles to capture food. Some cnidarians have two or more nerve nets. In some jellyfish, a slow-transmission nerve net coordinates movement of the tentacles, and a second nerve net, which is faster, coordinates swimming.

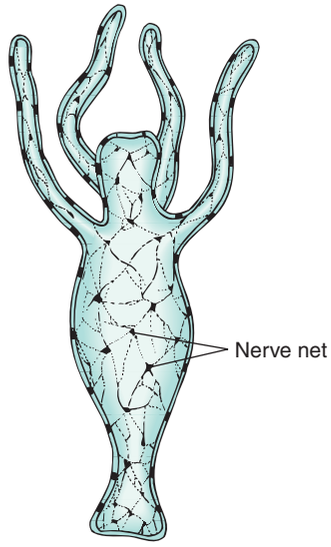


FIGURE **40-1**

***Hydra's* nerve net.**

Hydra and other cnidarians have a network of neurons with no central control organ.

The **radial nervous system** of the sea star and other echinoderms (see Chapter 30) is a modified nerve net. This system shows some degree of selective organization of neurons into more than a diffuse network. It consists of a nerve ring around the mouth, from which a large radial nerve extends into each arm. Branches of these nerves, which form a network somewhat similar to the nerve net of *Hydra,* coordinate the animal's movement.

Bilaterally symmetrical animals have a **bilateral nervous system.** We can identify the following trends in the evolution of nervous systems:

1. *Increased number of nerve cells.*
2. *Concentration of nerve cells,* forming masses of tissue that become **ganglia** and **brain,** and thick cords of tissue that become **nerve cords** and **nerves.**
3. *Specialization of function.* For example, transmission of nerve impulses in one direction requires both **afferent nerves,** which conduct impulses toward a central nervous system (CNS), and **efferent nerves,** which transmit impulses away from the CNS to the **effectors** (muscles and glands). Certain parts of the CNS are typically specialized to perform specific functions, and distinct structural and functional regions can be identified.
4. *An increased number of interneurons and more complex synaptic contacts* permit greater integration of incoming

messages, provide a greater range of responses, and allow more precision in responses.

5. ***Cephalization,*** *or formation of a head.* A bilaterally symmetrical animal generally moves in a forward direction. Concentration of sense organs at the front end of the body lets the animal detect an enemy quickly enough to escape or to see or smell food in time to capture it. Response can be rapid if short pathways link sense organs to decision-making nerve cells nearby. Therefore, nerve cells are typically concentrated in the head region and organized to form ganglia or a brain.

In planarian flatworms, the head region contains concentrations of nerve cells called **cerebral ganglia** (Fig. 40-2). These serve as a primitive brain and have some control over the rest of the nervous system. Typically, two solid ventral longitudinal nerve cords extend from the ganglia to the posterior end of the body. Transverse nerves connect the two nerve cords and connect the brain with the eyespots. This arrangement is called a "ladder-type" nervous system.

Annelids and arthropods typically have a ventral nerve cord (Fig. 40-3). The cell bodies of many of the neurons are massed into ganglia. Afferent and efferent neurons lie in lateral nerves that link the ganglia with muscles and other body structures. If an earthworm's brain is removed, the animal can move almost as well as before. However, when it bumps into an obstacle, it persists in a futile effort to move forward rather than turning aside. To respond adaptively to environmental change, the earthworm needs its brain.

The cerebral ganglia of some arthropods differ from those of annelids in that they have specific functional regions. These areas are specialized for integrating information transmitted to the ganglia from sense organs.

Mollusks with inactive lifestyles have relatively simple nervous systems with little cephalization and very simple sense organs. In contrast, the active cephalopod mollusks (squids and octopods) have complex nervous systems with neurons concentrated in a central region. Ganglia are massed in a ring surrounding the esophagus, making up a brain that contains about 168 million nerve cells. This complex nervous system, which includes well-developed sense organs, is an adaptation that correlates with the active, predatory lifestyle of these animals. With its highly developed nervous system, the octopus is capable of considerable learning and can be taught quite complex tasks. In fact, cephalopods are considered the most intelligent invertebrates.

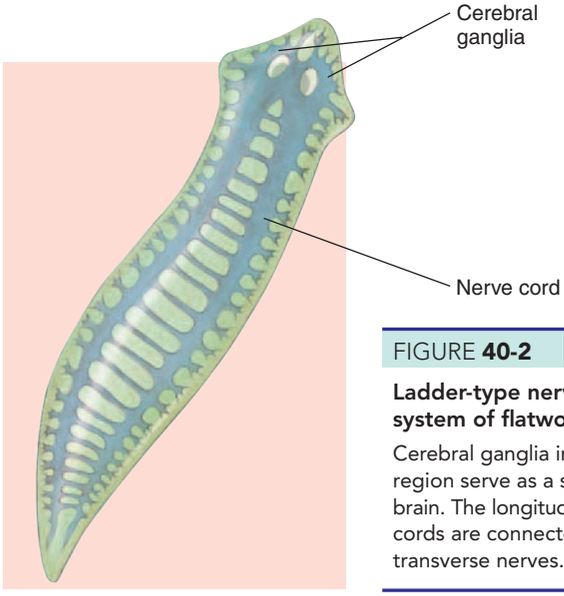

FIGURE **40-2**

Ladder-type nervous system of flatworms.

Cerebral ganglia in the head region serve as a simple brain. The longitudinal nerve cords are connected by transverse nerves.

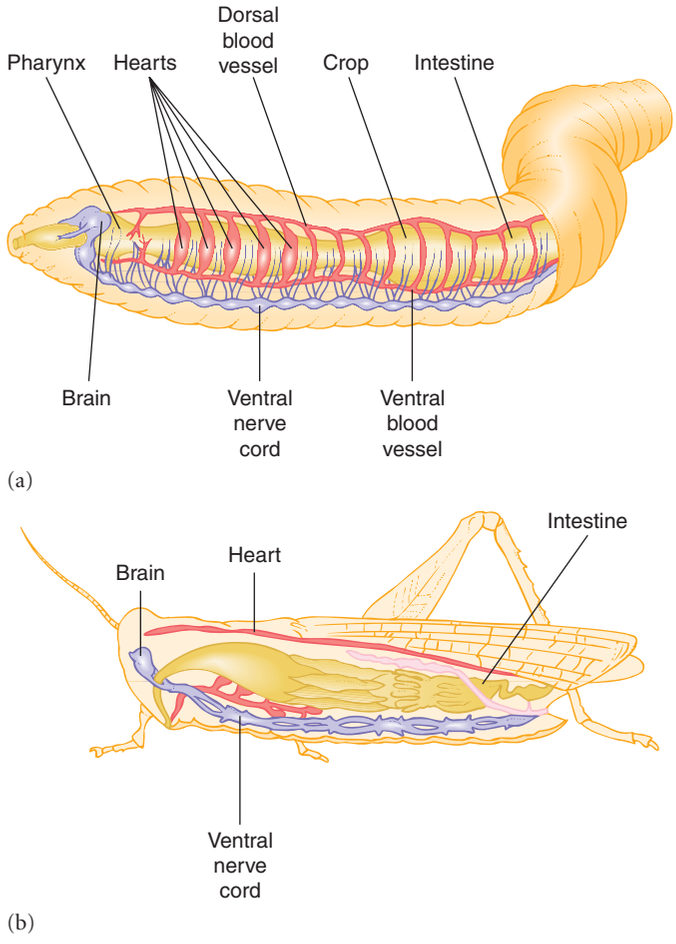

FIGURE **40-3**

The annelid and arthropod nervous systems.

(a) Like other annelids, the earthworm nervous system includes a dorsal anterior brain and one or more ventral nerve cords. Cell bodies of the neurons are located in ganglia that are connected by the ventral nerve cord. **(b)** In the insect nervous system, the brain is connected to a ventral nerve cord. The brain is more specialized than in annelids.

Review

- What are some trends in the evolution of nervous systems?
- What are some advantages of cephalization?

ORGANIZATION OF THE VERTEBRATE NERVOUS SYSTEM

Learning Objective

3 Describe the two main divisions of the vertebrate nervous system.

An animal's range of possible responses depends in large part on the number of its neurons and how they are organized in the nervous system. As animal groups evolved, nervous systems became increasingly complex. The vertebrate nervous system has two main divisions: the **central nervous system (CNS)** and the **peripheral nervous system (PNS)** (Table 40-1). The CNS consists of a complex brain that is continuous with the dorsal tubular **spinal cord.** Serving as central control, these organs integrate incoming information and determine appropriate responses.

The PNS is made up of the sensory receptors (for example, tactile, auditory, and visual receptors) and the nerves, which are the communication lines. Various parts of the body are linked to the brain by cranial nerves and to the spinal cord by spinal nerves. Afferent neurons in these nerves continuously inform the CNS of changing conditions. Then efferent neurons transmit the "decisions" of the CNS to appropriate muscles and glands, which make the adjustments needed to maintain homeostasis.

For convenience the PNS is subdivided into somatic and autonomic divisions. Most of the receptors and nerves concerned with changes in the external environment are somatic. Those that regulate the internal environment are autonomic. Both divisions have afferent nerves, which transmit messages from receptors to the CNS, and efferent nerves, which transmit information back from the CNS to the structures that respond. The autonomic division has two kinds of efferent pathways: sympathetic and parasympathetic nerves.

TABLE 40-1 Divisions of the Vertebrate Nervous System

Central Nervous System (CNS)

- Brain
- Spinal cord

Peripheral Nervous System (PNS)

- Somatic division
  1. Receptors
  2. Afferent (sensory) nerves—transmit information from receptors to CNS
  3. Efferent (motor) nerves—transmit information from CNS to skeletal muscles
- Autonomic division
  1. Receptors
  2. Afferent (sensory) nerves—transmit information from receptors in internal organs to CNS
  3. Efferent nerves—transmit information from CNS to glands and involuntary muscle in organs
     a. Sympathetic nerves—generally stimulate activity that results in mobilization of energy (e.g., speeds heartbeat)
     b. Parasympathetic nerves—action results in energy conservation or restoration (e.g., slows heart but speeds digestion)

Review

- What are the main components of the CNS?
- What are the main components of the PNS?

EVOLUTION OF THE VERTEBRATE BRAIN

Learning Objective

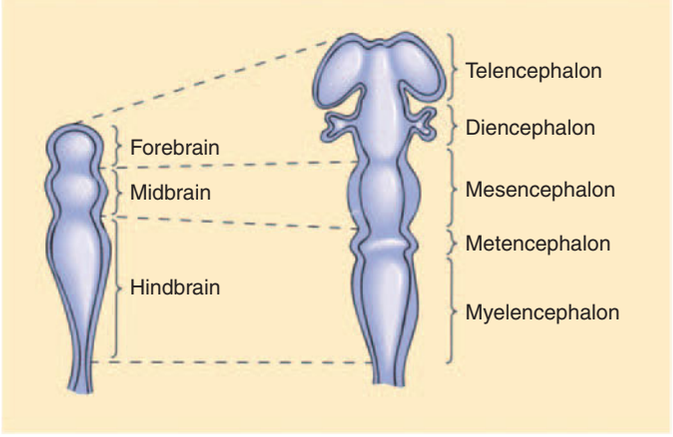
4 Trace the development of the principal vertebrate brain regions from the forebrain, midbrain, and hindbrain, and compare the brains of fishes, amphibians, reptiles, birds, and mammals.

All vertebrates, from fishes to mammals, have the same basic brain structure. Different parts of the brain are specialized in the various vertebrate classes, and the evolutionary trend is toward increasing complexity, especially of the cerebrum and cerebellum.

In the early vertebrate embryo, the brain and spinal cord differentiate from a single tube of tissue, the **neural tube.** Anteriorly, the tube expands and develops into the brain. Posteriorly, the tube becomes the spinal cord. Brain and spinal cord remain continuous, and their cavities communicate. As the brain begins to differentiate, three bulges become visible: the hindbrain, midbrain, and forebrain (Fig. 40-4).

FIGURE 40-4 Early development of the vertebrate nervous system.

Early in the development of the vertebrate embryo, the anterior end of the neural tube differentiates into the forebrain, midbrain, and hindbrain. These primary divisions subdivide and eventually give rise to specific structures of the adult brain (see Table 40-2).



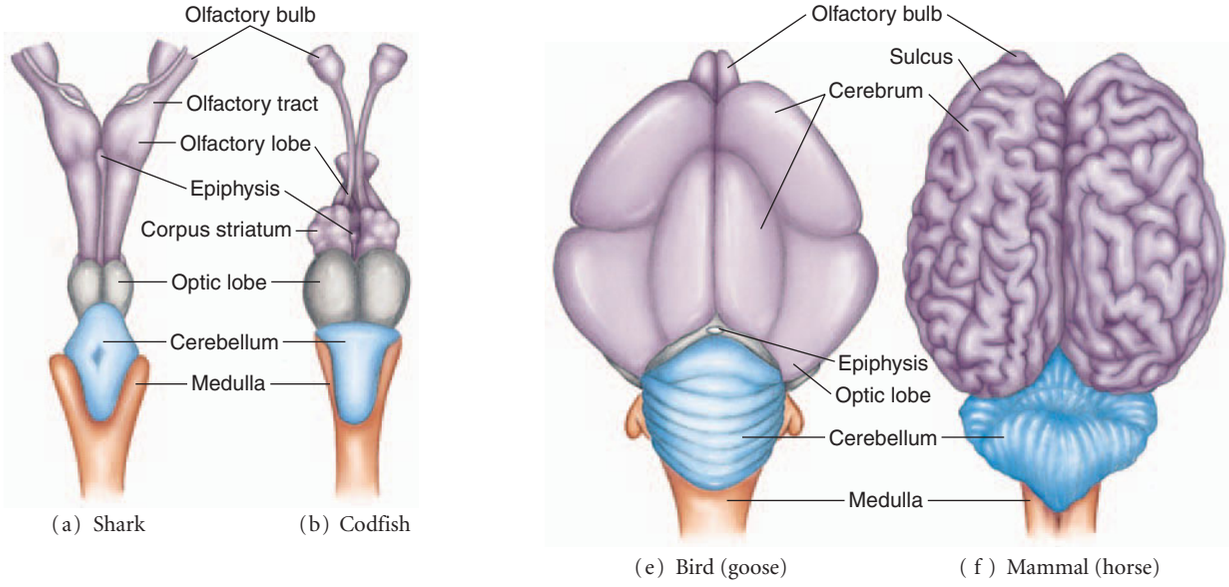


FIGURE **40-5** **Evolution of the vertebrate brain.**

Comparison of the brains of members of six vertebrate classes reveals basic similarities and evolutionary trends. (Brains are not drawn to scale.) Note that different parts of the brain are specialized in the various groups. The large olfactory lobes in the shark brain **(a)** are essential to this predator's highly developed sense of smell. **(b** through **f)** During the course of evolution, the cerebrum and cerebellum have become larger and more complex. In mammals **(f),** the cerebrum is the most prominent part of the brain; the cerebral cortex, the thin outer layer of the cerebrum, is highly convoluted (folded), which greatly increases its surface area.

The hindbrain develops into the medulla, pons, and cerebellum

The **hindbrain** subdivides to form the **metencephalon,** which gives rise to the **cerebellum** and **pons,** and the **myelencephalon,** which gives rise to the **medulla.** The medulla, pons, and midbrain make up the **brain stem,** the elongated portion of the brain that looks like a stalk holding up the cerebrum.

The medulla, the most posterior part of the brain, is continuous with the spinal cord. Its cavity, the **fourth ventricle,** is continuous with the central canal of the spinal cord and with a channel that runs through the midbrain. The walls of the medulla are thick and made up largely of *nerve tracts* (bundles of axons) that connect the spinal cord with various parts of the brain. In complex vertebrates, the medulla contains vital centers that regulate respiration, heartbeat, and blood pressure. Other reflex centers in the medulla regulate activities such as swallowing, coughing, and vomiting.

The size and shape of the cerebellum vary among the vertebrate classes (Fig. 40-5). Development of the cerebellum in different animals is roughly correlated with the extent and complexity of muscular activity, reflecting the principle that the relative size of a brain part correlates with its importance to the behavior of the species. In some fishes, birds, and mammals, the cerebellum is highly developed, whereas it tends to be small in jawless fishes, amphibians, and reptiles. The cerebellum coordinates muscle activity and is responsible for muscle tone, posture, and equilibrium.

Injury or removal of the cerebellum results in impaired muscle coordination. A bird without a cerebellum cannot fly, and its wings thrash about jerkily. When the human cerebellum is injured by a blow or by disease, muscular movements are uncoordinated. Any activity requiring delicate coordination, such as threading a needle, is very difficult, if not impossible.

In mammals, a large mass of fibers forms the pons, a bridge connecting the spinal cord and medulla with upper parts of the brain. The pons contains centers that help regulate respiration and nuclei that relay impulses from the cerebrum to the cerebellum. A **nucleus** is a group of cell bodies within the CNS.

The midbrain is prominent in fishes and amphibians

In fishes and amphibians, the **midbrain,** or **mesencephalon,** is the most prominent part of the brain, serving as the main asso-

ciation area. It receives incoming sensory information, integrates it, and sends decisions to appropriate motor nerves. The dorsal portion of the midbrain is differentiated to some extent. For example, the optic lobes are specialized for visual interpretations.

In reptiles, birds, and mammals, many functions of the optic lobes are assumed by the cerebrum, which develops from the forebrain. In mammals, the midbrain consists of the **superior colliculi,** centers for visual reflexes such as pupil constriction, and the **inferior colliculi,** centers for certain auditory reflexes. The mammalian midbrain also contains a center (the *red nucleus*) that helps maintain muscle tone and posture.

The forebrain gives rise to the thalamus, hypothalamus, and cerebrum

As indicated in Table 40-2, the **forebrain** subdivides to form the **telencephalon** and **diencephalon.** The telencephalon gives rise to the **cerebrum,** and the diencephalon to the **thalamus** and **hypothalamus.** The *lateral ventricles* (also called the first and second ventricles) lie within the cerebrum. Each lateral ventricle connects with the third ventricle (within the diencephalon) by way of a channel.

In all vertebrate classes, the thalamus is a relay center for motor and sensory messages. In mammals, all sensory messages except those from the olfactory receptors are delivered to the thalamus before they are relayed to the sensory areas of the cerebrum.

The hypothalamus, which lies below the thalamus, forms the floor of the third ventricle. The hypothalamus is a major coordinating center for regulating autonomic and somatic responses. It integrates incoming information and provides input to centers in the medulla and spinal cord that regulate activities such as heart rate, respiration, and digestive system function. In reptiles, birds, and mammals, the hypothalamus controls body temperature. It also contains olfactory centers, regulates appetite and water balance, and is important in emotional and sexual responses. As discussed in Chapter 47, the hypothalamus links the nervous and endocrine systems and produces certain hormones.

The telencephalon gives rise to the cerebrum and, in most vertebrate groups, the **olfactory bulbs.** These structures are important in the chemical sense of smell—the dominant sense in most aquatic and terrestrial vertebrates. In fact, much of brain development in vertebrates appears to focus on integrating olfactory information. In fish and amphibians, the cerebrum is almost entirely devoted to this function.

Birds are an exception among the vertebrates in that their sense of smell is generally poor. A part of their cerebrum, the *corpus striatum,* however, is highly developed. This structure controls eating, flying, singing, and other complex action patterns.

In most vertebrates, the cerebrum is divided into right and left **cerebral hemispheres.** Most of the cerebrum is made of **white matter,** which consists mainly of myelinated axons that connect various parts of the brain. In mammals and most reptiles, a layer of **gray matter,** the **cerebral cortex,** makes up the outer portion of the cerebrum. Gray matter contains cell bodies and dendrites.

Certain reptiles and all mammals have a type of cerebral cortex, the **neocortex,** not found in less complex vertebrates. The neocortex serves as an association area—a region that links sensory and motor functions and is responsible for higher functions such as learning. The neocortex is very extensive in mammals, making up the bulk of the cerebrum. In humans, about 90% of the cerebral cortex is neocortex, consisting of six distinct cell layers.

In mammals, the cerebrum is the most prominent part of the brain. During embryonic development, it expands and grows backward, covering many other brain structures. The cerebrum is responsible for many functions performed by other parts of the brain in other vertebrates. In addition, the mammalian brain has many complex association functions that reptiles, amphibians, and fishes lack.

In small or simple mammals, the cerebral cortex may be smooth. However, in large complex mammals, the surface area is greatly expanded by numerous folds called **convolutions.** The furrows between them are called **sulci** (sing., *sulcus*) if shallow and **fissures** if deep. The number of folds (not the size of the brain) has been associated with complexity of brain function.

Review

- What structures of the vertebrate brain derive from the embryonic forebrain?
- How does the mammalian brain differ from the brain of an amphibian?

BiologyNow™ Assess your understanding of **the evolution of the vertebrate brain** by taking the pretest on your BiologyNow CD-ROM.

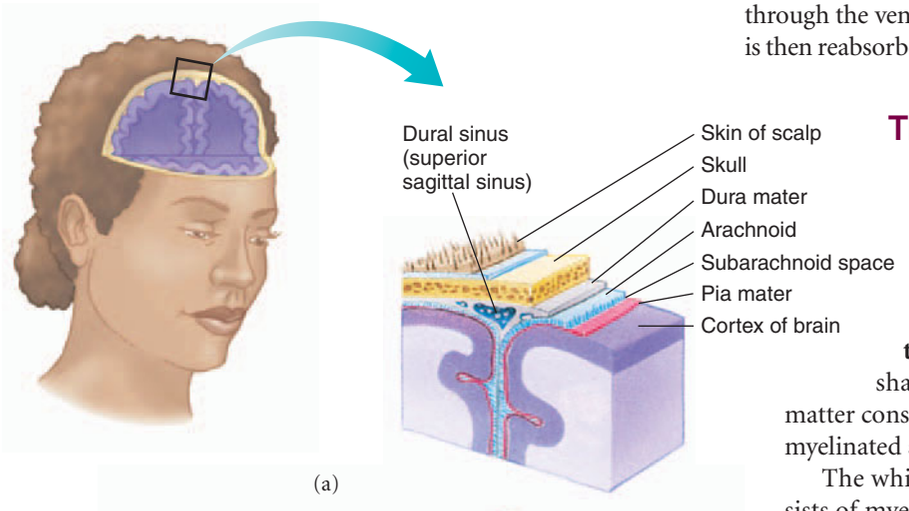
THE HUMAN CENTRAL NERVOUS SYSTEM

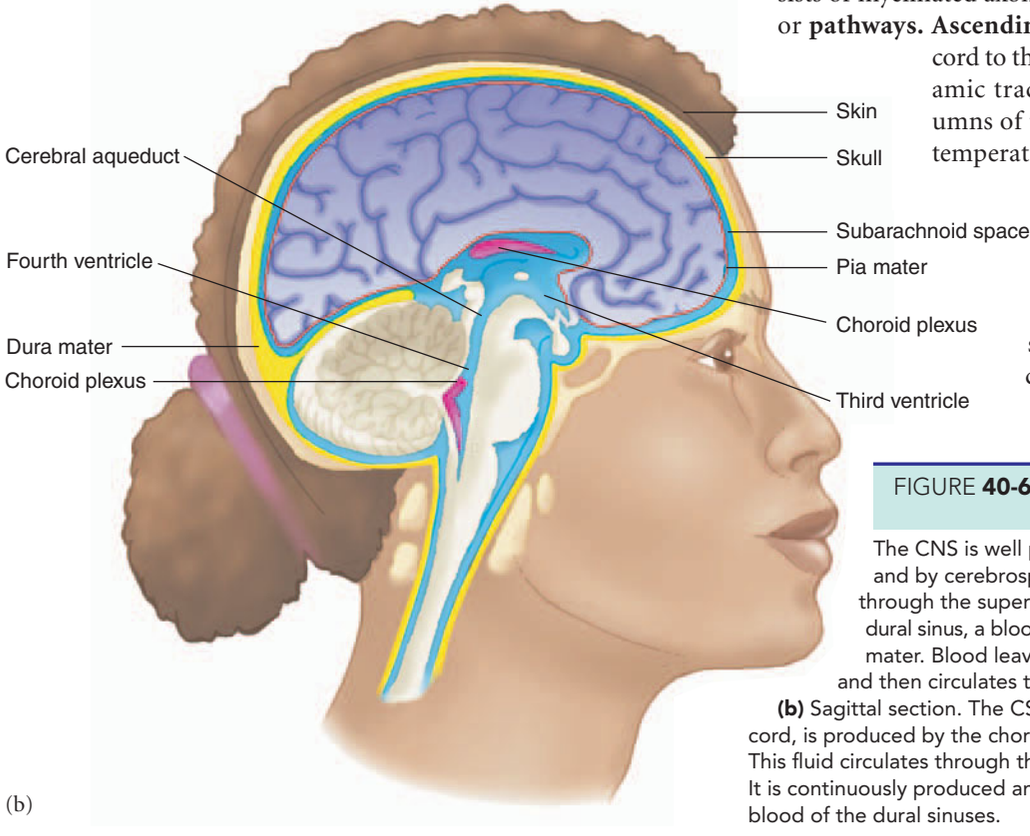
Learning Objectives

5 Describe the structure and functions of the human spinal cord.
6 Describe the structure and functions of the human cerebrum.
7 Describe the sleep–wake cycle, and contrast rapid-eye-movement (REM) sleep and non-REM sleep.
8 Describe the actions of the limbic system.
9 Summarize how the brain processes information.

The soft, fragile human brain and spinal cord are well protected. Encased within bone, they are covered by three layers of connective tissue, the **meninges.** The three meningeal layers are the tough, outer **dura mater,** the middle **arachnoid,** and the thin, vascular **pia mater,** which adheres closely to the tissue of the brain and spinal cord (Fig. 40-6). *Meningitis* is a disease in which these coverings become infected and inflamed.

The space between the arachnoid and the pia mater is the subarachnoid space, which contains **cerebrospinal fluid (CSF).** This fluid is produced by special networks of capillaries, collectively called the **choroid plexus,** that extend from the pia mater into the ventricles. CSF is a shock-absorbing fluid that cushions the brain and spinal cord against mechanical injury. This fluid also serves as a medium for exchange of nutrients and waste products between the blood and brain. CSF circulates down through the ventricles and passes into the subarachnoid space. It is then reabsorbed into large blood sinuses within the dura mater.





The spinal cord transmits impulses to and from the brain

The tubular **spinal cord** extends from the base of the brain to the level of the second lumbar vertebra. A cross-section view through the spinal cord reveals a small **central canal** surrounded by an area of gray matter shaped a bit like the letter H (Fig. 40-7). The gray matter consists of large masses of cell bodies, dendrites, unmyelinated axons, and glial cells.

The white matter, found outside the gray matter, consists of myelinated axons arranged in bundles called **tracts** or **pathways. Ascending tracts** conduct impulses up the cord to the brain. For example, the spinothalamic tracts in the anterior and lateral columns of the white matter conduct pain and temperature information from sensory neurons in the skin. The pyramidal tracts are **descending tracts** that convey impulses from the cerebrum to motor nerves at various levels in the cord. We describe the spinal nerves later in this chapter.

FIGURE **40-6** **Protection of the brain and spinal cord.**

The CNS is well protected by the skull and meninges and by cerebrospinal fluid (CSF). **(a)** Frontal section through the superior part of the brain. Note the large dural sinus, a blood sinus, between two layers of the dura mater. Blood leaving the brain flows into such sinuses and then circulates to the large jugular veins in the neck. **(b)** Sagittal section. The CSF, which cushions the brain and spinal cord, is produced by the choroid plexi in the walls of the ventricles. This fluid circulates through the ventricles and subarachnoid space. It is continuously produced and continuously reabsorbed into the blood of the dural sinuses.

In addition to transmitting impulses to and from the brain, the spinal cord controls many reflex activities. A **reflex action** is a relatively simple, involuntary motor response to a stimulus. Although most reflex actions are much more complex, let us consider a **withdrawal reflex,** in which a neural circuit consisting of three types of neurons carries out a response to a stimulus (Fig. 40-8). Suppose you touch a flame. Almost instantly, and even before you become consciously aware of what has happened, you jerk your hand away. In this brief instant a sensory neuron transmits a message from pain receptors in the skin to the spinal cord. Within the spinal cord, a sensory neuron transmits the signal to an interneuron. The interneuron integrates the information and signals an appropriate motor neuron, which conducts it to groups of muscles. The muscles respond by contracting and moving the limb toward the midline of the body, moving the hand away from the flame. Actually, many neurons

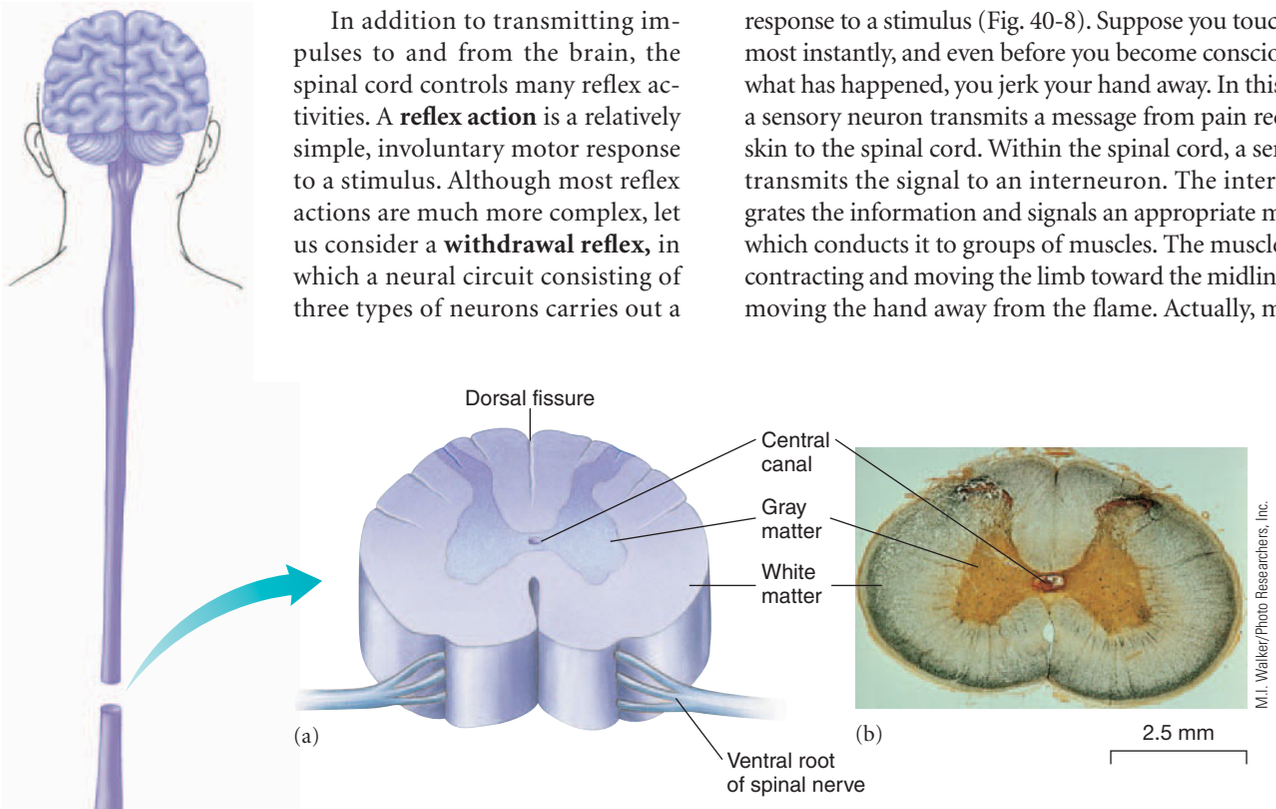


FIGURE **40-7** **Structure of the spinal cord.**

The spinal cord consists of gray matter and white matter. **(a)** Cross section through the spinal cord. **(b)** LM of a cross section through the spinal cord.

KEY CONCEPT: A reflex action is a coordinated, involuntary motor response to a stimulus.

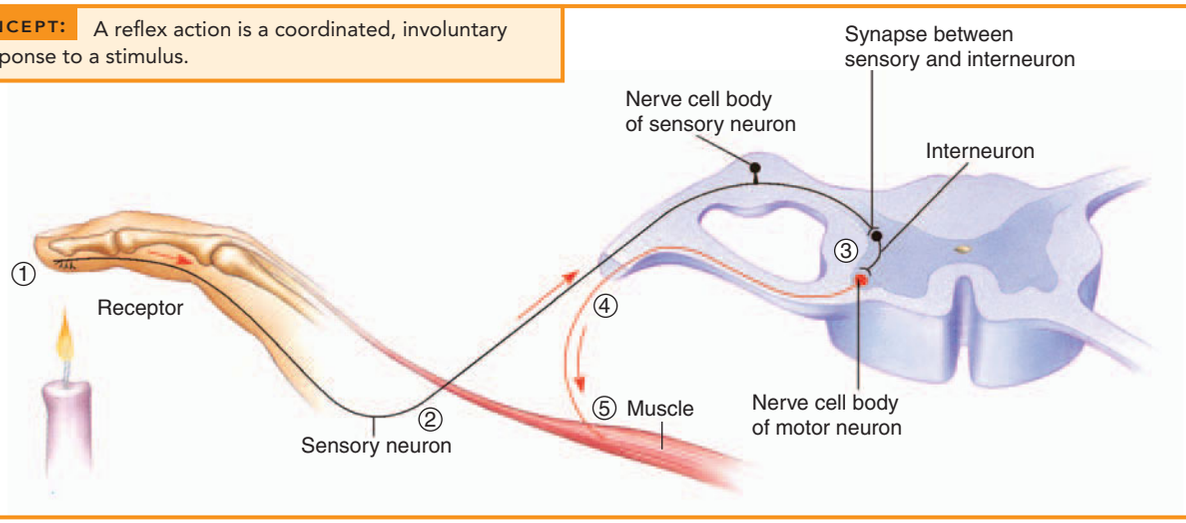

FIGURE **40-8** **Withdrawal reflex.**

① A sensory receptor signals a sensory neuron that ② transmits impulses to the CNS. ③ An interneuron integrates the information. ④ Then an appropriate motor neuron *(shown in red)* transmits impulses to the muscles. ⑤ The muscles contract, moving the hand away from the flame (the actual response).

in sensory, association, and motor nerves participate in such a reflex action. Generally we are not even consciously aware all these responding muscles exist. In summary, signals are transmitted through a withdrawal reflex in the following sequence:

Reception by sensory receptor in skin ⟶ sensory neuron transmits signal ⟶ CNS interneuron integrates information ⟶ motor neuron transmits signal ⟶ muscle contracts

At the same time the reflex pathway is activated, a message is sent up the spinal cord to the conscious areas of the brain. As you pull back your hand from the flame, you become aware of what has happened and feel the pain. This awareness, however, is not part of the reflex response.

Contrary to long-accepted dogma, the spinal cord has plasticity and is capable of training. For example, sensory feedback from walking exercise may increase the strength of neural connections in the spinal cord. If descending connections with the brain are intact, some victims of spinal cord injury (some 200,000 patients in the United States alone) could potentially develop at least some limited ability to walk again.

The most prominent part of the human brain is the cerebrum

The structure and functions of the main parts of the human brain are summarized in Table 40-3, and the brain is illustrated in Figures 40-9 and 40-10. As in other mammals, the human cerebral cortex consists of right and left *cerebral hemispheres* and is functionally divided into three areas: (1) **sensory areas** that receive incoming signals from the sense organs; (2) **motor areas** that control voluntary movement; and (3) **association areas** that link the sensory and motor areas and are responsible for thought, learning, language, memory, judgment, and personality.

Investigators have mapped the cerebral cortex, locating the areas responsible for different functions. The **occipital lobes** contain the visual centers. Stimulation of these areas, even by a blow on the back of the head, causes the sensation of light; their removal causes blindness. The centers for hearing are located in the **temporal lobes** of the brain above the ear; stimulation by a blow causes a sensation of noise. Removal of both auditory areas causes deafness. Removal of one does not cause deafness in

TABLE **40-3** The Human Brain

Structure	Description	Function
Brain stem		
Medulla	Continuous with spinal cord; primarily made up of nerves passing from spinal cord to rest of brain	Contains vital centers (clusters of neuron cell bodies) that control heartbeat, respiration, and blood pressure; contains centers that control swallowing, coughing, vomiting
Pons	Forms bulge on anterior surface of brain stem	Connects various parts of brain with one another; contains respiratory and sleep centers
Midbrain	Just above pons	Center for visual and auditory reflexes (e.g., pupil reflex, blinking, adjusting ear to volume of sound)
Thalamus	At top of brain stem	Main sensory relay center for conducting information between spinal cord and cerebrum; neurons in thalamus sort and interpret all incoming sensory information (except olfaction) before relaying messages to appropriate neurons in cerebrum
Hypothalamus	Just below thalamus; pituitary gland is connected to hypothalamus by stalk of neural tissue	Contains centers for control of body temperature, appetite, fat metabolism, and certain emotions; regulates pituitary gland
Cerebellum	Second largest division of brain	Reflex center for muscular coordination and refinement of movements
Cerebrum	Largest, most prominent part of human brain; longitudinal fissure divides cerebrum into right and left hemispheres, each divided into lobes: frontal, parietal, temporal, and occipital lobes	Center of intellect, memory, consciousness, and language; also controls sensation and motor functions
Cerebral cortex (outer gray matter)	Arranged into convolutions (folds) that increase surface area; functionally, cerebral cortex is divided into	
	1. Motor areas	Control movement of voluntary muscles.
	2. Sensory areas	Receive incoming information from eyes, ears, pressure and touch receptors, etc.
	3. Association areas	Sites of intellect, memory, language, and emotion; interpret incoming sensory information
White matter	Consists of myelinated axons of neurons that connect various regions of brain; these axons are arranged into bundles (tracts)	Connects the following: 1. Neurons within same hemisphere 2. Right and left hemispheres 3. Cerebrum with other parts of brain and spinal cord

Half of the brain has been cut away, exposing structures normally covered by the cerebrum. Compare the diagram **(a)** with the photograph of the human brain **(b).**

one ear but rather produces a decrease in the auditory acuity of both ears.

A groove called the **central sulcus** crosses the top of each hemisphere from medial to lateral edge. This groove partially separates the **frontal lobes** from the **parietal lobes.** The frontal lobes have important motor and association areas. The **prefrontal cortex** is an association area in each frontal lobe that is crucial in evaluation, judgment, planning, and organizing responses. The **general motor areas** in the frontal lobes control the skeletal muscles. The **primary sensory areas** in the parietal lobes receive information regarding heat, cold, touch, and pressure from sense organs in the skin.

The size of the motor area in the brain for any given part of the body is proportional not to the amount of muscle, but to the complexity of movement involved. Predictably, areas that control the hands and face are relatively large (Fig. 40-11). A similar relationship exists between the sensory area and the sensitivity of the region of the skin from which it receives impulses. Neural fibers in the brain cross so that one side of the brain controls the opposite side of the body. As a result of another "reversal," the uppermost part of the cortex controls the lower limbs of the body.

When all the areas of known function are plotted, they cover almost all of the rat's cortex, a large part of the dog's, a moderate amount of the monkey's, and only a small part of the total surface of the human cortex. The remaining cortical areas are the association areas. Somehow the association regions integrate all the diverse impulses reaching the brain into a meaningful unit so that an appropriate response is made. When disease or accident destroys the functioning of one or more association areas, the ability to recognize certain kinds of symbols may be lost. For example, the names of objects may be forgotten, although their functions are remembered and understood.

The white matter of the cerebrum lies beneath the cerebral cortex. Nerve fibers of the white matter connect the cortical areas with one another and with other parts of the nervous system. A large band of white matter, the **corpus callosum,** connects the right and left hemispheres (see Fig. 40-10).

Deep within the white matter of the cerebrum lie the **basal ganglia,** paired groups of nuclei (gray matter). These nuclei play

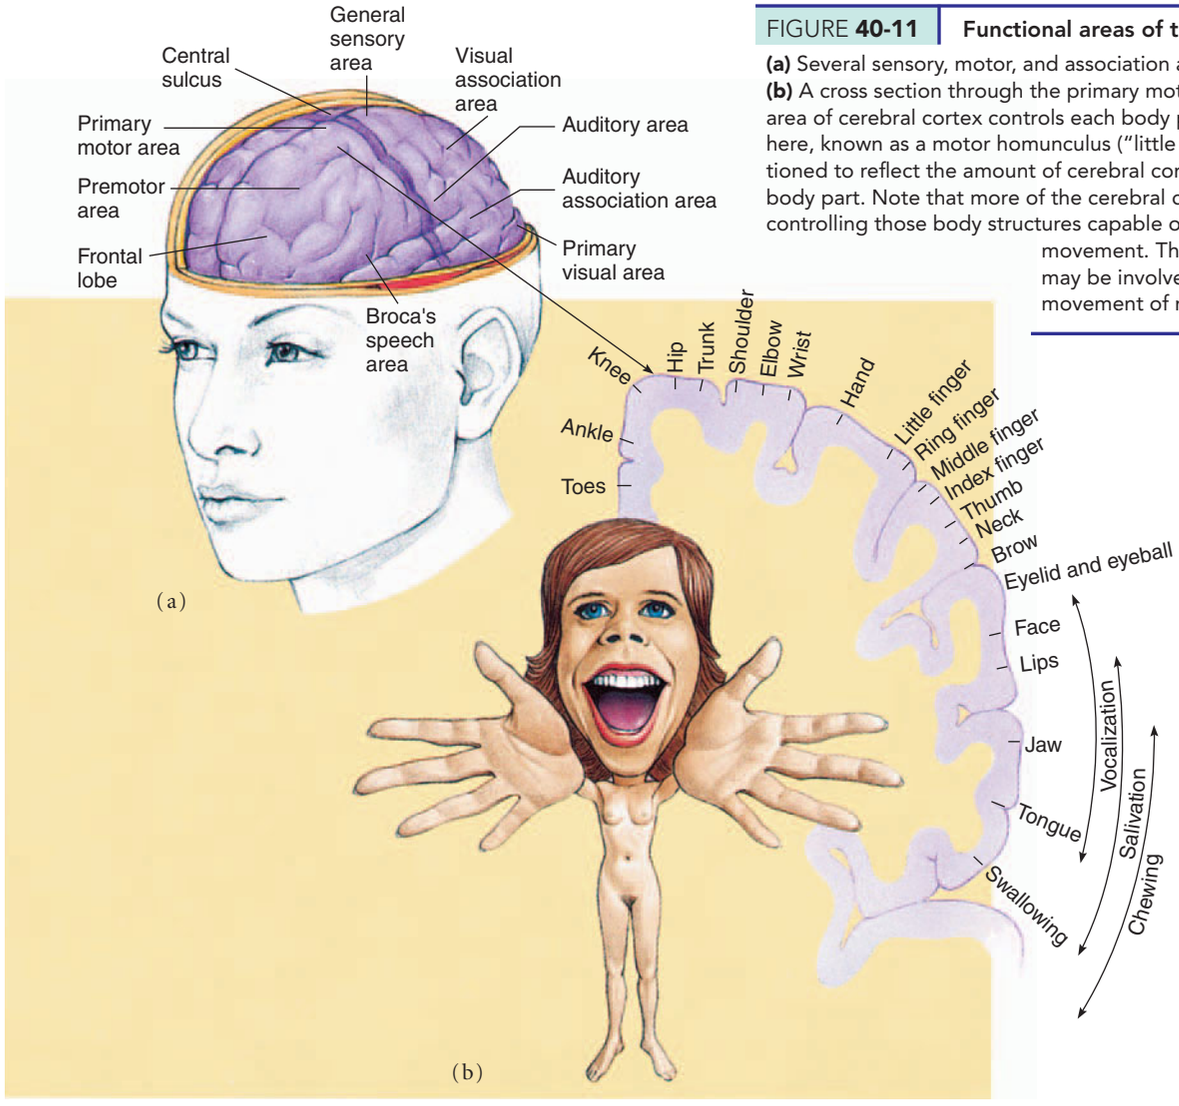

FIGURE **40-11** **Functional areas of the brain.**

(a) Several sensory, motor, and association areas are shown. **(b)** A cross section through the primary motor area showing which area of cerebral cortex controls each body part. The figure shown here, known as a motor homunculus ("little person"), is proportioned to reflect the amount of cerebral cortex that controls each body part. Note that more of the cerebral cortex is devoted to controlling those body structures capable of skilled, complex movement. The primary motor area may be involved in coordinated movement of many muscle groups.

an important role in coordinating movement. The basal ganglia send signals to the **substantia nigra** in the midbrain, and they receive inputs back from the substantia nigra. The neurons that project (extend) to the basal ganglia produce **dopamine,** a neurotransmitter essential for sensory-motor coordination. Dopamine helps balance inhibition and excitation of neurons involved in motor function. Other neurons from the substantia nigra signal nuclei in the thalamus, which in turn relay information to the motor cortex. The substantia nigra neurons that signal the thalamus release the neurotransmitter **gamma-aminobutyric acid (GABA).** Just how these areas work together to coordinate motor function is not yet fully understood.

Brain activity cycles in a sleep–wake pattern

Brain activity can be studied by measuring and recording the electrical potentials, or "brain waves," generated by thousands of active neurons in various parts of the brain. This electrical activity can be recorded by a device known as an *electroencephalograph.* To obtain a recording of this electrical activity, called an **electroencephalogram (EEG),** electrodes are taped to different parts of the scalp, and the activity of the cerebral cortex is measured. The EEG shows the brain is continuously active. The most regular indication of activity appears to be **alpha waves,** which occur rhythmically at the rate of about 10 per second (Fig. 40-12).

Alpha waves are generated mainly from the visual areas in the occipital lobes when the person being tested is resting quietly with eyes closed. When the eyes are opened, alpha waves disappear and are replaced by more rapid, irregular waves. As you are reading this biology text, your brain is emitting **beta waves.** These waves have a fast-frequency rhythm that represent heightened mental activity such as information processing. During sleep, the brain emits waves with a lower frequency and a higher amplitude. The slow, large waves associated with certain stages of sleep are called **delta waves** and **theta waves.** During dreaming, flurries of irregular waves occur.

Certain brain diseases change the pattern of brain waves. Individuals with epilepsy, for example, exhibit a distinctive, recognizable, abnormal wave pattern. The location of a brain tumor or the site of brain damage caused by a blow to the head can sometimes be determined by noting the part of the brain that shows abnormal waves.

The **reticular activating system (RAS)** is a complex neural pathway within the brain stem and thalamus. The RAS receives messages from neurons in the spinal cord and from many other parts of the nervous system and communicates with the cerebral cortex by complex neural circuits. Components of the RAS help regulate **consciousness**—a state of awareness, or of selective attention. When certain neurons of the RAS bombard the cerebral cortex with stimuli, you feel alert and can focus on specific thoughts. If the RAS is severely damaged, the victim may pass into a deep, permanent coma.

Sleep is an alteration of consciousness during which there is decreased electrical activity of the cerebral cortex and from which a person can be aroused. Two main stages of sleep are recognized: **non-REM** and **REM.** *REM* is an acronym for *rapid eye movement.* During non-REM sleep, sometimes called normal sleep, metabolic rate decreases, breathing slows, and blood pressure decreases. Slower-frequency, higher-amplitude waves (theta and delta waves) are characteristic of non-REM sleep. This electrical activity is thought to be generated spontaneously by the cerebral cortex when it is not driven by impulses from other parts of the brain.

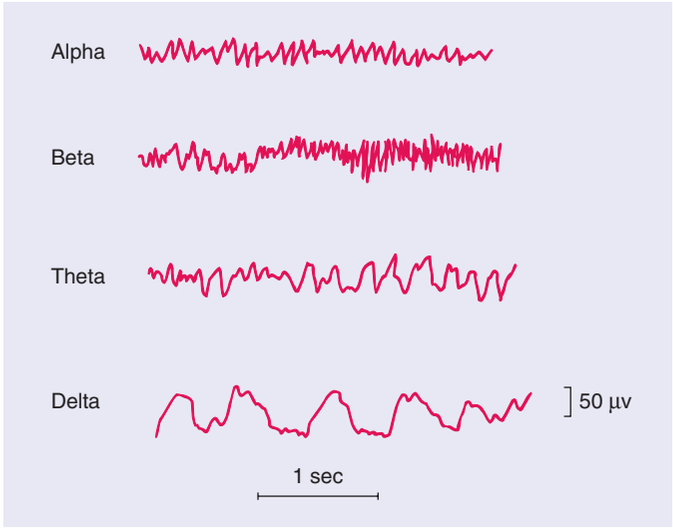

FIGURE **40-12** **EEGs showing electrical activity in the brain.**

The regular waves characteristic of the relaxed state are called *alpha waves.* During mental activity, rapid, low-amplitude beta waves are dominant. Recordings made in various stages of sleep show theta and delta waves, which have a lower frequency and greater amplitude.

Every 90 minutes or so, a sleeping person enters the REM stage for a time. During this stage (about one fourth of total sleep time), the eyes move about rapidly beneath the closed but fluttering lids. Brain waves change to a desynchronized pattern. Sleep researchers claim everyone dreams, especially during REM sleep. Positron emission tomography (PET) scans of sleeping subjects indicate that during REM sleep, blood flow in the frontal lobes is reduced. In contrast, blood flow increases in areas that produce visual scenes and emotion. During REM sleep, neurons in the RAS release the neurotransmitter **norepinephrine,** which stimulates heightened activity in certain regions of the brain.

The hypothalamus and brain stem regulate the sleep-wake cycle. Using rats, researchers have demonstrated that stimulation of the *preoptic nucleus* of the hypothalamus results in non-REM sleep. The preoptic nucleus is located near the **suprachiasmatic nucleus,** the most important of the body's biological clocks. The suprachiasmatic nucleus receives information about the duration of light and dark from the retina of the eye and apparently transmits this information to the preoptic nucleus. The fatigue and decreased physical and mental performance referred

to as jet lag occur when we fly to a different time zone where the body is no longer synchronized with the light–dark cycle.

The *raphe nuclei* in the brain stem (lower pons and medulla) appear important in producing REM sleep. Many neurons that project from the raphe nuclei release **serotonin,** a neurotransmitter involved in sleep. After many hours of activity, the sleep–wake cycle may be affected by fatigue of the RAS. Sleep centers are then activated, and their neurons release serotonin. After sufficient rest, the inhibitory neurons of the sleep centers become less excitable, and the excitatory neurons of the RAS become more excitable.

Although birds, mammals, and many other animals have a sleep–wake cycle, neurophysiologists do not know why sleep is necessary. Recent research suggests sleep may be important in learning and in processing memories. When a person stays awake for unusually long periods, fatigue and irritability result, and even routine tasks aren't performed well. Both non-REM and REM sleep are necessary. In sleep deprivation experiments with human volunteers, lack of REM sleep makes the participants anxious and irritable. When they are permitted to sleep normally again, they spend more time than usual in the REM stage for a while. Many types of drugs, such as amphetamines, alter sleep patterns and affect the amount of REM sleep. Certain drugs that induce sleep may increase total sleeping time but decrease REM time. When a person stops taking such a drug, several weeks may be required before normal sleep patterns are re-established.

The limbic system affects emotional aspects of behavior

The **limbic system** includes parts of the cerebrum (parts of the frontal lobe, temporal lobe, hippocampus, and amygdala), parts of the thalamus, and hypothalamus, several nuclei in the midbrain, and the neural pathways that connect these structures. The limbic system affects the emotional aspects of behavior, evaluates rewards, and is important in motivation. This system also plays a role in sexual behavior, biological rhythms, and autonomic responses.

The **hippocampus** functions in the formation and retrieval of verbal and emotional memories. It lets us place our experience in categories and store it along with similar memories. The **amygdala** evaluates the emotional aspects of experience and when it perceives a threat, it signals danger. The amygdala becomes hypersensitive to possible danger following a traumatic experience (see *On the Cutting Edge: The Neurophysiology of Traumatic Experience.*)

Researchers first discovered that the limbic system is part of an important motivational system in the 1950s when they implanted electrodes in certain areas of the brains of laboratory animals. They found that a rat may press, as many as 15,000 times per hour, a lever that stimulates a reward circuit in the brain. The rat forgoes food and water in favor of self-stimulation until it drops from exhaustion. This reward circuit, the **mesolimbic dopamine pathway,** includes two important areas in the midbrain, the substantia nigra and adjacent ventral tegmental area. These areas, which extend into behavioral control centers in the limbic system, contain the largest group of neurons that release dopamine in the brain. The mesolimbic dopamine pathway (important in motivation and experiencing emotion) enables an individual to experience pleasure in response to certain events or substances.

Dopamine neurons are activated by novel stimuli associated with reward or pleasure. These neurons signal us about surprising events or stimuli that predict rewards. Dopamine may motivate us to act when something important is happening. These mechanisms may help us understand attention deficit disorder (ADD) and schizophrenia, disorders associated with excessive amounts of dopamine and other neurotransmitters in the brain. People with these disorders have difficulty filtering out sensory stimuli. The presence of excess dopamine may drive them to divert their attention to so many sensory stimuli that they have difficulty focusing on the most important stimuli.

Learning involves the storage of information and its retrieval

Learning is the process by which we acquire information as a result of experience. Laboratory experiments have shown that members of every animal phylum can learn. For learning to occur, we must be able to remember what we experience. **Memory** is the process by which information is encoded, stored, and retrieved. **Implicit memory** is unconscious memory for perceptual and motor skills, such as riding a bicycle. **Explicit memory** involves factual knowledge of people, places, or objects, and requires conscious recall of the information.

Information processing involves short- and long-term memory

At any moment you are bombarded with thousands of bits of sensory information. At this very moment, your eyes are receiving information about the words on this page, the objects around you, and the intensity of the light in the room. At the same time you may be hearing a variety of sounds—music, your friends talking in the next room, the hum of an air conditioner. Your olfactory epithelium may sense cologne or the smell of coffee. Maybe you are eating as you read. Sensory receptors in your hands may be receiving information regarding the weight and position of your book. Most sensory stimuli are not important to remember and so are filtered out.

When we select information to remember, we must process it. Information processing involves both **short-term memory,** which lasts only minutes, and **long-term memory,** which may last for many years. Typically, we can hold only about seven chunks of information (a chunk is some unit such as a word, syllable, or number) at a time in short-term memory. Short-term memory lets us recall information for a few minutes. Usually when we look up a phone number, for example, we remember it only long enough to dial. If we need the same number an

Hypothesis: Traumatic experience can cause changes in the brain that affect information processing.

Method: Neuroimaging studies were performed on the brain structure and function of individuals who had survived traumatic experiences.

Results: Both structural and functional changes were identified, including increased activation of the amygdala and decreased activity in the anterior cingulate cortex and in Broca's area.

Conclusion: Traumatic experience causes changes in the brain that may mediate responses to reminders of the experience.

Terrorist acts, such as the 9/11 terrorist attack on the World Trade Center and the recent war in Iraq, have heightened our awareness of the effects of traumatic experiences. A *traumatic experience* is an event (or events) that causes intense fear, helplessness, or horror and that overwhelms normal coping and defense mechanisms. Whether you are a combat veteran, a survivor of childhood abuse, or the victim of a robbery, rape, a hurricane, or domestic violence, you may have experienced the effects of trauma.

We can process moderately disturbing experiences more easily than traumatic experiences. If you were one of the millions of people who were glued to their television sets on 9/11 or watched as people were wounded in Iraq, you may have been disturbed by the events you witnessed. You probably processed what you saw and heard by thinking and talking about it, perhaps even writing about it. You may have dreamed about your experience. As the brain actively reviews and sorts out an experience, we make sense of what happened and store the memory along with other memories of more ordinary past events. The emotional intensity decreases, and the memory of the uncomfortable experience fades in importance.

Traumatic events are more difficult to process. If you are one of the survivors who actually ran for your life as the World Trade Center fell, or if you are a combat veteran, your body's response to the danger is more intense. Years later, your brain may still be secreting abnormally high amounts of norepinephrine and other neurotransmitters, and you may remain on red alert for possible danger.

How does the brain respond in a traumatic experience, and how does the experience affect the brain? When danger threatens, the amygdala sends messages to both the hypothalamus (which signals the autonomic system and the endocrine system) and the neocortex (which allows us to be conscious of our experience). The amygdala is programmed to remember the smells, sounds, and sensations that are part of the experience. Until the memories of the experience are fully processed, similar smells, sounds, and sensations remind us of the traumatic event and trigger the body to prepare for danger. The individual experiences fear and anxiety. Some trauma survivors develop Posttraumatic Stress Disorder (PTSD), a condition in which they experience (1) intrusive thoughts, images, sensory experiences, memories, and dreams; (2) an urge to avoid reminders of the traumatic event; and (3) physiological hyperarousal, a condition in which the body is on red alert, continuously scanning the environment for potential danger.

Because they are so overwhelming, traumatic memories are very difficult to process. They cause us so much discomfort and anxiety that we tend to avoid them rather than intentionally focus on them and sort them out. As a result, traumatic memories seem to stay "stuck" in the limbic system, and when triggered, the experience is replayed with its original emotional intensity (a flashback).

Several neuroimaging studies have shown an association between prolonged trauma (for example, severe child abuse) and long-term changes in the brain. These changes include significantly smaller total brain and cerebral volumes, decreased right–left hemisphere integration, decreased size of the corpus callosum, EEG abnormalities, and decreased volume of the hippocampus and amygdala.*

Neuroimaging studies have also demonstrated changes in brain function, including increased amygdalar response and decreased cortical response. Scott Rauch, of Massachusetts General Hospital and Harvard Medical School, and his colleagues used functional magnetic resonance imaging (fMRI) to measure amygdalar response to masked, fearful face targets.† They found exaggerated amygdalar responses in subjects with PTSD. These investigators suggested these intense responses occurred in the absence of the normal mediating influence of the medial prefrontal cortex.

Using fMRI, Lisa Shin of Harvard Medical School, and her colleagues reported findings that support the hypothesis of the Rauch group.‡ When these researchers presented subjects with reminders of their traumatic experience, they observed decreased activity in the rostral anterior cingulate cortex (ACC). This area, part of the medial prefrontal cortex, normally inhibits the amygdala so that it does not respond too strongly. When the ACC does not function normally, cerebral blood flow to the amygdala increases (and can be seen on neuroimages). The amygdala overresponds, and the individual experiences physiological hyperarousal, distress, and anxiety, which may lead to intense emotional reactions that are rooted in the traumatic experience.

Broca's area, a region in the posterior part of the left frontal cortex, is also affected by trauma. Broca's area is critically important in generating words and thus in expressing language. Researchers have shown that when subjects are exposed to accounts of their traumatic experiences, activity in Broca's area decreases. This deactivation appears to be the physiologic basis for the difficulty that trauma survivors have describing their experience in words. Trauma survivors have described flashbacks of their experience as being in a state of "speechless terror." Without words, it is difficult to process and resolve a traumatic experience.

Given these and other studies, we can conclude that traumatic experience affects the brain and that many trauma survivors respond strongly to triggers that remind them of their experience. The exaggerated responses of the amygdala to harmless stimuli perceived as threatening is dissociated from cortical (medial prefrontal) activation. Responses generated by the limbic system are rooted in emotion rather than in rationality and judgment.

hour later, most of us have to look it up again. One hypothesis of short-term memory suggests that reverberating circuits are involved (see Fig. 39-12). A memory circuit may continue to reverberate for several minutes until it fatigues or until new signals interfere with the old.

When we begin to process information, we *encode* it. We recognize patterns and meaningfully associate the stimuli to past experience or knowledge. We integrate the new information with other knowledge already stored in the brain. When information is selected for long-term storage, the brain rehearses the material and then stores it in long-term memory in association with similar memories. Several minutes are required for the brain to *consolidate* a new memory. Consolidation depends on the hippocampus and involves expression of genes and protein synthesis. If a person suffers a brain concussion or undergoes electroconvulsive therapy, memory of what happened immediately before the incident may be completely lost. This is known as *retrograde amnesia.* When the hippocampus is damaged, short-term memory is unimpaired and the patient can still recall information stored in the past. However, new short-term memories can no longer be converted to long-term memories. The hippocampus temporarily holds new information and may integrate various aspects of an experience, including odors, sounds, and other information. Consolidation allows memories to be *stored* for long periods.

Where are memories stored? Some forms of learning take place in association areas within lower brain regions, such as the thalamus. When large areas of the mammalian cerebral cortex are destroyed, information is lost somewhat in proportion to the extent of lost tissue. However, no specific area can be labeled the "memory bank." Rather, memories seem to be stored within many areas of the brain. For example, visual memories may be stored in the visual centers of the occipital lobes, and auditory memories may be stored in the temporal lobes. Researchers think memories are integrated in many areas of the brain, including the amygdala and the hippocampus, association areas of the cerebral cortex, and the thalamus and hypothalamus. **Wernicke's area** in the temporal lobe has been identified as a very important association area for complex thought processes. This area is an important center for language function involved in recognizing and interpreting words. Neurons within the association areas form highly complex pathways that permit complicated reverberation.

Retrieval of information stored in long-term memory is of considerable interest—especially to students! The challenge is to find information when you need it. When you seem to forget something, the problem may be that you have not searched effectively for the memory. Information retrieval can be improved by careful encoding, for example, forming strong associations between items.

Neurophysiological changes occur during learning

Short-term memory involves changes in the neurotransmitter receptors of postsynaptic neurons. These changes strengthen synaptic connections. The receptors are linked by second messengers (for example, cyclic AMP) to ion channels.

In long-term memory, gene expression and protein synthesis take place. This process involves slower, but longer lasting, changes in synaptic connections. Long-term memory depends on activated receptors linked to G proteins. Cyclic AMP acts as a second messenger. A high level of cyclic AMP activates a protein kinase that enters the nucleus, leading to gene activation and protein synthesis. In this process, protein kinase phosphorylates a transcription factor known as **CREB** (for *cyclic AMP response element binding protein*). CREB then turns on the transcription process of certain genes. CREB has been shown to be a signaling molecule in the memory pathway in many animals, including fruit flies and mice. The molecules and processes involved in learning and memory have been highly conserved during evolution.

In some types of learning, changes take place in presynaptic terminals or postsynaptic neurons that permanently enhance or inhibit the transmission of impulses. In some cases, specific neurons may become more sensitive to neurotransmitter. Unraveling the mechanisms that change the strength of synaptic connections appears important in understanding learning. Neurons typically transmit action potentials in bursts, and the amount of neurotransmitter released by each action potential may increase or decrease.

Recall from the beginning of the chapter that repeated electrical stimulation of neurons causes a functional change at synapses. When a presynaptic neuron continues to transmit action potentials at a high rate for a minute or longer, there is a long-lasting, *increased* response of postsynaptic neurons. This increased strength of the synaptic connections is known as **long-term potentiation (LTP).** (Potentiation means to strengthen or make more potent.)

Low-frequency stimulation of neurons results in a long-lasting *decrease* in the strength of their synaptic connections, called **long-term depression (LTD),** also known as synaptic depression. Induction of LTP and LTD require activation of *NMDA receptors,* which are present on the plasma membranes of postsynaptic neurons. These receptors control the passage of calcium ions into neurons. Information storage and forgetting appear to depend on the strengthening and weakening of synaptic connections brought about by LTP and LTD.

Experience affects development and learning

Many studies have demonstrated neural plasticity, the ability to change in response to environmental stimuli, in rats and other laboratory animals exposed to enriched environments. In contrast with rats housed in standard cages and provided with the basic necessities, those exposed to enriched environments are given toys and other stimulating objects, as well as the opportunity to socially interact with other rats. Animals reared in a complex environment exhibit increased synaptic contacts and process and remember information more quickly than animals not given such advantages. Mice exposed to enriched environ-

ments develop significantly greater numbers of neurons in the hippocampus and learn mazes significantly faster than controls.

Early environmental stimulation can also enhance the development of motor areas in the brain. For example, the brains of rats encouraged to exercise become slightly heavier than those of control animals. Characteristic changes occur within the cerebellum, including the development of larger dendrites.

Apparently, during early life certain critical or sensitive periods of nervous system development occur that are influenced by environmental stimuli. For example, when the eyes of young mice first open, neurons in the visual cortex develop large numbers of dendritic spines (structures on which synaptic contact takes place). If the animals are kept in the dark and deprived of visual stimuli, fewer dendritic spines form. If the mice are exposed to light later in life, some new dendritic spines form, but never as many as develop in a mouse reared in a normal environment.

Studies linking the development of the brain with environmental experience indicate that early stimulation is important for the sensory, motor, and intellectual development of children. Such studies have led to the rapidly expanding educational toy market and to widespread acceptance of early education programs. Researchers have also suggested that continuing environmental stimulation is needed to maintain the status of the cerebral cortex in later life.

THE PERIPHERAL NERVOUS SYSTEM

Learning Objectives

10 Describe the organization of the peripheral nervous system, comparing the somatic and autonomic divisions.

11 Contrast the sympathetic and parasympathetic divisions of the autonomic system, giving examples of the effects of these systems on specific organs such as the heart and intestine.

The peripheral nervous system (PNS) consists of the sensory receptors, the nerves that link these receptors with the CNS, and the nerves that link the CNS with the effectors (muscles and glands). The somatic division of the PNS helps the body respond to changes in the external environment. The nerves and receptors that maintain homeostasis despite internal changes make up the autonomic division.

The somatic division helps the body adjust to the external environment

The **somatic division** of the PNS includes the receptors that react to changes in the external environment, the sensory neurons that inform the CNS of those changes, and the motor neurons that adjust the positions of the skeletal muscles that help maintain the body's posture and balance. In mammals, 12 pairs of **cranial nerves** emerge from the brain. They transmit information regarding the senses of smell, sight, hearing, and taste from the special sensory receptors as well as information from the general sensory receptors, especially in the head region. For example, cranial nerve II, the optic nerve, transmits signals from the retina of the eye to the brain. The cranial nerves also bring orders from the CNS to the voluntary muscles that control movements of the eyes, face, mouth, tongue, pharynx, and larynx. Cranial nerve VII, the facial nerve, for example, transmits signals to the muscles used in facial expression and to the salivary glands.

In humans, 31 pairs of **spinal nerves** emerge from the spinal cord. Named for the general region of the vertebral column from which they originate, they comprise 8 pairs of cervical, 12 pairs of thoracic, 5 pairs of lumbar, 5 pairs of sacral, and 1 pair of coccygeal spinal nerves.

Each spinal nerve has a dorsal root and a ventral root (Fig. 40-13). The dorsal root consists of afferent fibers that transmit information from the sensory receptors to the spinal cord. Just before the dorsal root joins with the cord, it is marked by a swelling, the spinal ganglion, which consists of the cell bodies of the sensory neurons. The ventral root is a grouping of the efferent fibers leaving the cord en route to the muscles and glands. Cell bodies of the motor neurons occur within the gray matter of the cord.

Peripheral to the junction of the dorsal and ventral roots, each spinal nerve divides into branches. The autonomic branch innervates the viscera. The dorsal branch serves the skin and muscles of the back. The ventral branch serves the skin and muscles of the sides and ventral part of the body. The ventral branches of several spinal nerves form tangled networks called *plexi* (sing., *plexus*). Within a plexus, the fibers of a spinal nerve may separate and then regroup with fibers that originated in other spinal nerves. Thus nerves emerging from a plexus consist of neurons from several different spinal nerves.

The autonomic division regulates the internal environment

The **autonomic division** helps maintain homeostasis in the internal environment. For instance, it regulates the heart rate and helps maintain a constant body temperature. The autonomic system works automatically and without voluntary input. Its effectors are smooth muscle, cardiac muscle, and glands. Like the somatic system, it is functionally organized into reflex pathways. Receptors within the viscera relay information via afferent nerves to the CNS. The information is integrated at various

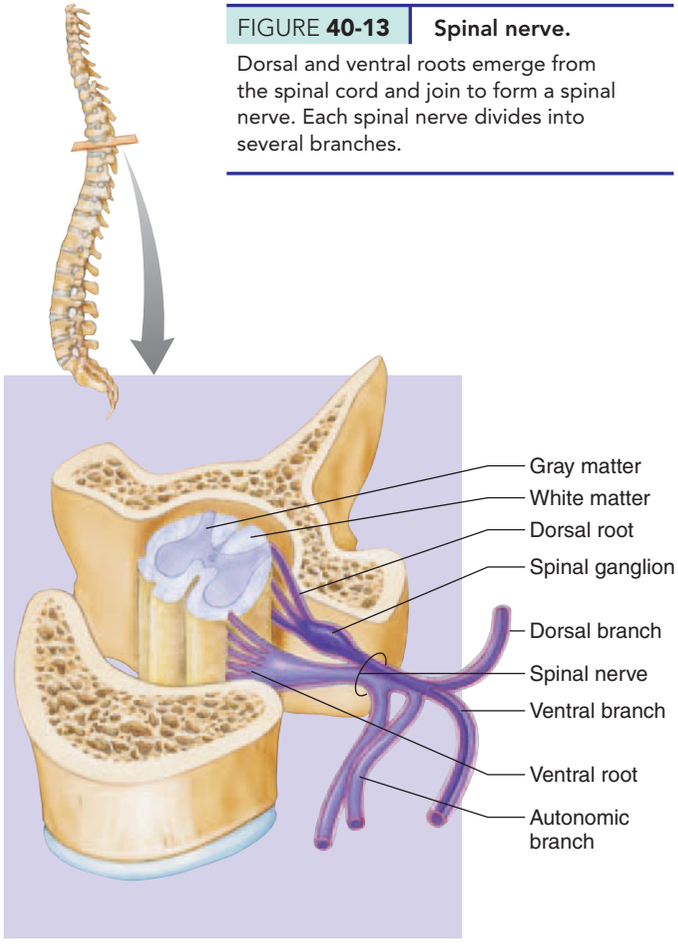

FIGURE 40-13 Spinal nerve.

Dorsal and ventral roots emerge from the spinal cord and join to form a spinal nerve. Each spinal nerve divides into several branches.

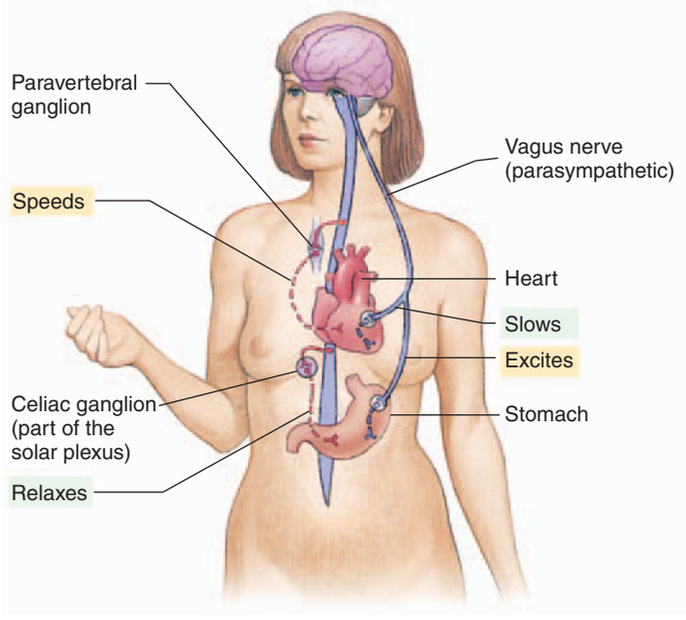

FIGURE 40-14 Dual innervation of the heart and stomach.

A sympathetic nerve increases the heart rate, whereas the vagus nerve, a parasympathetic nerve, slows the heartbeat. In contrast, sympathetic nerves slow contractions of the stomach and intestine while the vagus nerve stimulates contractions of the digestive organs. Sympathetic nerves are shown in red; postganglionic fibers are shown as dotted lines.

levels. Then the decision is transmitted along efferent nerves to the appropriate muscles or glands.

Afferent and efferent neurons of the autonomic division lie within cranial or spinal nerves. For example, afferent fibers of cranial nerve X, the vagus nerve, transmit signals from many organs of the chest and upper abdomen to the CNS. Its efferent fibers transmit signals from the brain to the heart, stomach, small intestine, and several other organs.

The efferent portion of the autonomic division is subdivided into **sympathetic** and **parasympathetic systems.** Many organs are innervated by both types of nerves. In general, sympathetic and parasympathetic systems have *opposite* effects (Figs. 40-14 and 40-15). For example, the heart rate is speeded up by messages from sympathetic nerve fibers and slowed by impulses from its parasympathetic nerve fibers. In many cases sympathetic nerves operate to stimulate organs and to mobilize energy, especially in response to stress, whereas the parasympathetic nerves influence organs to conserve and restore energy, particularly during quiet, calm activities.

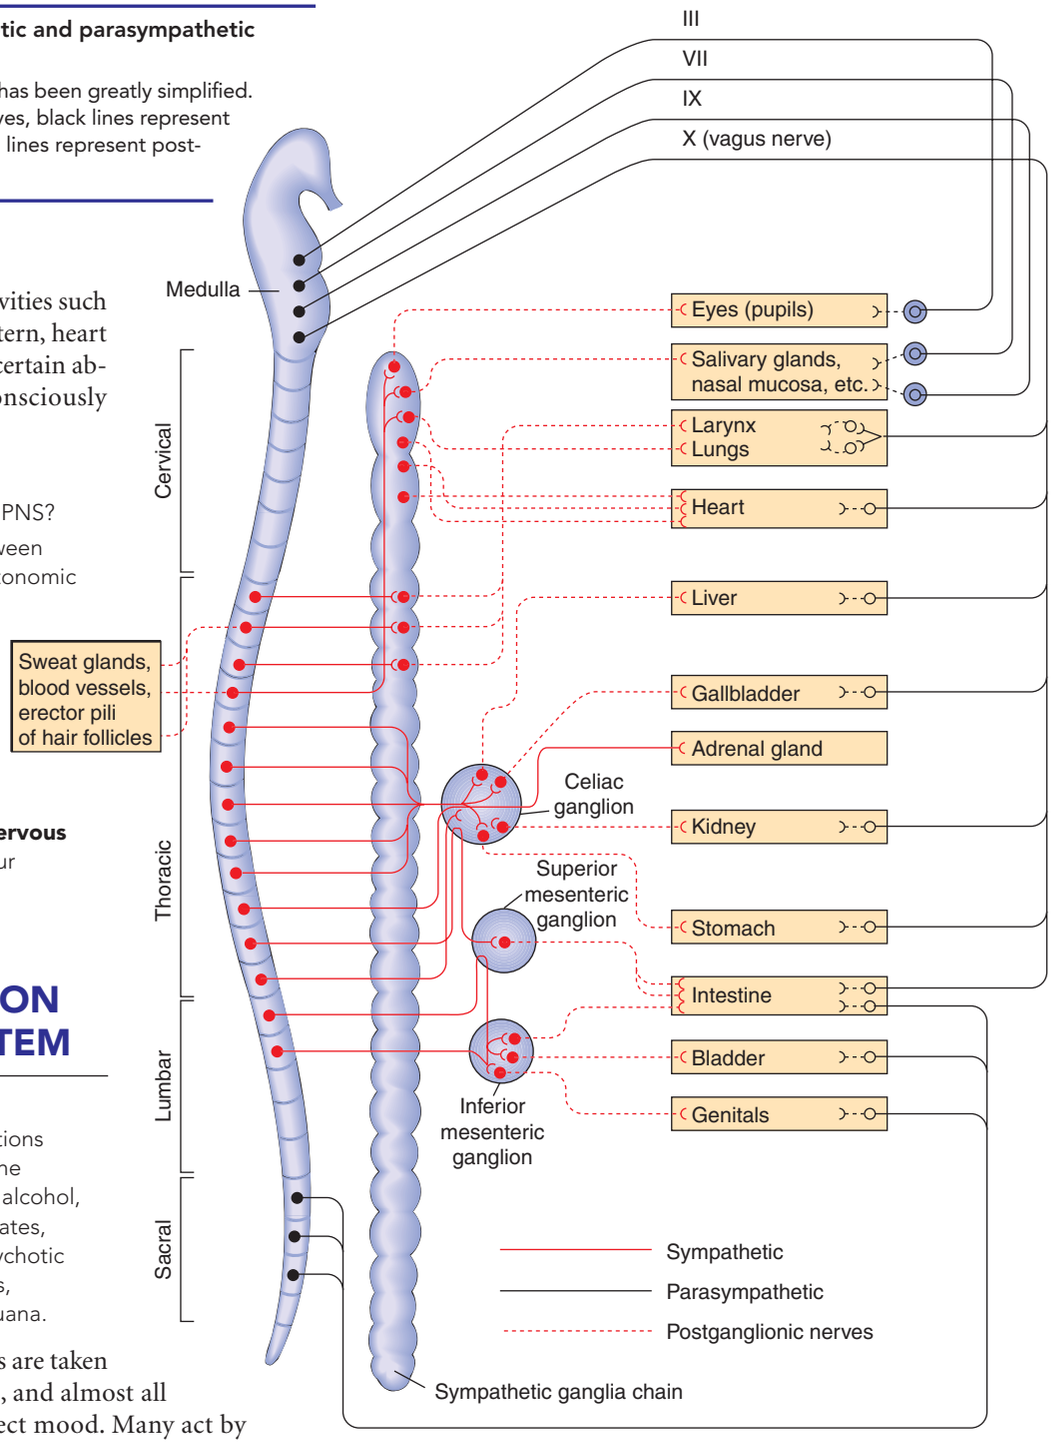
Instead of using a single efferent neuron, as in the somatic system, the autonomic system uses a relay of two neurons between the CNS and the effector. The first neuron, called the **preganglionic neuron,** has a cell body and dendrites within the CNS. Its axon, part of a peripheral nerve, ends by synapsing with a **postganglionic neuron.** The dendrites and cell body of the postganglionic neuron are in a ganglion outside the CNS. Its axon terminates near or on the effector. The sympathetic ganglia are paired, and a chain of them, the **paravertebral sympathetic ganglion chain,** runs on each side of the spinal cord from the neck to the abdomen. Some sympathetic preganglionic neurons do not end in these ganglia but instead pass on to **collateral ganglia** in the abdomen, close to the aorta and its major branches. Parasympathetic preganglionic neurons synapse with postganglionic neurons in **terminal ganglia** near or within the walls of the organs they innervate.

The sympathetic and parasympathetic systems also differ in the neurotransmitters they release at the synapse with the effector. Both preganglionic and postganglionic parasympathetic neurons secrete acetylcholine. Sympathetic postganglionic neurons release norepinephrine (although preganglionic sympathetic neurons secrete acetylcholine).

The autonomic division got its name from the original belief that it was independent of the CNS, that is, autonomous. Neurobiologists have shown that this is not so and that the hypothalamus and many other parts of the CNS help regulate the autonomic system. Although the autonomic system usually functions automatically, its activities can be consciously influenced. Biofeedback provides a person with visual or auditory evidence concerning the status of an autonomic body function. For example, a tone may be sounded when blood pressure reaches a desirable level. Using such techniques, subjects have

FIGURE **40-15** **The sympathetic and parasympathetic systems.**

Complex as it appears, this diagram has been greatly simplified. Red lines represent sympathetic nerves, black lines represent parasympathetic nerves, and dotted lines represent postganglionic nerves.



learned to control autonomic activities such as blood pressure, brain wave pattern, heart rate, and blood sugar level. Even certain abnormal heart rhythms can be consciously modified.

Review

EFECTS OF DRUGS ON THE NERVOUS SYSTEM

Learning Objective

12 Discuss the biological actions and effects on mood of the following types of drugs: alcohol, antidepressants, barbiturates, antianxiety drugs, antipsychotic drugs, opiates, stimulants, hallucinogens, and marijuana.

About 25% of all prescribed drugs are taken to alter psychological conditions, and almost all the commonly abused drugs affect mood. Many act by changing the levels of neurotransmitters within the brain. In particular, levels of norepinephrine, serotonin, and dopamine influence mood.

According to the Substance Abuse and Mental Health Services Administration, an estimated 15.9 million individuals in the United States were current users of illicit drugs in 2001, meaning they used an illicit drug at least once during the 30 days before the interview. More than 9 million children live with a parent who is dependent on alcohol and/or illicit drugs. Table 40-4 lists several commonly used and abused drugs and gives their effects. Also see *Focus On: Alcohol: The Most Abused of All Drugs.*

Habitual use of almost any mood-altering drug can result in **psychological dependence,** in which the user becomes emotionally dependent on the drug. When deprived of it, the user craves the feeling of euphoria (well-being) the drug induces. Some drugs induce **tolerance** after several days or weeks. Response to the drug therefore decreases, and greater amounts are required to obtain the desired effect. Tolerance often occurs because the liver cells are stimulated to produce more of the enzymes that metabolize and inactivate the drug. It can also occur when the number of postsynaptic receptors that bind with the drug decrease (a mechanism known as *downregulation*).

TABLE **40-4** Effects of Some Commonly Used Drugs

Name of Drug	Effect on Mood	Actions on Body	Side Effects/Dangers Associated with Abuse
Antidepressants			
Tricyclic antidepressants (e.g., Elavil, Anafranil)	Elevate mood; relieve depression; also used to treat obsessive-compulsive behavior	Most block reuptake of biogenic amines (especially norepinephrine), increasing their concentration in synapses	Sedation, weight gain, sexual dysfunction
Selective serotonin reuptake inhibitors (SSRIs) (e.g., Prozac, Zoloft, Lexapro)	Relieve depression; used to treat obsessive-compulsive behavior	Block serotonin reuptake	Nausea, headache, insomnia, anxiety
MAO inhibitors (e.g., Parnate, Nardil)	Relieve depression	Block enzymatic breakdown of biogenic amines, increasing their concentration in synapses	Liver toxicity, excessive CNS stimulation; overdose may affect blood pressure, cause hallucinations
Anti-anxiety Drugs			
Benzodiazepines (e.g., Xanax, Valium, Librium)	Sedation; induce sleep	Bind to GABA receptors on post-synaptic neuron; increase effectiveness of GABA in opening chloride channels, causing hyperpolarization; cause relaxation of skeletal muscles	Drowsiness, confusion; psychological dependence, addiction; effects additive with alcohol
Barbiturates "Downers" (e.g., phenobarbital)	Sedation; induce sleep	Bind to receptor adjacent to GABA receptor on chloride channels; chloride channels open so more chloride ions move in, causing hyperpolarization	Drowsiness, confusion; psychological dependence, tolerance, addiction; severe CNS depression, resulting in coma and death (especially lethal in combination with alcohol)
Antipsychotic Medications			
Phenothiazines (e.g., Thorazine, Mellaril, Stelazine)	Relieve symptoms of schizophrenia; reduce impulsive and aggressive behavior	Block dopamine receptors	Muscle spasms, shuffling gait, and other symptoms of Parkinson's disease
Newer antipsychotic medications (e.g., Abilify, Risperdal)	Similar to phenothiazines, but also increase motivation	Block dopamine receptors and other neurotransmitter receptors	Fewer side effects than with the phenothiazines
Narcotic Analgesics			
Opiates (e.g., morphine, codeine, Demerol, heroin)	Euphoria; sedation; relieve pain	Mimic actions of endorphins; bind to opiate receptors	Depress respiration; constrict pupils; impair coordination; tolerance, psychological dependence, addiction; convulsions, death from overdose
Cocaine	Brief, intense high with euphoria, followed by fatigue and depression	Stimulates release and inhibits reuptake of norepinephrine and dopamine, leading to CNS stimulation followed by depression; autonomic stimulation; dilation of pupils; local anesthesia	Mental impairment, convulsions, hallucinations, unconsciousness; death from overdose
Marijuana	Euphoria	Impairs coordination; impairs depth perception and alters sense of timing; impairs short-term memory (probably by decreasing acetylcholine levels in the hippocampus); inflames eyes; causes peripheral vasodilation	In large doses, sensory distortions, hallucinations, evidence of lowered sperm counts and testosterone levels

Drug addiction is a serious societal problem that involves compulsive use of a drug despite negative health consequences and negative effects on the ability to function socially and occupationally. Use of some drugs, such as heroin, tobacco, alcohol, and barbiturates, may also result in physical dependence, in which physiological changes occur that make the user dependent on the drug. For example, when heroin or alcohol is withheld, the addict suffers characteristic withdrawal symptoms. Physical addiction can occur when a drug, for example, morphine, has components similar to substances that body cells normally manufacture on their own. Some highly addictive drugs such as crack cocaine and methamphetamine do not cause serious withdrawal symptoms.

TABLE **40-4** Effects of Some Commonly Used Drugs (continued)

Name of Drug	Effect on Mood	Actions on Body	Side Effects/Dangers Associated with Abuse
Amphetamines			
"Uppers," "pep pills," "crystal meth" (e.g., Dexedrine); methamphetamine is a popular club drug	Euphoria, stimulation, hyperactivity	Stimulate release and block reuptake of dopamine and norepinephrine; enhance flow of impulses in RAS, leading to increased heart rate, blood pressure; pupil dilation	Tolerance, physical dependence; hallucinations; increased blood pressure; psychotic episodes; death from overdose
MDMA (3,4-methylenedioxy-methamphetamine) "ecstasy" (most popular of club drugs)	Stimulant, sense of pleasure, self-confidence, feelings of closeness to others; mild hallucinogenic	CNS stimulant; damages serotonin pathways in rat and monkey brains	Hyperthermia (excessive body heat); overdose causes rapid heartbeat, high blood pressure, panic attacks, and seizures; long-term neurological changes; cognitive impairment
Rohypnol (flunitrazepam) "Date rape" drug, "roofies," "roach"	Sedative-hypnotic	Muscle relaxation; amnesia	Physical and psychological dependence; withdrawal may cause seizures; may be lethal when mixed with alcohol and/or other depressants
PCP (phencyclidine) "Angel dust," "ozone"	Feelings of strength, power, invulnerability, and a numbing effect on the mind	Increase in blood pressure and heart rate; shallow respiration; flushing, profuse sweating; numbness of extremities; muscular incoordination; changes in body awareness, similar to those associated with alcohol intoxication	Psychological dependence, craving; in adolescents, interferes with hormones related to growth and development; may interfere with learning; causes hallucinations, delusions, disordered thinking; high doses cause drop in blood pressure and heart rate, seizures, coma, and death; chronic use causes memory loss, difficulties with speech and thinking, and depression
LSD (lysergic acid diethylamide)	Overexcitation; sensory distortions, hallucinations	Alters levels of transmitters in brain; potent CNS stimulator; dilates pupils, sometimes unequally; increases heart rate; raises blood pressure	Irrational behavior
Methaqualone (e.g., Quaalude, Sopor)	Hypnotic	Depresses CNS; depresses certain spinal reflexes	Tolerance, physical dependence; convulsions, death
Caffeine	Increases mental alertness; decreases fatigue and drowsiness	Acts on cerebral cortex; relaxes smooth muscle; stimulates cardiac and skeletal muscle; increases urine volume	Very large doses stimulate centers in the medulla (may slow the heart); toxic doses may cause convulsions
Nicotine	Lessens psychological tension	Stimulates sympathetic nervous system; increases dopamine in mesolimbic pathway	Tolerance, physical dependence; stimulates development of atherosclerosis by stimulating synthesis of lipid in arterial wall
Alcohol	Euphoria, relaxation, release of inhibitions	Depresses CNS; impairs vision, coordination, judgement; lengthens reaction time	Physical dependence; damage to pancreas and liver (e.g., cirrhosis), brain damage

The neurophysiological mechanisms for drug addiction involve the *mesolimbic dopamine pathway*. Neurons in this pathway signal neurons in an area of the limbic system (the nucleus accumbens). Facilitation of neurons in the mesolimbic dopamine pathway has been demonstrated in nicotine, heroin, amphetamine, and cocaine addiction. For example, amphetamines stimulate dopamine release. Cocaine blocks the reuptake of dopamine into presynaptic neurons, prolonging the stimulation. Amphetamines or cocaine can increase dopamine concentration in the limbic system by up to 1000 times normal amounts! Prolonged drug use alters gene expression and changes neuron structure.

Review

- How does each of the following drugs affect the CNS: (a) alcohol (b) antipsychotic drugs (c) antidepressants (d) amphetamines (e) MDMA ("ecstasy")?

BiologyNow™ Assess your understanding of **the effects of drugs on your nervous system** by taking the pretest on your BiologyNow CD-ROM.

FOCUS ON ALCOHOL: THE MOST ABUSED OF ALL DRUGS

After tobacco, alcohol is the leading cause of premature death in the United States. It is linked to more than 100,000 deaths every year and costs our society more than $185 billion annually. According to the National Institute on Alcohol Abuse and Alcoholism, in 2002 an estimated 14 million Americans—1 in every 13 adults—abused alcohol or were alcoholic. More than half of men and women in the United States report that one or more of their close relatives have a drinking problem. Alcohol abuse is not limited to adults. About 4.6 million adolescents, or nearly one of every three high school students, experience negative consequences from alcohol use, including difficulty with parents, poor performance at school, and trouble with the law.

Alcohol abuse results in physiological, psychological, and social impairment for the abuser and has serious negative consequences for family, friends, and society. Alcohol abuse has been linked to the following:

- More than 50% of all traffic fatalities
- More than 50% of violent crimes, and more than 60% of child abuse and spouse abuse cases
- More than 50% of suicides
- More than 15,000 babies born each year with serious birth defects because their mothers drank alcohol during pregnancy; **fetal alcohol syndrome** is the leading cause of preventable mental retardation in the United States
- Increased risk for certain cancers, especially those of the liver, esophagus, throat, and larynx

A single drink, that is, 12 oz of beer, 5 oz of wine, or 1.5 oz of 80-proof liquor, results in a blood alcohol concentration of approximately 20 mg/dL (milligrams per deciliter). This represents about 0.5 oz of pure alcohol in the blood. Alcohol accumulates in the blood because absorption occurs more rapidly than do oxidation and excretion. Every cell in the body can take in alcohol from the blood. At first the drinker may feel stimulated, but alcohol actually depresses the CNS.

As blood alcohol concentration rises, information processing, judgment, memory, sensory perception, and motor coordination all become progressively impaired. Depression and drowsiness generally occur. Contrary to popular belief, alcohol decreases sexual performance. Some individuals become loud, angry, or violent. A blood alcohol concentration of 80 mg/dL (or 0.08 gm 100 mL) legally defines driving while intoxicated (DWI). A 170-pound man typically reaches this level by drinking four drinks in an hour on an empty stomach.

Alcohol metabolism occurs at a fixed rate in the liver so only time, not coffee, decreases its effects. Because alcohol inhibits water reabsorption in the kidneys, more fluid is excreted as urine than is consumed. This results in dehydration that, together with low blood sugar level, may cause the stupor produced by excessive drinking.

In chronic drinkers, cells of the CNS adapt to the presence of the drug. This causes *tolerance* (more and more alcohol is needed to experience the same effect) and physical dependence. Abrupt withdrawal can result in sleep disturbances, severe anxiety, tremors, seizures, hallucinations, and psychoses.

The *A1* allele of the D2 dopamine receptor gene increases the risk for alcoholism. Individuals with this allele have fewer D2 dopamine receptors in their brain. Alcohol, as well as cocaine, heroin, amphetamines, and nicotine, enhances dopamine activity in the *mesolimbic dopamine pathway* of the brain. Individuals with the *A1* allele may compensate for their low dopamine levels by using alcohol and other drugs. However, the mechanisms underlying alcohol addiction are far more complex. Evidence suggests that many neurotransmitters are involved, including glutamate, serotonin, GABA, and opioid peptides.

Treatment for alcohol problems includes various forms of psychotherapy, including relapse prevention therapy, in which individuals are encouraged not to consider lapses from abstinence as failure. The group support offered by Alcoholics Anonymous (AA) has proved effective for many struggling with alcohol abuse.

SUMMARY WITH KEY TERMS

1 Contrast nerve nets and radial nervous systems with bilateral nervous systems.

- Nerve nets and radial nervous systems are typical of radially symmetrical invertebrates. Bilateral nervous systems are characteristic of bilaterally symmetrical animals.
- Cnidarians have a **nerve net** of nerve cells scattered throughout the body; they have no central control organ. Echinoderms typically have a **radial nervous system** consisting of a nerve ring and nerves that extend to various parts of the body.
- In a **bilateral nervous system,** nerve cells concentrate to form **nerves, nerve cords, ganglia,** and **brain;** typically, sense organs are concentrated in the head region. An increased number of association neurons and more complex synaptic contacts permit a wide range of responses.
- In planarian flatworms the bilateral nervous system includes **cerebral ganglia** and, typically, two solid ventral nerve cords connected by transverse nerves. Annelids and arthropods typically have a ventral nerve cord and numerous ganglia. The cerebral ganglia of arthropods have specialized regions. Octopods and other cephalopod mollusks have complex nervous systems with neurons concentrated in a central region.

2 Identify trends in the evolution of the invertebrate nervous system.

- Trends in nervous system evolution include increased numbers and concentration of nerve cells, specialization of function, increased number of association neurons; more complex synaptic contacts and **cephalization,** formation of a head.

3 Describe the two main divisions of the vertebrate nervous system.

- The vertebrate nervous system consists of the **central nervous system (CNS)** and **peripheral nervous system (PNS).** The CNS consists of the brain and dorsal, tubular **spinal cord.** The PNS consists of sensory receptors and nerves.

4 Trace the development of the principal vertebrate brain regions from the forebrain, midbrain, and hindbrain, and compare the brains of fishes, amphibians, reptiles, birds, and mammals.

- In the vertebrate embryo, the brain and spinal cord arise from the **neural tube.** The anterior end of the tube differentiates into **forebrain, midbrain,** and **hindbrain.**
- The hindbrain subdivides into the **metencephalon** and **myelencephalon.** The myelencephalon develops into the **medulla,** which contains vital centers and other reflex centers. The **fourth ventricle,** the cavity of the medulla, communicates with the central canal of the spinal cord. The metencephalon gives rise to the **cerebellum,** which is responsible for muscle tone, posture, and equilibrium, and to the **pons,** which connects various parts of the brain.
- The midbrain is the largest part of the brain in fishes and amphibians. It is their main association area, linking sensory input and motor output. In reptiles, birds, and mammals, the midbrain serves as a center for visual and auditory reflexes.
- The medulla, pons, and midbrain make up the **brain stem.**
- The forebrain differentiates to form the **diencephalon** and **telencephalon.** The diencephalon develops into the thalamus and hypothalamus. The **thalamus** is a relay center for motor and sensory information. The **hypothalamus** controls autonomic functions; links nervous and endocrine systems; controls temperature, appetite, and fluid balance; and is involved in some emotional and sexual responses.
- The telencephalon develops into the cerebrum and **olfactory bulbs.** In most vertebrates the **cerebrum** is divided into right and left **hemispheres.** In fishes and amphibians, the cerebrum mainly integrates incoming sensory information.
- In birds, the corpus striatum controls complex behavior patterns, such as flying and singing.
- In mammals, the **neocortex** accounts for a large part of the **cerebral cortex,** the **gray matter** of the brain. The cerebrum has complex association functions.

5 Describe the structure and functions of the human spinal cord.

- The human brain and spinal cord are protected by bone and three **meninges**—the **dura mater, arachnoid,** and **pia mater;** brain and spinal cord are cushioned by **cerebrospinal fluid (CSF).**
- The spinal cord transmits impulses to and from the brain and controls many **reflex actions.** The spinal cord consists of **ascending tracts,** which transmit information to the brain, and **descending tracts,** which transmit information from the brain. Its gray matter contains nuclei that serve as reflex centers.
- A **withdrawal reflex** involves sensory receptors; sensory neurons, interneurons, and motor neurons; and effectors, such as muscles.

6 Describe the structure and functions of the human cerebrum.

- The human cerebral cortex consists of gray matter, which forms folds or **convolutions.** Deep furrows between the folds are called **fissures.**
- The cerebrum is functionally divided into **sensory areas** that receive incoming sensory information; **motor areas** that control voluntary movement; and **association areas** that link sensory and motor areas and are responsible for learning, language, thought, and judgment.
- The cerebrum consists of lobes including the **frontal lobes, parietal lobes, temporal lobes,** and **occipital lobes.**
- The **white matter** of the cerebrum lies beneath the cerebral cortex. The **corpus callosum,** a large band of white matter, connects right and left hemispheres. The **basal ganglia,** a cluster of **nuclei** within the white matter, are important centers for motor function.

7 Describe the sleep–wake cycle, and contrast rapid-eye-movement (REM) sleep and non-REM sleep.

- Brain activity cycles in a sleep–wake pattern that is regulated by the hypothalamus and brain stem.
- **Alpha wave** patterns are characteristic of relaxed states. **Beta wave** patterns accompany heightened mental activity; and slower-frequency, higher-amplitude **theta** and **delta waves,** are characteristic of non-REM sleep.
- The **reticular activating system (RAS)** is an arousal system; its neurons filter sensory input, selecting which information is transmitted to the cerebrum.
- Electrical activity of the cerebral cortex and metabolic rate slows during **non-REM sleep,** whereas dreaming characterizes **REM sleep.**
- The body's main biological clock—the **suprachiasmatic nucleus**—receives information about light and dark and apparently transmits it to other nuclei that regulate sleep. When sleep centers are activated, they release **serotonin.**

8 Describe the actions of the limbic system.

- The **limbic system** of the brain affects the emotional aspects of behavior, motivation, sexual behavior, autonomic responses, and biological rhythms. The **hippocampus** is important in categorizing information and consolidating memories. The **amygdala** evaluates incoming information and signals danger.

9 Summarize how the brain processes information.

- **Learning** is the process by which we acquire information as a result of experience. **Memory** is the process by which information is encoded, stored, and retrieved.
- **Implicit memory** is unconscious memory for perceptual and motor skills. **Explicit memory** is factual memory of people, places, or objects.
- **Short-term memory** lets us recall information, such as a telephone number, for a few minutes. Information can be transferred from short-term memory to **long-term memory.**
- **Synaptic plasticity** is the ability of the nervous system to modify synapses during learning and remembering. Long-term memory storage involves gene activation and long-term functional changes at synapses. Known as **long-term potentiation (LTP),** such changes involve increased sensitivity to an action potential by a postsynaptic neuron. **Long-term depression (LTD)** is a long-lasting decrease in the strength of synaptic connections.
- The physical structure and chemistry of the brain can be altered by environmental experience.

10 Describe the organization of the peripheral nervous system, comparing the somatic and autonomic divisions.

SUMMARY WITH KEY TERMS *(continued)*

- The PNS consists of sensory receptors and nerves, including the **cranial nerves** and **spinal nerves** and their branches.
- The **somatic division** of the PNS responds to changes in the external environment. The **autonomic division** regulates the internal activities of the body.

11 Contrast the sympathetic and parasympathetic divisions of the autonomic system, giving examples of the effects of these systems on specific organs such as the heart and intestine.

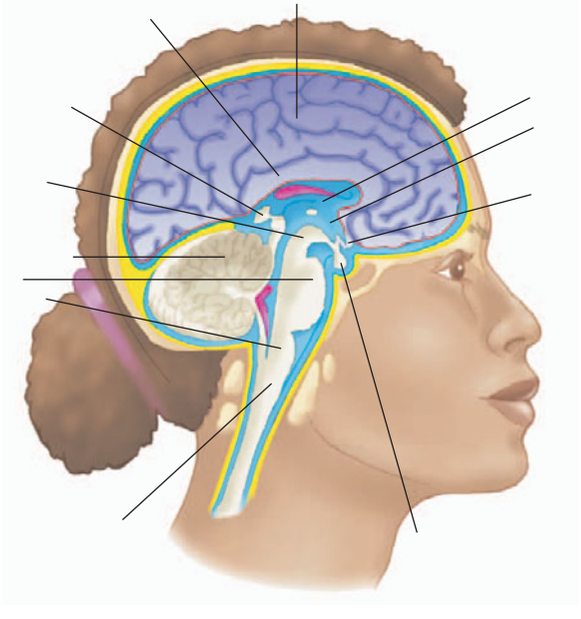
- The **sympathetic system** permits the body to respond to stressful situations. The **parasympathetic system** influences organs to conserve and restore energy.
- Many organs are innervated by sympathetic and parasympathetic nerves, which function in an opposite way. For example, the sympathetic system increases heart rate, whereas the parasympathetic system decreases heart rate.

12 Discuss the biological actions and effects on mood of the following types of drugs: alcohol, antidepressants, barbiturates, antianxiety drugs, antipsychotic drugs, opiates, stimulants, hallucinogens, and marijuana.

- Many drugs alter mood by increasing or decreasing the concentrations of specific neurotransmitters within the brain. See Table 40-4 for a summary of these drugs.
- Habitual use of mood-altering drugs can result in **psychological dependence** or **drug addiction.** Many drugs induce **tolerance,** in which the body's response to the drug decreases so that greater amounts are needed to obtain the desired effect.

POST-TEST

1. A radially symmetrical animal is likely to have (a) a forebrain (b) a nerve net (c) cerebral ganglia (d) a ventral nerve cord (e) cerebral ganglia and a nerve net
2. In vertebrate embryos the brain develops from the (a) spinal cord (b) sympathetic nervous system (c) parasympathetic nervous system (d) neural tube (e) forebrain
3. Which part of the brain maintains posture, muscle tone, and equilibrium? (a) cerebrum (b) medulla (c) cerebellum (d) neocortex (e) thalamus
4. Which part of the brain controls autonomic functions and regulates body temperature? (a) cerebrum (b) hypothalamus (c) cerebellum (d) pons (e) thalamus
5. In a withdrawal reflex, following reception, a signal is transmitted by (a) a motor neuron to an association neuron in the CNS (b) an association neuron in the CNS to an afferent neuron (c) an afferent neuron in the CNS to a motor neuron (d) a sensory neuron to an interneuron in the CNS (e) a sensory neuron to an interneuron in the PNS
6. Association areas in the human brain are concentrated in the (a) cerebral cortex (b) medulla (c) ventricle (d) hippocampus (e) meninges
7. The human brain is protected by (a) meninges, cerebrospinal fluid, and skull bones (b) meninges and skull bones only (c) dura mater and fourth ventricle (d) pia mater and skull bones (e) arachnoid, pia mater, cerebrospinal fluid, and ganglia
8. Which of the following is *not* a function of the spinal cord? (a) controls many reflex actions (b) transmits information to the brain (c) transmits information from the brain (d) regulates sleep–wake cycles (e) controls the withdrawal reflex
9. The most prominent part of the amphibian brain is the (a) midbrain (b) medulla (c) cerebellum (d) neocortex (e) cerebrum
10. The visual centers are located in the (a) parietal lobes (b) thalamus (c) occipital lobes (d) limbic lobes (e) frontal lobes
11. As you are answering these questions, what is the predominant type of wave your brain is emitting? (a) REM (b) alpha (c) theta (d) delta (e) beta
12. Implicit memory is (a) short-term memory (b) long-term memory (c) factual knowledge of people, places, or objects (d) unconscious memory for perceptual or motor skills (e) learning that depends on long-term depression (LTD)
13. Long-term potentiation (LTP) (a) is mainly the responsibility of cranial nerve X (b) is a long-lasting increase in synaptic strength (c) is associated with short-term memory (d) is a long-lasting decrease in synaptic strength (e) occurs mainly during REM sleep
14. The heart rate is slowed by (a) sympathetic nerves (b) parasympathetic nerves (c) corpus callosum (d) both sympathetic and parasympathetic nerves (e) the hippocampus working together with sympathetic nerves
15. After taking a mood-altering drug for several weeks, a patient notices it no longer works as effectively. This is an example of (a) psychological dependence (b) withdrawal (c) addiction (d) tolerance (e) neurotransmitter increases
16. Amphetamines (a) facilitate neurons in the mesolimbic dopamine pathway (b) decrease the amount of dopamine secreted (c) do not result in tolerance (d) are sometimes referred to as "downers" (e) are CNS depressants
17. Label the diagram. Use Figure 40-10a to check your answers.



CRITICAL THINKING

1. What general trends can you identify in the evolution of the vertebrate brain?
2. Imagine you have just become a parent. What kind of things can you do to enhance the development of your child's intellectual abilities?
3. Hypothesize a possible relationship between inheritance and intelligence based on gene activation during information processing.
4. What is the adaptive function of the limbic system when you are in danger?

Sensory Reception

Merlin D. Tuttle/Bat Conservation International/Photo Researchers, Inc.

Bats are guided by echoes. This California leaf-nosed bat (*Macrotus californicus*) has located an insect.

CHAPTER OUTLINE

- Types of Sensory Receptors
- How Sensory Receptors Function
- Mechanoreceptors
- Chemoreceptors
- Photoreceptors

Have you heard dolphins make clicking sounds? Humans can hear only a limited number of the wide range of sound frequencies that dolphins emit. Bats, dolphins, and a few other vertebrates detect distant objects by **echolocation,** sometimes called biosonar. Echolocation works something like radar but uses sound rather than radio waves. For example, a bat emits high-pitched sounds that bounce off objects in its path and echo back. By rapidly responding to the echo, the bat skillfully avoids obstacles and captures prey (see photograph). Using echolocation, bats and dolphins determine the size, shape, texture, and density of an object, as well as its location. The ability to detect sounds emitted by some foraging bats has evolved in certain moths and other insect prey. Some species of bats have adapted, in turn, by emitting very high-frequency sounds that their prey cannot detect.

Sensory receptors are structures that detect information about changes in the internal or external environment. By informing an animal about its environment, sensory receptors are the link between the animal and the outside world. The kinds of sensory receptors an animal has determine just how it perceives its surroundings. We humans live in a world of rich colors, numerous shapes, and varied sounds. But we cannot hear the high-pitched whistles that are audible to dogs and cats, or the ultrasonic echoes by which bats navigate. Nor do we ordinarily recognize our friends by their distinctive odors! And although vision is our dominant and most refined sense, we are blind to the ultraviolet (UV) hues that light up the world for insects.

Sensory receptors consist of specialized neuron endings or specialized cells in close contact with neurons. These receptors *transduce* or convert the energy of the stimulus to electrical signals, the information currency of the nervous system. The transduction mechanisms that couple the stimulus with the opening or closing of ion channels in the plasma membrane of sensory receptors is the focus of current research. When a sensory receptor is depolarized, an action potential may be initiated in a sensory neuron. As we discussed in Chapter 40, **sensory neurons,**

also known as *afferent neurons,* transmit information from receptors to the central nervous system (CNS).

Sensory receptors, along with other types of cells, make up complex **sense organs,** such as eyes, ears, nose, and taste buds. A human taste bud, for example, consists of modified epithelial cells that detect chemicals dissolved in saliva. In addition to the five senses of sight, hearing, smell, taste, and touch, neurobiologists recognize balance as a sense. They view touch as a compound sense that allows us to detect pressure, pain, and temperature. In this chapter, we also consider sensory receptors that enable us to sense muscle tension and joint position. ■

TYPES OF SENSORY RECEPTORS

Learning Objective

1 Distinguish among five kinds of sensory receptors according to the types of energy they transduce.

Animals receive information about their environment in various energy forms. Sensory receptors transduce these types of energy into graded potentials that can result in action potentials (see Chapter 39). **Mechanoreceptors** transduce mechanical energy—touch, pressure, gravity, stretching, and movement (Table 41-1). These receptors convert mechanical forces directly into electrical signals. **Chemoreceptors** transduce certain chemical compounds, and **photoreceptors** transduce light energy.

Thermoreceptors respond to heat and cold. Mosquitoes, ticks, and other blood-sucking arthropods use thermoreception in their search for an endothermic host. Some have temperature receptors on their antennae that are sensitive to changes of less than 0.5°C. At least two types of snakes—pit vipers and boas—use thermoreceptors to locate their prey (Fig. 41-1). In mammals, which are endothermic, free nerve endings and specialized receptors in the skin and tongue detect temperature changes in the outside environment. Thermoreceptors in the

Carmela Leszczynski/ Animals Animals

FIGURE **41-1** **Thermoreception.**

The pit organ of this bamboo viper (*Trimeresurus stejnegeri*) is a sense organ located between each eye and nostril. The pit organ of many snakes can detect the heat from an endothermic animal up to a distance of 1 to 2 m.

TABLE **41-1** **Classification of Receptors by Type of Energy They Transduce**

Type of Receptor	Examples	Effective Stimuli
Mechanoreceptors	Tactile receptors	Touch, pressure
	Pacinian corpuscles; Merkel discs; Ruffini corpuscles; Meissner corpuscles	
	Nociceptors (pain receptors)	Strong touch, pressure, temperature extreme
	Proprioceptors	Movement, body position
	Muscle spindles	Muscle contraction
	Golgi tendon organs	Stretch of a tendon
	Joint receptors	Movement in ligaments
	Statocysts in invertebrates (hair cells)	Gravity
	Lateral line organs in fish	Waves, currents in water
	Vestibular apparatus	
	Saccule and utricle (hair cells)	Gravity; linear acceleration
	Semicircular canals (hair cells)	Angular acceleration
	Organ of Corti of the cochlea (hair cells)	Pressure waves (sound)
Chemoreceptors	Taste buds; olfactory epithelium	Specific chemical compounds
Thermoreceptors	Temperature receptors in blood-sucking insects and ticks; pit organs in pit vipers; nerve endings and receptors in skin and tongues of many animals	Heat
Electroreceptors	Organs in skin of some fishes	Electrical currents in water
Photoreceptors	Eyespots; ommatidia of arthropods; rods and cones in retinas of vertebrates	Light energy

hypothalamus detect internal changes in temperature, and receive and integrate information from thermoreceptors on the body surface. The hypothalamus then initiates homeostatic mechanisms that ensure a constant body temperature.

Electroreceptors sense differences in electrical potential. Some predatory species of sharks, rays, and bony fishes detect electrical fields generated in the water by the muscle activity of their prey. Some electroreceptors are sensitive enough to detect Earth's magnetic field.

Several groups of fishes have electric organs, specialized muscle or nerve cells that produce external electrical fields. In species that produce a weak electric current, such organs may help in orientation. This is particularly useful in murky water, where visibility and olfaction are poor. Electroreception also appears important in communication, for example, in recognizing a potential mate. Males and females have different frequencies of electric discharge. A few fishes, such as electric eels or electric rays, have electric organs in their heads capable of delivering powerful shocks that stun prey or predators.

Each kind of sensory receptor is especially sensitive to one particular form of energy. The photoreceptors of the human eye are stimulated by an extremely faint beam of light, and taste receptors are stimulated by a minute amount of a chemical compound.

Sensory receptors can also be classified according to the source of the stimuli to which they respond. **Exteroceptors** receive stimuli from the outside environment, enabling an animal to know and explore the world, search for food, find and attract a mate, recognize friends, and detect enemies. **Interoceptors** are sensory receptors within body organs that detect changes in pH, osmotic pressure, body temperature, and the chemical composition of the blood. You are not usually aware of messages sent to the CNS by these receptors as they work continuously to maintain homeostasis. You become aware of their activity when they signal certain internal conditions such as thirst, hunger, nausea, pain, and orgasm.

Review

- Name the five kinds of sensory receptors. What is the specific function of each?

Biology Now™ Assess your understanding of **types of sensory receptors** by taking the pretest on your BiologyNow CD-ROM.

HOW SENSORY RECEPTORS FUNCTION

Learning Objective

2 Describe how a sensory receptor functions; define *energy transduction, receptor potential,* and *sensory adaptation* as part of your answer.

Sensory receptors produce receptor potentials. They (1) absorb a small amount of energy from some stimulus; (2) convert the energy of the stimulus into electrical energy, the process known as **energy transduction;** and (3) produce a **receptor potential,** a depolarization or hyperpolarization of the membrane. With minor variations, this is how all receptors operate.

The function of a receptor potential is to generate action potentials that transmit information to the CNS. However, as we discuss later, each receptor potential does not directly trigger an action potential. When unstimulated, a sensory receptor maintains a resting potential, that is, a difference in charge between the inside and the outside of the cell. When the receptor cell is stimulated and its membrane potential changes, specific types of ion channels in its plasma membrane open or close, altering the permeability of the plasma membrane to various ions. A change in ion distribution can cause a change in voltage across the membrane. If the difference in charge increases, the receptor becomes hyperpolarized. If the potential decreases, the receptor becomes depolarized. The change in membrane potential is the receptor potential.

Like an excitatory postsynaptic potential, or EPSP (see Chapter 39), the receptor potential is a **graded response** in which the magnitude of change depends on the energy of the stimulus. A graded response spreads relatively slowly down the dendrite, fading as it goes. In contrast, according to the *all-or-none law,* the amplitude (size) of each action potential does not vary and has no relation to the magnitude of the stimulus.

The specialized region of the receptor plasma membrane that transduces energy does not generate action potentials. Current generated by receptor potentials flows to a region along the axon where an action potential can be generated. If the receptor membrane is part of a separate cell, receptor potentials stimulate the release of a neurotransmitter, which flows across the synapse and binds to sites on the sensory neuron. When the sensory neuron becomes sufficiently depolarized to reach its threshold level, an action potential is generated. The action potential travels along the axon of the sensory neuron to the CNS. In summary,

Stimulus (such as light energy) ⟶ transduction into electrical energy ⟶ receptor potential ⟶ action potential

Sensation depends on transmission of a coded message

How do you know whether you are seeing a blue sky, tasting a doughnut, or hearing a note played on a piano? All action potentials are qualitatively the same. Light of the wavelength 450 nm (blue), sugar molecules (sweet), and sound waves of 440 hertz (Hz) (*A* above middle *C*) all cause transmission of similar action potentials. Our ability to differentiate stimuli depends on both the sensory receptor itself and on the brain. We can distinguish the color of a blue sky from the scent of cologne; a sweet taste from a light breeze; or the sound of a piano from the heat of the sun because cells of each sensory receptor are connected to specific neurons in particular parts of the brain. Because a receptor normally responds to only one type of stimulus, (for example, light), the brain interprets a message arriving from a particular receptor as meaning that a certain type of stimulus occurred (such as a flash of color).

Sensation takes place in the brain. Interpretation of the message and the type of sensation depends on which association neu-

rons receive the message. The rods and cones of the eye do not see. When stimulated, they send a message to the brain that interprets the signals and translates them into a rainbow, an elephant, or a child. Artificial (for example, electrical) stimulation of brain centers can also result in sensation. In contrast, many sensory messages never give rise to sensations at all. For example, certain chemoreceptors sense internal changes in the body but never stir our consciousness.

When stimulated, a sensory receptor initiates what might be considered a coded message, composed of action potentials transmitted by sensory neurons. This coded message is later decoded in the brain. Impulses from the sensory receptor may differ in the (1) total number of sensory neurons transmitting the signal, (2) specific neurons transmitting action potentials and their targets, (3) total number of action potentials transmitted by a given neuron, and (4) frequency of the action potentials transmitted by a given fiber. The intensity of a stimulus is coded by the frequency of action potentials fired by sensory neurons during the stimulus. A strong stimulus results in a greater depolarization of the receptor membrane, causing the sensory neuron to fire action potentials with greater frequency than would a weak stimulus. This variation is possible because as a graded response, the receptor potential can vary in magnitude.

The difference in sound intensity between the gentle rustling of leaves and a clap of thunder depends on the number of neurons transmitting action potentials, as well as the frequency of the action potentials transmitted by each neuron. Just how the sensory receptor initiates different codes and how the brain analyzes and interprets them to produce various sensations are not yet completely understood.

Sensory receptors adapt to stimuli

Many sensory receptors do not continue to respond at the initial rate, even if the stimulus continues at the same intensity. With time, the response to a continued, constant stimulus decreases. This decrease in frequency of action potentials in a sensory neuron, even though the stimulus is maintained, is called **sensory adaptation.** Sensory adaptation occurs for two reasons. First, during a sustained stimulus, the receptor sensitivity decreases and produces a smaller receptor potential (resulting in a lower frequency of action potentials in the sensory neurons). Second, changes take place at synapses in the neural pathway activated by the receptor. For example, the release of neurotransmitter from a presynaptic terminal may decrease in response to a series of action potentials.

Some receptors, such as those for pain or cold, adapt so slowly that they continue to trigger action potentials as long as the stimulus persists. Other receptors adapt rapidly, permitting an animal to ignore persistent unpleasant or unimportant stimuli. For example, when you first pull on a pair of tight jeans, your pressure receptors let you know that you are being squished, and you may feel uncomfortable. Soon, though, these receptors adapt, and you hardly notice the sensation of the tight fit. In the same way, people quickly adapt to odors that at first seem to assault their senses. Sensory adaptation enables an animal to discriminate between unimportant background stimuli that can be ignored and new or important stimuli that require attention.

Review

- What is a receptor potential?
- What is the function of sensory adaptation?

MECHANORECEPTORS

Learning Objectives

3 Describe the following mechanoreceptors: tactile receptors, nociceptors, proprioceptors, statocysts, hair cells, and lateral line organs.

4 Compare the function of the saccule and utricle with that of the semicircular canals in maintaining equilibrium.

5 Trace the path taken by sound waves through the structures of the ear, and explain how the organ of Corti functions as an auditory receptor.

Mechanoreceptors are activated when they change shape as a result of being mechanically pushed or pulled. They transduce mechanical energy, permitting animals to feel, hear, and maintain balance. These receptors provide information about the shape, texture, weight, and topographic relations of objects in the external environment. Some mechanoreceptors are extremely sensitive. For example, alligators have pressure receptors on their faces that can detect the movement in the surrounding water caused by a single falling drop of water.

Certain mechanoreceptors enable an organism to maintain its body position with respect to gravity (for us, head up and feet down; for a dog, dorsal side up and ventral side down; for a tree sloth, ventral side up and dorsal side down). When displaced from its normal position, the animal quickly adjusts its body to reassume normal orientation. In complex animals, receptors continually send information to the CNS regarding the position and movements of the body. Mechanoreceptors also provide information about the operation of internal organs. For example, they inform us about the presence of food in the stomach, feces in the rectum, urine in the bladder, and a fetus in the uterus.

Touch receptors are located in the skin

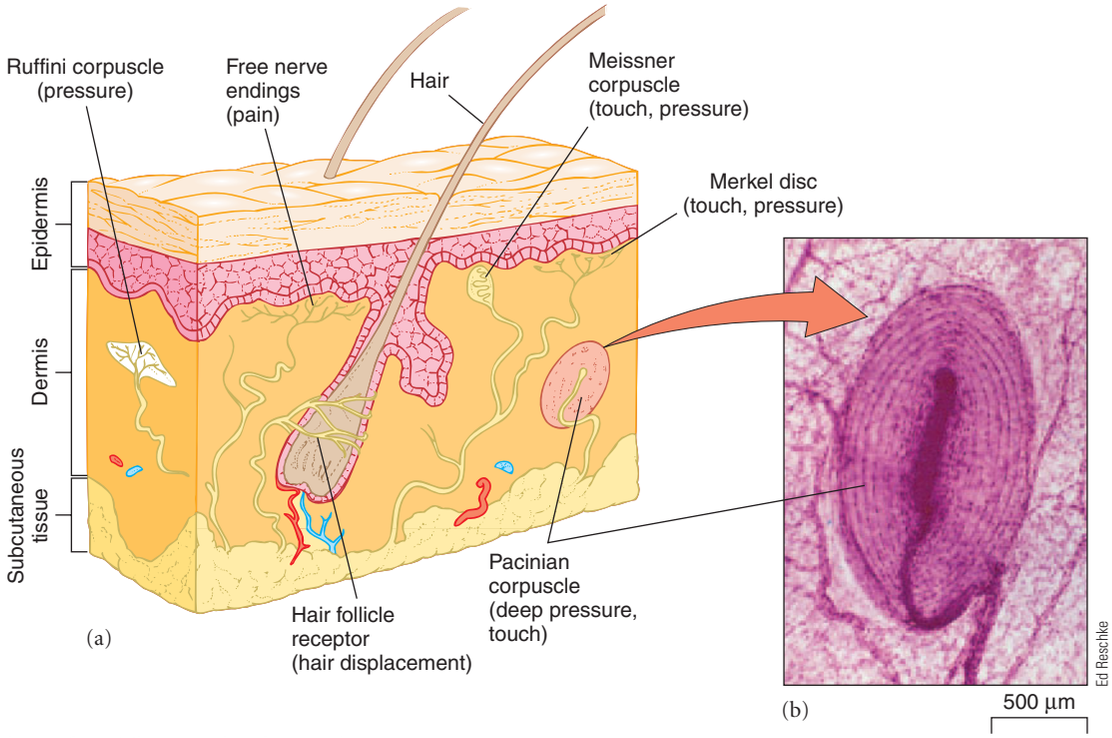
In many invertebrates as well as vertebrates, **tactile** (touch) **receptors** lie at the base of a hair or bristle. Tactile hairs may sense the body's orientation in space with respect to gravity. They may also detect air and water vibrations and contact with other objects. The tactile receptor is stimulated indirectly when the hair is bent or displaced. A receptor potential develops, and a few action potentials may be generated. This type of receptor responds only when the hair is moving. Even though the hair may be maintained in a displaced position, the receptor is not stimulated unless there is motion.

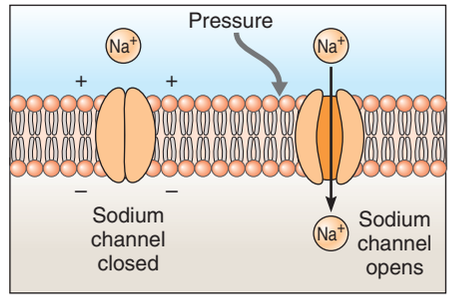
The simplest mechanoreceptors are free nerve endings in the skin. They detect touch, pressure, and pain when stimulated

FIGURE **41-2**

Sensory reception in human skin.

(a) This diagrammatic section through the human skin illustrates several mechanoreceptors that respond to touch and pressure. Also shown are free nerve endings that respond to pain. **(b)** Pacinian corpuscle, a deep pressure receptor. **(c)** The mechanical forces these receptors sense cause Na^+ channels to open, depolarizing the axon.





(c) Membrane of the Pacinian corpuscle

by objects that contact the body surface. Thousands of specialized tactile receptors are located in mammalian skin (Fig. 41-2). **Merkel discs** sense touch and pressure. They adapt slowly, permitting us to know that an object continues to touch the skin. Three types of mechanoreceptors in the skin have encapsulated endings: Meissner corpuscles, Ruffini corpuscles, and Pacinian corpuscles. **Meissner corpuscles** are sensitive to light touch and pressure and adapt quickly to a sustained stimulus. **Ruffini corpuscles,** which adapt very slowly, inform us of heavy and continuous touch and pressure.

The **Pacinian corpuscle** is sensitive to deep pressure that causes rapid movement of the tissues. It is especially sensitive to stimuli that vibrate. The Pacinian corpuscle consists of a neuron ending surrounded by concentric connective tissue layers interspersed with fluid. Compression causes displacement of the layers, which stimulates the axon. Even though the displacement is maintained under steady compression, the receptor potential rapidly falls to zero, and action potentials cease—an excellent example of sensory adaptation. The Pacinian corpuscle is stimulated only when there is movement of the tissue.

In humans, pain receptors, called **nociceptors** (from the Latin *nocere,* to injure), are free nerve endings (dendrites) of certain sensory neurons found in almost every tissue. Several types of nociceptors have been identified. Mechanical nociceptors respond to strong tactile stimuli such as penetration by sharp objects or pinching. Thermal nociceptors respond to temperature extremes (temperatures above 45°C or below 5°C). Other nociceptors respond to a variety of stimuli, including certain chemicals.

When stimulated, nociceptors transmit signals through sensory neurons to interneurons in the spinal cord. The sensory neurons release the neurotransmitter *glutamate,* as well as several neuropeptides, including **substance P,** that enhance and prolong the actions of glutamate. The interneuron transmits the message to the opposite side of the spinal cord and then upward to the thalamus, where pain perception begins. From the thalamus, impulses are sent into the parietal lobes and several other cortical regions, including areas of the limbic system where the emotional aspects of the pain are processed. When pain signals reach the cerebrum, we become fully aware of the pain and can evaluate the situation.

Proprioceptors help coordinate muscle movement

Proprioceptors help animals maintain postural relations—the position of one part of the body with respect to another. Located within muscles, tendons, and joints, proprioceptors continually respond to tension and movement. With their continuous input, an animal can perceive the positions of its arms, legs, head, and other body parts, along with the orientation of its body as a whole. This information is essential for all forms of locomotion and for all coordinated and skilled movements, from spinning a cocoon to completing a reverse one-and-a-half dive with twist. With the help of proprioceptors, we carry out activities such as dressing or playing the piano even in the dark.

Vertebrates have three main types of proprioceptors: **muscle spindles,** which detect muscle movement (Fig. 41-3); **Golgi tendon organs,** which respond to tension in contracting muscles and in the tendons that attach muscle to bone; and **joint receptors,** which detect movement in ligaments. Impulses from the proprioceptors help coordinate the contractions of the several distinct muscles involved in a single movement. Without such receptors, complicated, skilled acts would be impossible. Proprioceptors are also important in maintaining balance.

Proprioceptors are probably more numerous and more continually active than any of the other sensory receptors, although we are less aware of them than of most of the others. As long as the stimulus is present, receptor potentials are maintained (although not at constant magnitude) and action potentials continue to be generated. Proprioceptors continuously send signals to inform the brain about position.

The mammalian muscle spindle, one of the more versatile stretch receptors, helps maintain muscle tone. It is a bundle of specialized muscle fibers, with a central region encircled by sensory neuron endings. These neurons continue to transmit signals for a prolonged period, in proportion to the degree of stretch.

Many invertebrates have gravity receptors called statocysts

Many invertebrates—from jellyfish to crayfish—have gravity receptors called **statocysts.** A statocyst is basically an infolding of the epidermis lined with receptor cells, called sensory hair cells, equipped with sensory hairs (not true hairs) (Fig. 41-4). The cavity contains one or more **statoliths,** tiny granules of loose sand grains or calcium carbonate, held together by an adhesive material secreted by cells of the statocyst. Normally the particles are pulled downward by gravity and stimulate the sensory cells. When the animal changes position, the position of the statolith also changes, stimulating different sensory cells. Each sensory cell responds maximally when the animal is at a particular position with respect to gravity. The mechanical displacement results in receptor potentials and action potentials that inform the CNS of the change in position. By "knowing" which sensory cells are firing, the animal knows where "down" is and can correct any abnormal orientation.

In a classic experiment, the function of the statocyst was demonstrated by substituting iron filings for sand grains in the statocysts of crayfish. The force of gravity was overcome by holding magnets above the animals. The iron filings were attracted upward toward the magnets, and the crayfish began to swim upside down in response to the new information provided by their gravity receptors.

Hair cells are characterized by stereocilia

Vertebrate hair cells are mechanoreceptors that detect movement. They are the sensory receptors in the lateral line of fish that detect water movements. Hair cells help maintain position

FIGURE **41-3** **Proprioceptors.**

Muscle spindles detect muscle movement. A muscle spindle consists of an elongated bundle of specialized muscle fibers. Golgi tendon organs respond to tension in muscles and their associated tendons.

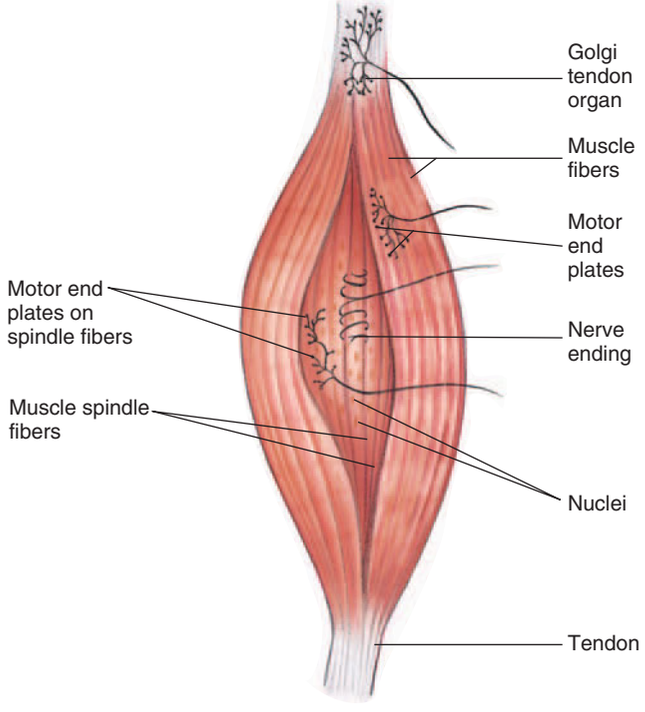


FIGURE **41-4** **A statocyst.**

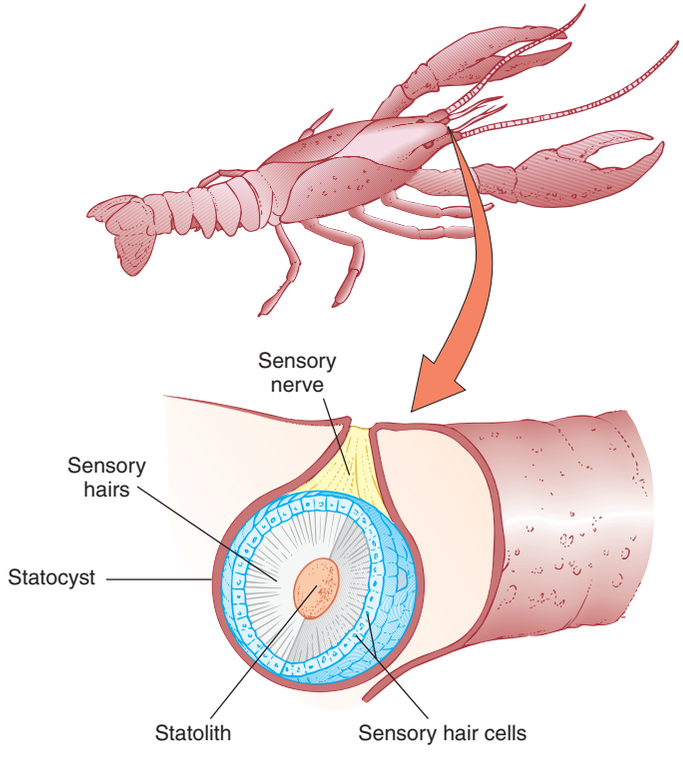
Many invertebrates have statocysts, receptors that sense gravitational force and provide information about orientation of the body with respect to gravity.



and equilibrium, and are important in hearing. The surface of a vertebrate hair cell typically has a single long **kinocilium** and a number of shorter **stereocilia,** hairlike projections that increase in length from one side of the hair cell to the other. A kinocilium is a true cilium with a 9 + 2 arrangement of microtubules (see Chapter 4). In contrast, stereocilia are not really cilia. They are microvilli that contain actin filaments.

Mechanical stimulation of the stereocilia causes voltage changes. Mechanical stimulation in one direction causes depolarization and release of neurotransmitter, whereas mechanical stimulation in the opposite direction results in hyperpolarization. However, hair cells have no axons and do not produce their own action potentials. Rather, they release neurotransmitters that depolarize associated neurons.

Lateral line organs supplement vision in fish

Lateral line organs of fish and aquatic amphibians detect vibrations in the water. They inform the animal of obstacles in its way and of moving objects such as prey, enemies, and others in its school. Typically the lateral line organ is a long canal running the length of the body and continuing into the head (Fig. 41-5). The canal is lined with sensory hair cells. The tips of the stereocilia are enclosed by a **cupula,** a mass of gelatinous material secreted by the hair cells.

Pressure waves, currents, and even slight movement in the water cause vibrations in the lateral line organ. The water moves the cupula, bending the stereocilia. This changes the membrane potential of the hair cell which may then release neurotransmitter. If a sensory neuron is sufficiently stimulated, an action potential may be dispatched to the CNS.

The vestibular apparatus maintains equilibrium

Probably, when you think of the ear you think of hearing. However, in vertebrates its main function is to help maintain equilibrium. Many vertebrates do not have outer or middle ears, but all have inner ears (Fig. 41-6). The mammalian **inner ear** contains organs of equilibrium equipped with hair cells that sense the position of the body with respect to gravity.

The inner ear is a complicated group of interconnected canals and sacs, called the **labyrinth,** which includes a membranous labyrinth that fits inside a bony labyrinth. In mammals the membranous labyrinth has two saclike chambers—the **saccule** and the **utricle**—and three **semicircular canals.** Collectively, the saccule, utricle, and semicircular canals are called the **vestibular apparatus** (see Fig. 41-6). Destruction of these organs leads to a considerable loss of the sense of equilibrium. A pigeon whose vestibular apparatus has been destroyed cannot fly but in time can relearn how to maintain equilibrium using visual stimuli.

The saccule and utricle house gravity detectors in the form of small calcium carbonate ear stones called **otoliths** (Fig. 41-7). The sensory cells of the saccule and utricle are hair cells similar to those of the lateral line organ. The stereocilia projecting from the hair cells are covered by a gelatinous cupula in which the otoliths are embedded. The hair cells in the saccule and utricle lie in different planes.

Normally, the pull of gravity causes the otoliths to press against the stereocilia, stimulating them to initiate impulses. Sensory neurons at the bases of the hair cells transmit these signals to the brain. When the head is tilted or in linear acceleration (increasing speed when the body is moving in a straight line), otoliths press on the stereocilia of different cells, deflecting them. Deflection of the stereocilia toward the kinocilium depolarizes the hair cell. Deflection in the opposite direction hyperpolarizes the hair cell. Thus, depending on the direction of movement, the hair cells release more or less neurotransmitter. The brain interprets the neural messages so the animal is aware of its full body position relative to the ground regardless of how its head is positioned.

Information about turning movements, referred to as angular acceleration, is provided by the three semicircular canals. Each canal, a hollow ring connected with the utricle, lies at right angles to the other two and is filled with fluid called **endolymph.**

FIGURE **41-5** **Lateral line organ.**

(a) The lateral line organ is a canal that extends the length of the body. **(b)** The canal has numerous openings to the outside environment. **(c)** The receptor cells are hair cells. Each hair cell has stereocilia and a kinocilium that are covered with a gelatinous cupula. The hair cells respond to waves, currents, or other disturbances in the water, informing the fish of obstacles or moving objects.

BiologyNow™ Watch the **human ear** in action by clicking on this figure on your BiologyNow CD-ROM.

At one of the openings of each canal into the utricle is a small, bulblike enlargement, the **ampulla.** Within each ampulla lies a clump of hair cells called a **crista** (pl., *cristae*), similar to the groups of hair cells in the utricle and saccule. No otoliths are present. The stereocilia of the hair cells of the cristae are stimulated by movements of the endolymph in the canals (Fig. 41-8).

When the head is turned, there is a lag in the movement of the fluid within the canals. The stereocilia move in relation to the fluid and are stimulated by its flow. This stimulation produces not only the consciousness of rotation but also certain reflex movements in response to it. These reflexes cause the eyes and head to move in a direction opposite that of the original rotation. Because the three canals are in three different planes, head movement in any direction stimulates fluid movement in at least one of the canals.

We humans are used to movements in the horizontal plane but not to vertical movements (parallel to the long axis of the upright body). The motion of an elevator or of a ship pitching in a rough sea stimulates the semicircular canals in an unusual way and may cause seasickness or motion sickness, with resultant nausea or vomiting. When a seasick person lies down, the movement stimulates the semicircular canals in a more familiar way, and nausea is less likely to occur.

Auditory receptors are located in the cochlea

Many arthropods and most vertebrates have sound receptors, but for many of them hearing does not seem to be a sensory priority. It is important in tetrapods, however, and both birds and mammals have a highly developed sense of hearing. Their auditory receptors, located in the **cochlea** of the inner ear, contain mechanoreceptor hair cells that detect pressure waves.

The cochlea is a spiral tube that resembles a snail's shell (Fig. 41-9). If the cochlea were uncoiled, you would see that it consists of three canals separated from each other by thin membranes and coming almost to a point at the apex. Two of these canals, or ducts, the **vestibular canal** and the **tympanic canal,** connect at the apex of the cochlea and are filled with a fluid known as **perilymph.** The middle canal, the **cochlear duct,** is filled with endolymph and contains the auditory organ, the **organ of Corti.**

Each organ of Corti contains about 18,000 hair cells, in rows that extend the length of the coiled cochlea. Each hair cell has stereocilia that extend into the cochlear duct. The hair cells rest on the **basilar membrane,** which separates the cochlear duct from the tympanic canal. Overhanging and in contact with the hair cells of the organ of Corti is another membrane, the **tectorial membrane.**

In terrestrial vertebrates sound waves in the air are transformed into pressure waves in the cochlear fluid. In the human ear, for example, sound waves pass through the **external auditory canal** and vibrate the **tympanic membrane,** or eardrum (the membrane separating the outer ear and the middle ear). The vibrations are transmitted across the middle ear by three

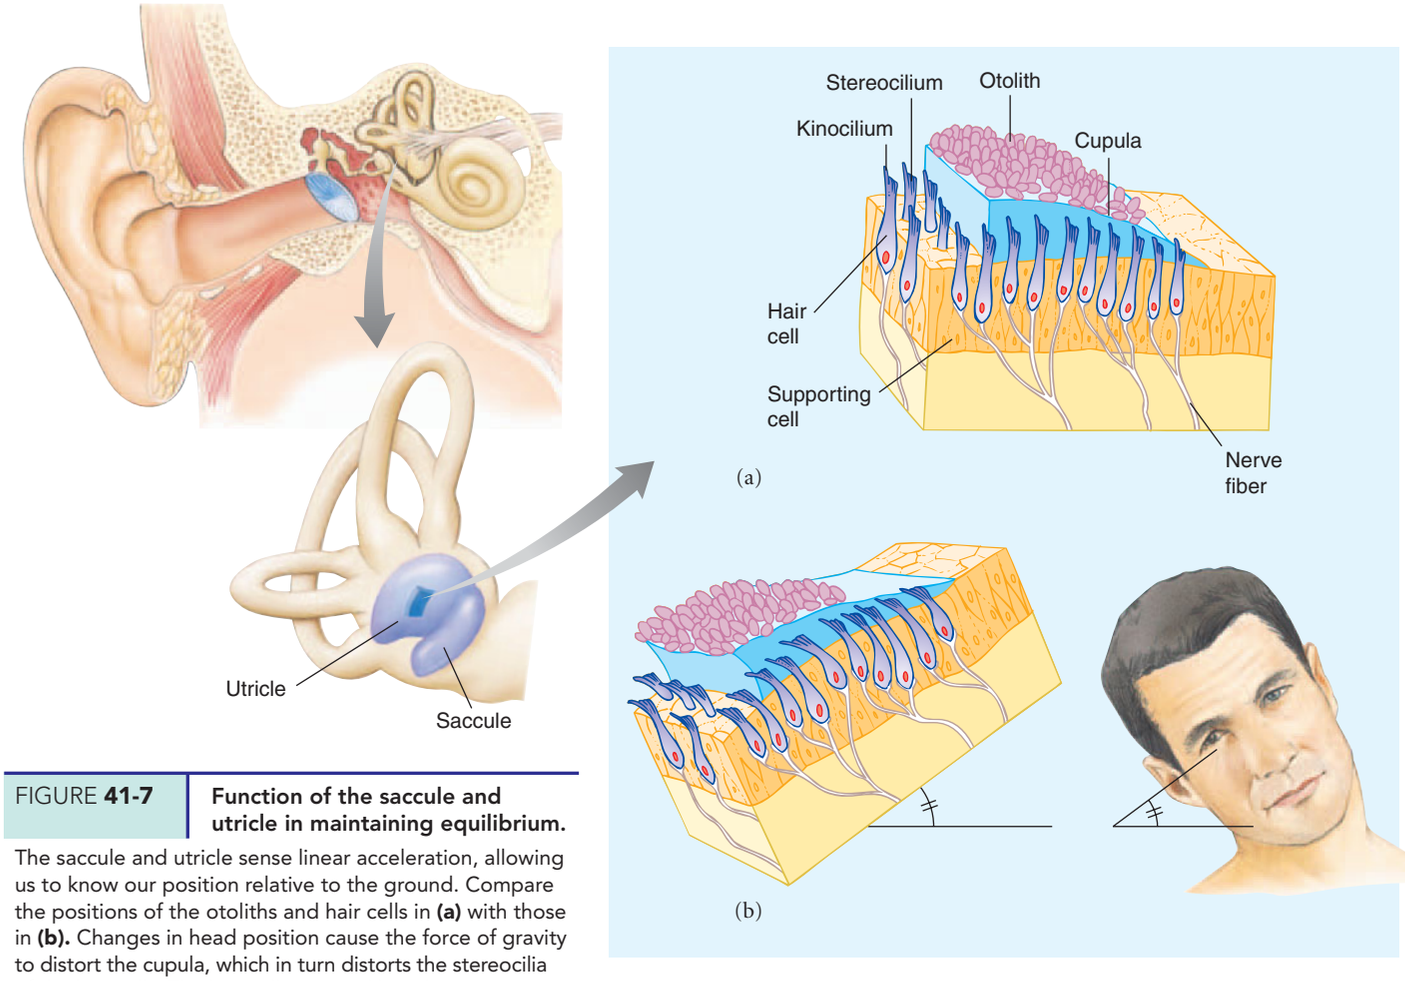

FIGURE **41-7** **Function of the saccule and utricle in maintaining equilibrium.**

The saccule and utricle sense linear acceleration, allowing us to know our position relative to the ground. Compare the positions of the otoliths and hair cells in **(a)** with those in **(b).** Changes in head position cause the force of gravity to distort the cupula, which in turn distorts the stereocilia of the hair cells. The hair cells respond by releasing neurotransmitters. Impulses are transmitted along the vestibulocochlear nerve to the brain.

tiny bones—the **malleus, incus,** and **stapes** (or hammer, anvil, and stirrup, so called because of their shapes). The malleus is in contact with the eardrum, and the stapes is in contact with a thin, membranous region of the cochlea, called the **oval window.** These bones act as three interconnected levers that amplify the vibrations. A very small movement in the malleus causes a larger movement in the incus and a very large movement in the stapes. The vibrations pass through the oval window to the perilymph in the vestibular canal. If sound waves were conducted directly from air to the oval window, much energy would be lost. The middle ear functions to couple sound waves in the air with the pressure waves conducted through the fluid in the cochlea.

Because liquids cannot be compressed, the oval window could not cause movement of the fluid in the vestibular canal if there were no escape valve for the pressure.

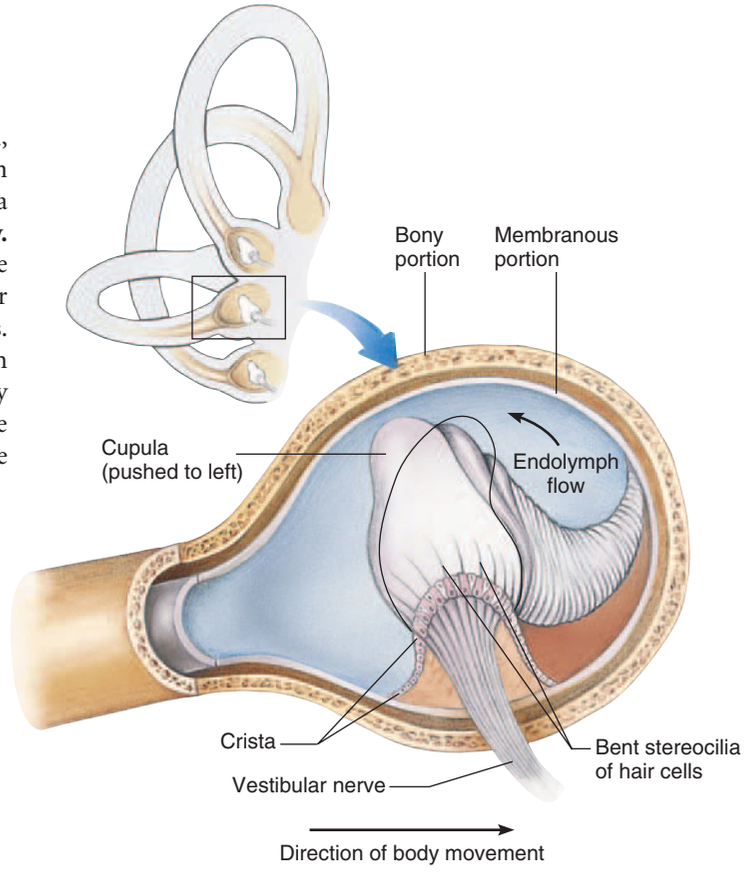

FIGURE **41-8** **Semicircular canals and equilibrium.**

When the head changes its rate of rotation, endolymph within the ampulla of the semicircular canal distorts the cupula. The stereocilia of the hair cells bend, increasing the frequency of action potentials in sensory neurons. Information is transmitted to the brain via the vestibular nerve.

KEY CONCEPT: The hair cells in the organs of Corti in the cochlea are the receptors for hearing.

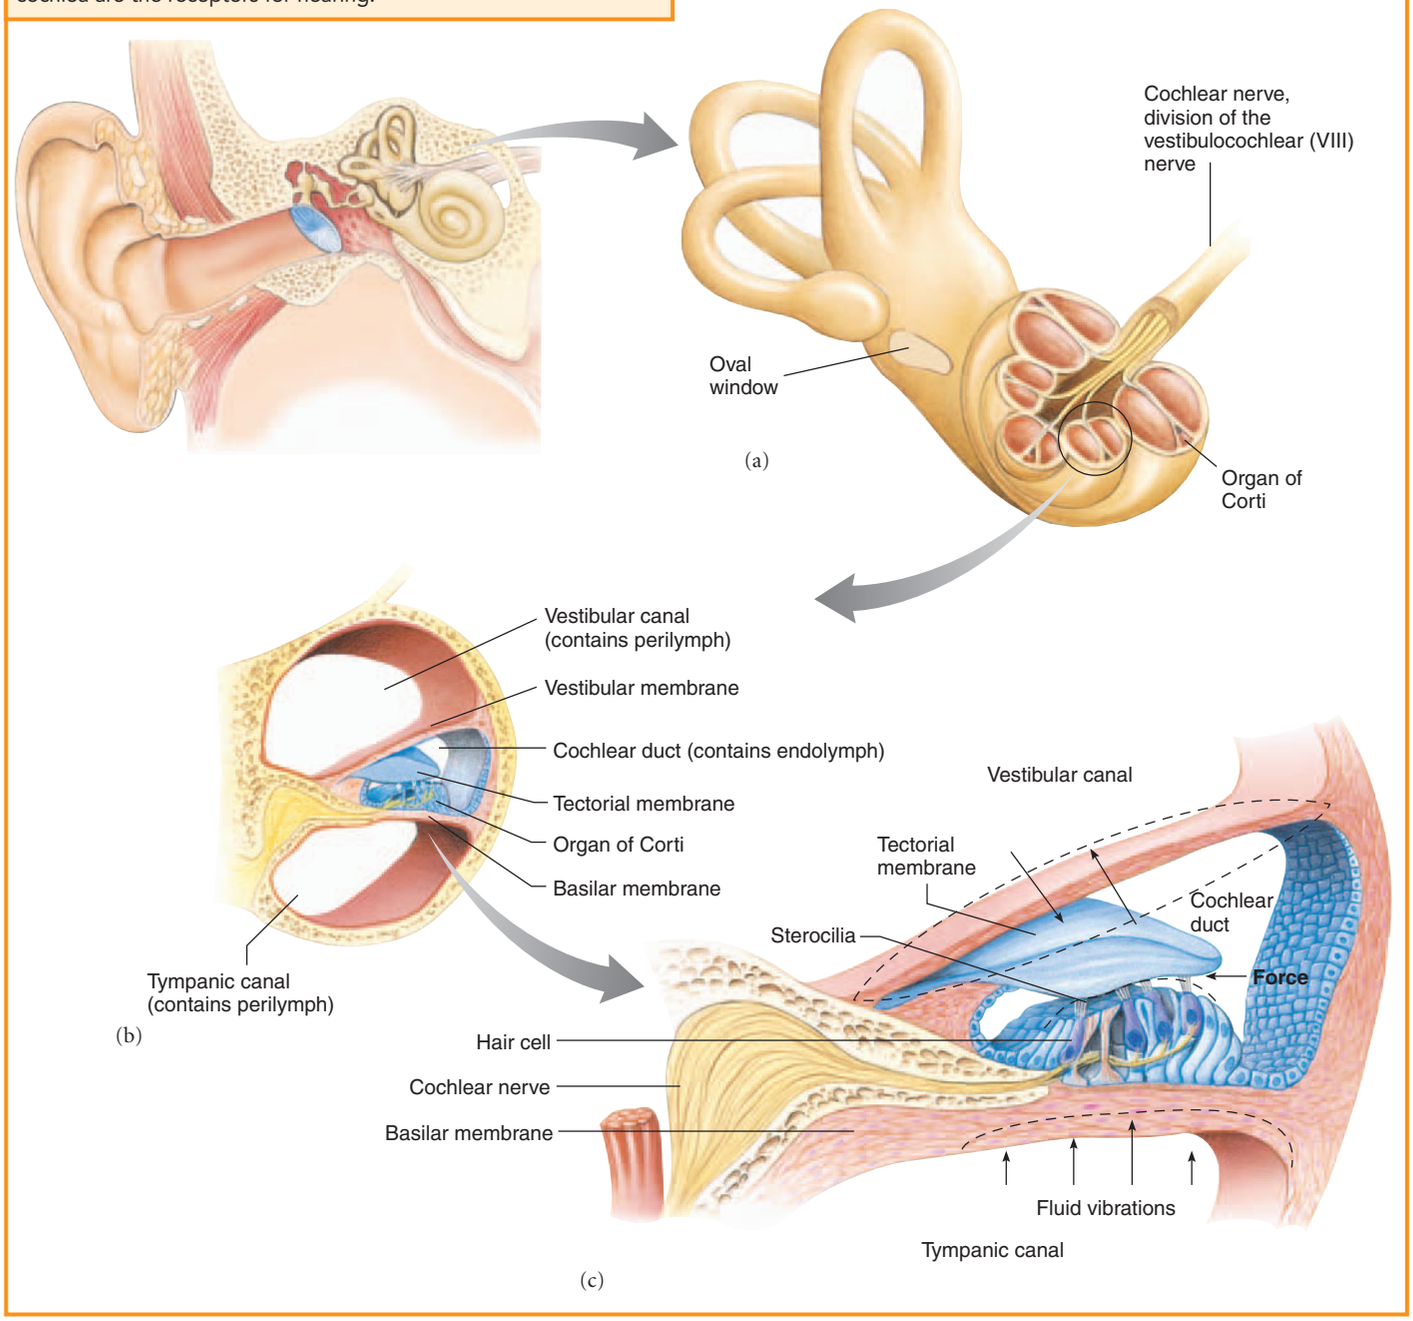

FIGURE **41-9** **The cochlea, organ of hearing.**

(a) Cross section through the cochlea showing the cochlear nerve. **(b)** Enlarged view of the organ of Corti resting on the basilar membrane and covered by the tectorial membrane. **(c)** How the organ of Corti works. Vibrations transmitted by the malleus, incus, and stapes set the fluid in the tympanic canal in motion. These vibrations *(dotted lines)* are transmitted to the basilar membrane, and, as the membrane vibrates, hair cells of the organ of Corti rub against the overlying tectorial membrane. This stimulation depolarizes the hair cells, prompting action potentials in the sensory neurons of the cochlear nerve.

This valve is provided by the membranous **round window** at the end of the tympanic canal. The pressure wave presses on the membranes separating the three ducts, is transmitted to the tympanic canal, and makes the round window bulge. The movements of the basilar membrane produced by these pulsations cause the stereocilia of the organ of Corti to rub against the overlying tectorial membrane. When stereocilia are bent by this contact, ion channels in the plasma membrane of the hair cells open. Calcium ions move into the hair cell, causing the release of the neurotransmitter *glutamate*, which binds to recep-

tors on sensory neurons that synapse on each hair cell. Glutamate binds to receptors on sensory neurons that synapse on each hair cell, leading to depolarization of sensory neurons. Axons of the sensory neurons join to form the **cochlear nerve,** a component of the vestibulocochlear nerve (cranial nerve VIII; also referred to as the *auditory nerve*).

We can summarize the sequence of events involved in hearing as follows:

Sound waves enter external auditory canal ⟶ tympanic membrane vibrates ⟶ malleus, incus, and stapes amplify vibrations ⟶ oval window vibrates ⟶ vibrations are conducted through fluid ⟶ basilar membrane vibrates ⟶ hair cells in organ of Corti are stimulated ⟶ cochlear nerve transmits impulses to brain

Sounds differ in pitch, loudness, and tone quality. **Pitch** depends on frequency of sound waves, or number of vibrations per second, and is expressed as hertz (Hz). Low-frequency vibrations result in the sensation of low pitch, whereas high-frequency vibrations result in the sensation of high pitch. Sounds of a given frequency set up resonance waves in the cochlear fluid that cause a particular section of the basilar membrane to vibrate. High frequencies are detected by hair cells located near the base of the cochlea, whereas low frequencies are sensed by hair cells near the apex of the cochlea. The brain infers the pitch of a sound from the particular hair cells that are stimulated.

Loud sounds cause resonance waves of greater amplitude (height). The hair cells are more intensely stimulated, and the cochlear nerve then transmits a greater number of impulses per second. Variations in quality of sound, such as when an oboe, a cornet, and a violin play the same note, depend on the number and kinds of overtones, or harmonics, produced. These stimulate different hair cells in addition to the main stimulation common to all three instruments. Thus differences in tone quality are recognized in the pattern of the hair cells stimulated.

Your ear typically registers sound frequencies between about 20 and 20,000 Hz. (Dogs and some other animals can hear sounds of much higher frequencies.) The human ear is most sensitive to sounds between 1000 and 4000 Hz. Comparing the energy of audible sound waves with the energy of visible light waves, your ear is 10 times more sensitive than your eye.

Deafness may be caused by injury to, or malformation of, either the sound-transmitting mechanism of the outer, middle, or inner ear, or the sound-perceiving mechanism of the inner ear. Efferent neurons from the brain stem protect the hair cells of the organ of Corti by dampening their response. Even so, exposure to high-intensity sound, such as heavily amplified music, damages hair cells in the organ of Corti.

Review

CHEMORECEPTORS

Learning Objective

6 Compare the structure and function of the receptors of taste and smell.

Two highly sensitive chemoreceptive systems are the senses of **taste** (gustation) and **smell** (olfaction). These chemical senses, found throughout the animal kingdom, allow animals to detect chemical substances in food, water, and air. Evaluating such chemical cues allows animals to find food and mates and to avoid predators. Chemoreception is also used by members of the same species to communicate information about food sources, potential mates, and danger.

For terrestrial vertebrates, the sense of smell involves gaseous substances that reach olfactory receptors through the air. The sense of taste involves materials dissolved in water (or saliva) in the mouth. For aquatic animals, these distinctions blur. Does a catfish smell or taste the water?

Taste buds detect dissolved food molecules

The ability to discriminate among tastes has survival value. For example, foods with a high caloric value often taste sweet, whereas poisons are generally bitter. The organs of taste in insects are sensory hairs. Mammals sense taste with **taste buds** located in the mouth. In humans, taste buds lie mainly in tiny elevations, or papillae, on the tongue. Each of the thousands of taste buds is an oval epithelial capsule containing about 100 taste receptor cells interspersed with supporting cells (Fig. 41-10).

The plasma membrane at the tip of each taste receptor cell has microvilli that extend into a taste pore on the surface of the tongue, where they are bathed in saliva. The taste receptors detect chemical substances dissolved in saliva. Certain molecules, such as those perceived as sweet, activate a signal transduction process involving a G protein (see Fig. 41-10c). Adenylyl cyclase activity increases, elevating cyclic AMP levels. A protein kinase is activated that phosphorylates and closes K^+ channels. This decrease in K^+ permeability sets up a depolarizing receptor potential. Action potentials are then generated in sensory neurons that synapse with the taste receptor cell. One sensory neuron can innervate several taste buds.

Traditionally, four basic tastes have been recognized: sweet, sour, salty, and bitter. In 2000, physiologists reported a fifth taste, glutamate. Although the idea of a fifth taste is still somewhat controversial, it was first suggested almost a century ago by the Japanese physiologist Kikunae Ikeda. In 1908, Ikeda identified glutamate as the compound that triggers the taste he called umami, responsible for the savoriness of certain aged cheeses, soy sauce, anchovy, and some seafoods.

Flavor depends on the four or five basic tastes in combination with smell, texture, and temperature. Smell affects flavor because odors pass from the mouth to the nasal chamber. No doubt you have observed that when your nose is congested, food seems to have little "taste." The taste buds are not affected, but the blockage of nasal passages severely reduces the participation of olfactory reception in the composite sensation of flavor.

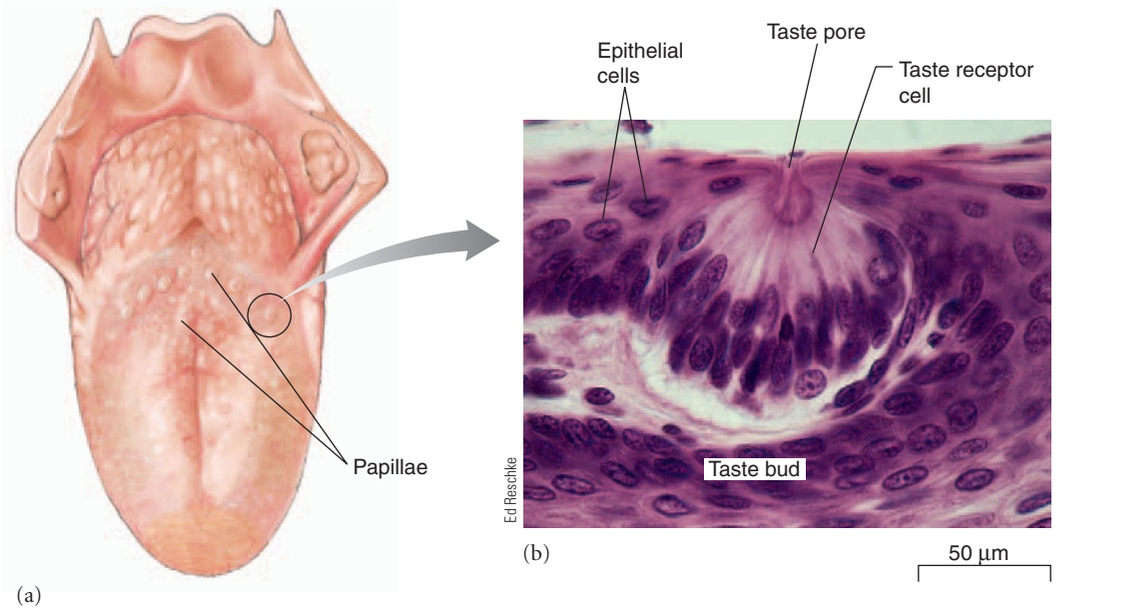

FIGURE **41-10** **Taste buds.**

(a) The taste buds are located in the papillae, which cover the surface of the tongue. **(b)** LM of a taste bud: an epithelial capsule containing several taste receptor cells. A single taste receptor cell may respond to more than one category of taste. **(c)** A sugar molecule activates a signal transduction process. (1) The sugar binds with a receptor in the plasma membrane of a taste receptor cell. (2) A G protein is activated, and (3) a GTP-coupled subunit of the G protein activates adenylyl cyclase. (4) ATP is converted to cyclic AMP (cAMP). (5) Cyclic AMP activates a protein kinase. (6) Action of the protein kinase closes K^+ channels. The decrease in K^+ permeability results in an action potential in a sensory neuron that synapses with the taste receptor cell.

PROCESS OF SCIENCE

Awareness of the genetic component of taste can be traced to 1931 when Arthur L. Fox, a chemist at the DuPont Company synthesized a compound called *phenylthiocarbamide (PTC)*. Some PTC blew into the air and was inhaled by a colleague, who experienced it as very bitter. Because Fox himself could not taste it, he became intrigued and asked other people to taste it. Fox found that about 25% of people were nontasters. Everyone else experienced PTC as bitter. Further research showed that the ability to taste PTC is inherited as a dominant trait.

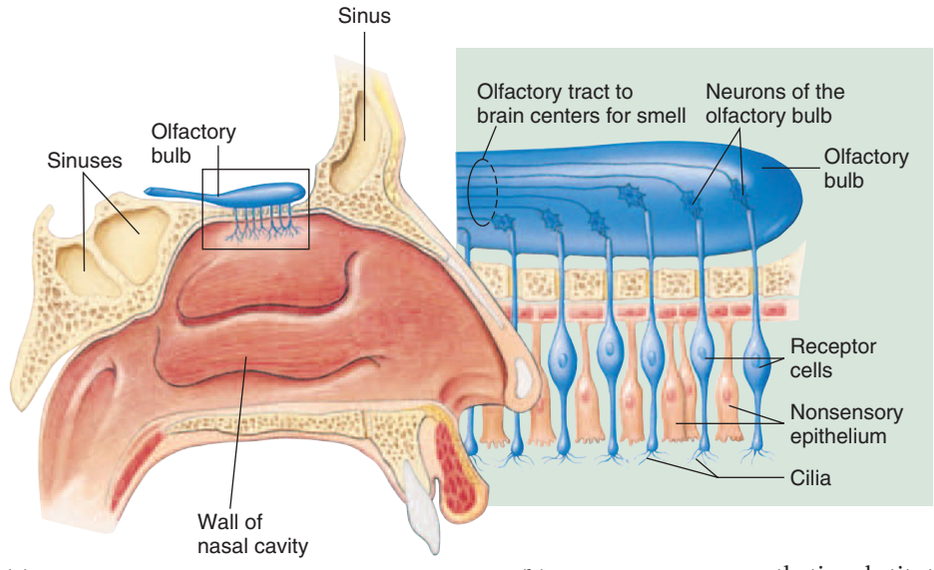
In the 1970s Linda Bartoshuk of Yale University continued taste research using a chemical compound called PROP (6-*n*-propylthiouracil). She found some tasters were especially sensitive to the bitter taste of PROP. Subsequent studies suggest that about 25% of the U.S. population are supertasters, 50% are regular tasters, and 25% are nontasters.

In 1997, Adam Drewnowski at the University of Michigan and his team reported that supertasters avoid broccoli, brussels sprouts, cabbage, and many other vegetables and fruits that taste bitter. These foods contain flavonoids and other compounds that are thought to protect against cancer. Continuing investigation of taste preferences and their nutritional consequences may lead to more effective approaches to improving nutrition and to a better understanding of the relative importance of genetics and learning in food selection.

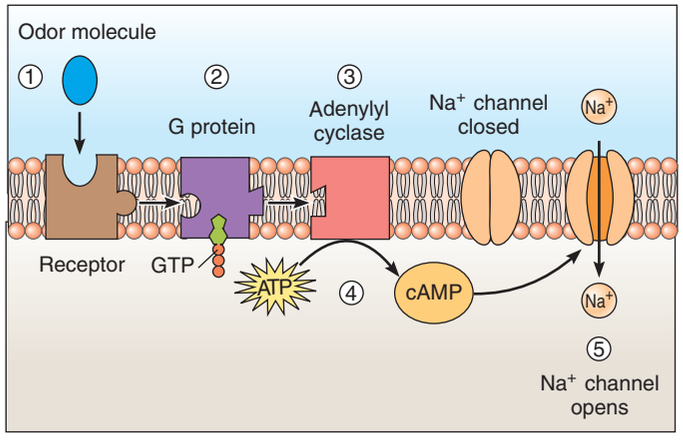
The olfactory epithelium is responsible for the sense of smell

Most invertebrates depend on **olfaction,** the detection of odors, as their main sensory modality. Recent findings indicate that the mechanisms for chemoreception have been highly conserved throughout the animal kingdom.

In terrestrial vertebrates, olfaction occurs in the nasal epithelium. In humans, the **olfactory epithelium** is found in the roof of the nasal cavity (Fig. 41-11). It contains about 100 million olfactory receptor cells with ciliated tips. The long, nonmotile cilia extend into a layer of mucus on the epithelial surface of the nasal passageway. Receptor molecules on the cilia bind with compounds dissolved in the mucus. The other end of each olfactory receptor cell is an axon that projects directly to the brain. These axons make up the **olfactory nerve** (the first cranial nerve), which extends to the olfactory bulb in the brain.



(a) (b)



(c)

FIGURE 41-11 Olfactory epithelium.

(a) Smell depends on thousands of chemoreceptor cells in the roof of the nasal cavity. **(b)** The receptor cells are neurons located in the olfactory epithelium. **(c)** In step ① an odor molecule binds to a receptor in the plasma membrane of an olfactory cell, triggering a signal transduction process. ② A G protein is activated, and ③ a GTP-coupled subunit of the G protein activates adenylyl cyclase. ④ ATP is converted to cyclic AMP, which ⑤ opens gated channels. Sodium ions enter the cell, leading to depolarization.

From there information is transmitted to the **olfactory cortex,** which is in the limbic system, a part of the brain also associated with emotional behavior. (Odors are often associated with feelings and memories.)

When a molecule binds with a receptor on the cilia of an olfactory receptor cell, a signal transduction process is initiated (see Fig. 41-11c). A G protein is activated, leading to the synthesis of cyclic AMP, which opens gated channels in the plasma membrane. These channels permit Na^+ and other cations to enter the cell, causing depolarization, which is the receptor potential. The number of odorous molecules determines the intensity, which in turn determines the magnitude of the receptor potential.

Humans can detect at least seven main groups of odors: camphor, musk, floral, peppermint, ethereal, pungent, and putrid. About 1000 genes code for 1000 types of olfactory receptors. Each odor consists of several component chemical groups, and each type of receptor may bind with a particular component. The combination of receptors activated determines what odor you perceive. You are capable of perceiving about 10,000 scents.

The olfactory receptors respond to remarkably small amounts of a substance. For example, most people can detect ionone, the synthetic substitute for the odor of violets, when it is present in a concentration of only one part to more than 30 billion parts of air. Smell is perhaps the sense that adapts most quickly. The olfactory receptors adapt about 50% in the first second or so after stimulation, so even offensively odorous air may seem odorless after only a few minutes.

Animals within many species communicate with one another by releasing **pheromones,** small volatile molecules that are secreted into the environment. For example, female moths release pheromones that attract males, and dogs and wolves use pheromones to mark territory. Mammals have specialized chemoreceptor cells that detect pheromones. These cells make up the **vomeronasal organ** located in the epithelium of the nose (separate from the main olfactory epithelium). The vomeronasal sensory neurons send signals to areas of the hypothalamus, which serves as a link with the endocrine system. (We discuss pheromones further in Chapter 50.)

Review

- How are the signal transduction processes of taste buds and olfactory receptor cells alike? How are they different?

BiologyNow™ Assess your understanding of **chemoreceptors** by taking the pretest on your BiologyNow CD-ROM.

PHOTORECEPTORS

Learning Objectives

7 Contrast simple eyes, compound eyes, and vertebrate eyes.

8 Describe the functions of each structure of the vertebrate eye.

9 Describe the events that take place in human vision; compare the two types of photoreceptors, and describe the signal transduction pathway as part of your explanation.

Most animals have photoreceptors that use pigments to absorb light energy. **Rhodopsins** are the photopigments in the eyes of cephalopod mollusks, arthropods, and vertebrates. Light energy striking a light-sensitive receptor cell containing these pigments

triggers chemical changes in the pigment molecules that result in receptor potentials.

Invertebrate photoreceptors include eyespots, simple eyes, and compound eyes

The simplest light-sensitive structures in animals are found in certain cnidarians and flatworms (Fig. 41-12). They are **eyespots,** called **ocelli,** that detect light but do not form images. Eyespots are often bowl-shaped clusters of light-sensitive cells within the epidermis. They may detect the direction of the light source and distinguish light intensity.

Effective image formation requires a more complex **eye,** usually with a **lens.** A lens is a structure that concentrates light on a group of photoreceptors. Vision also requires a brain that can interpret the action potentials generated by the photoreceptors. The brain integrates information about movement, brightness, location, position, and shape of the visual stimulus.

Two fundamentally different types of eyes evolved: the camera eye of vertebrates and some mollusks (squids and octopods), and the compound eye of arthropods.

The **compound eyes** of crustaceans and insects differ structurally and functionally from vertebrate eyes (Fig. 41-13). The surface of a compound eye appears faceted, which means "having many faces," like a diamond. Each **facet** is the convex *cornea* of one of the eye's visual units, called **ommatidia** (sing., *ommatidium*). The number of ommatidia varies with the species. For example, each eye of certain crustaceans has only 20 ommatidia, whereas the dragonfly eye has as many as 28,000.

The optical part of each ommatidium includes a biconvex lens and a **crystalline cone.** These structures focus light onto photoreceptor cells called **retinular cells.** These cells have a light-sensitive membrane made up of microvilli containing rhodopsin. The membranes of adjacent retinular cells may fuse, forming a rod-shaped **rhabdome** that is sensitive to light.

Compound eyes do not perceive form well. Although the lens system of each ommatidium is adequate to focus a small inverted image, little evidence suggests the animal actually perceives them as images. However, all the ommatidia together produce a composite image, or **mosaic** picture. Each ommatidium, in gathering a point of light from a narrow sector of the visual field, is in fact sampling a mean intensity from that sector. All these points of light taken together form a mosaic picture (Fig. 41-13d).

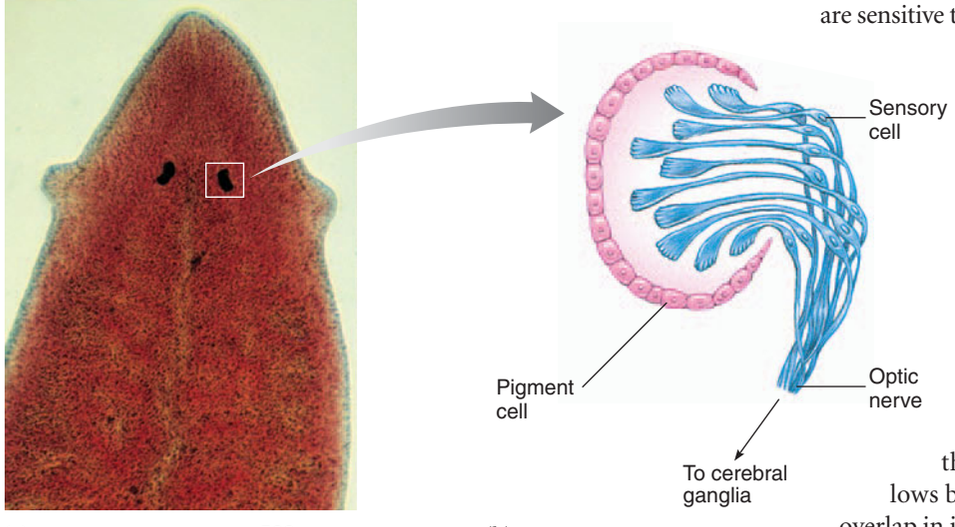
Arthropod eyes usually adapt to different intensities of light. A sheath of pigmented cells envelops each ommatidium, and screening pigments are present in cells called iris cells and in retinular cells. In nocturnal and crepuscular (active at dusk) insects and many crustaceans, pigment migrates proximally and distally within each pigmented cell. When the pigment is in the proximal position, each ommatidium is shielded from its neighbor, and only light entering directly along its axis can stimulate the receptors. When the pigment is in the distal position, light striking at any angle can pass through several ommatidia and stimulate many retinal units. As a result, sensitivity is increased in dim light, and the eye is protected from excessive stimulation in bright light. Pigment migration is under neural control in insects and under hormonal control in crustaceans. In some species it follows a daily rhythm.

Although the compound eye can form only coarse images, it compensates by following flickers to higher frequencies. Flies can detect up to about 265 flickers per second. In contrast, the human eye can detect only 45 to 53 flickers per second; for us, flickering lights fuse above these values, so we see light provided by an ordinary bulb as steady and the movement in motion pictures as smooth. To an insect, both room lighting and motion pictures must flicker horribly. The insect's high critical flicker fusion threshold permits immediate detection of even slight movement by prey or enemy. The compound eye is an important adaptation to the arthropod's way of life.

Compound eyes differ from our eyes in another respect. They are sensitive to wavelengths of light in the range from red to ultraviolet (UV). Accordingly, an insect can see UV light well, and its world of color is very different from ours. Because they reflect UV light to various degrees, flowers that appear identically colored to humans may appear strikingly dissimilar to insects (see Fig. 35-3).

FIGURE **41-12** **Eyespots.**

The simplest light-sensitive structures are the ocelli, or eyespots, found in certain invertebrates. **(a)** A planarian worm showing eyespots. **(b)** Structure of the eyespot of a planarian worm.



Vertebrate eyes form sharp images

The position of the eyes in the front of the head of primates and certain birds allows both eyes to focus on the same object. The overlap in information they receive results in the same visual information striking the two retinas (light-sensitive

The eye registers changes in light and shade, permitting the animal to detect movement. **(c)** Structure of an ommatidium. The rhabdome is the light-sensitive core of the ommatidium. **(d)** A bee eye view of a flower. This photo was taken using an optical device to achieve an approximate simulation of how the bee might see this flower. However, the bee would see UV light rather than red, and circles would be vertically elongated ellipses.

areas) at the same time. This **binocular vision** is important in judging distance and in depth perception.

The vertebrate eye can be compared to a camera. An adjustable lens can be focused for different distances, and a diaphragm, called the **iris,** regulates the size of the light opening, called the **pupil** (Fig. 41-14). The **retina** corresponds to the light-sensitive film used in a camera. Outside the retina is the **choroid layer,** a sheet of cells filled with black pigment that absorbs extra light, preventing light from being reflected back into the photoreceptors that would cause blurring of images. (Cameras are also black on the inside.) The choroid is rich in blood vessels that supply the retina.

The outer coat of the eyeball, called the **sclera,** is a tough, opaque, curved sheet of connective tissue that protects the inner structures and helps maintain the rigidity of the eyeball. On the front surface of the eye, this sheet becomes the thinner, transparent **cornea,** through which light enters. The cornea serves as a fixed lens that focuses light.

The lens of the eye is a transparent, elastic ball just behind the iris. It bends the light rays coming in and brings them to a focus on the retina. The lens is aided by the curved surface of the cornea and by the refractive properties (ability to bend light rays) of the liquids inside the eyeball. The **anterior cavity** between the cornea and the lens is filled with a watery substance, the **aqueous fluid.** The larger **posterior cavity** between the lens and the retina is filled with a more viscous fluid, the **vitreous body.** Both fluids are important in maintaining the shape of the eyeball by providing an internal fluid pressure.

At its anterior margin, the choroid is thick and projects medially into the eyeball to form the **ciliary body,** which consists of ciliary processes and the ciliary muscle. The ciliary processes are glandlike folds that project toward the lens and secrete the aqueous fluid.

We focus a camera by changing the distance between the lens and the film. The eye has the power of **accommodation,** the ability to change focus for near or far vision by changing the shape of the lens (Fig. 41-15). This is accomplished by the **ciliary muscle,** a part of the ciliary body. To focus on close objects, the ciliary muscle contracts, making the elastic lens rounder. To focus on more distant objects, the ciliary muscle relaxes and the lens assumes a flattened (ovoid) shape.

The amount of light entering the eye is regulated by the iris, a ring of smooth muscle that appears as blue, green, gray, or

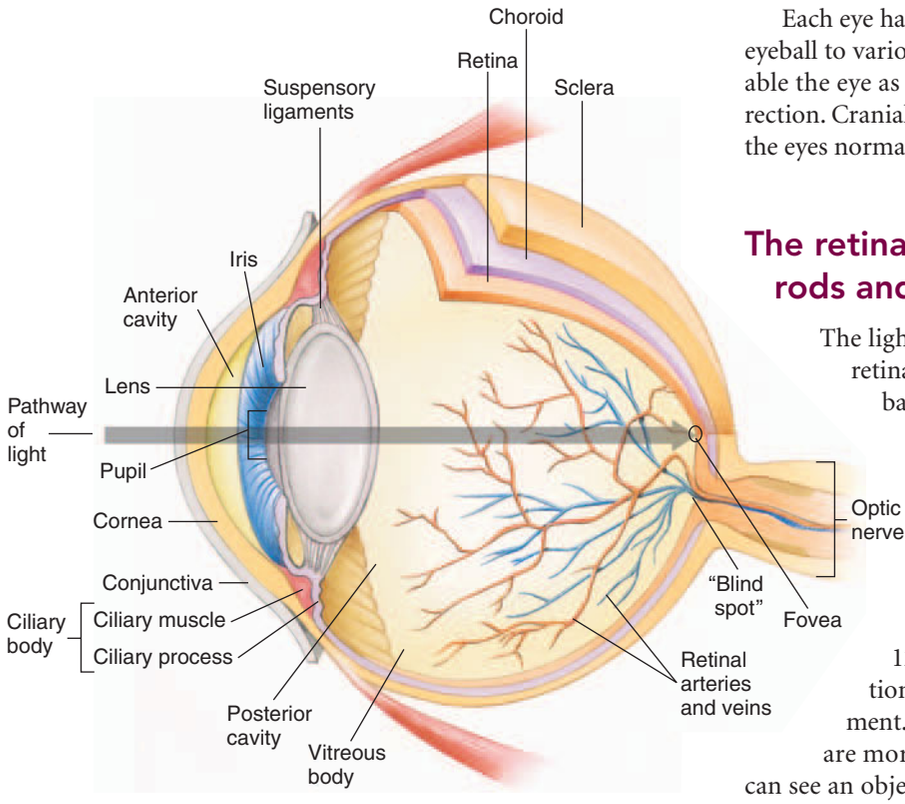

FIGURE **41-14** **Structure of the human eye.**

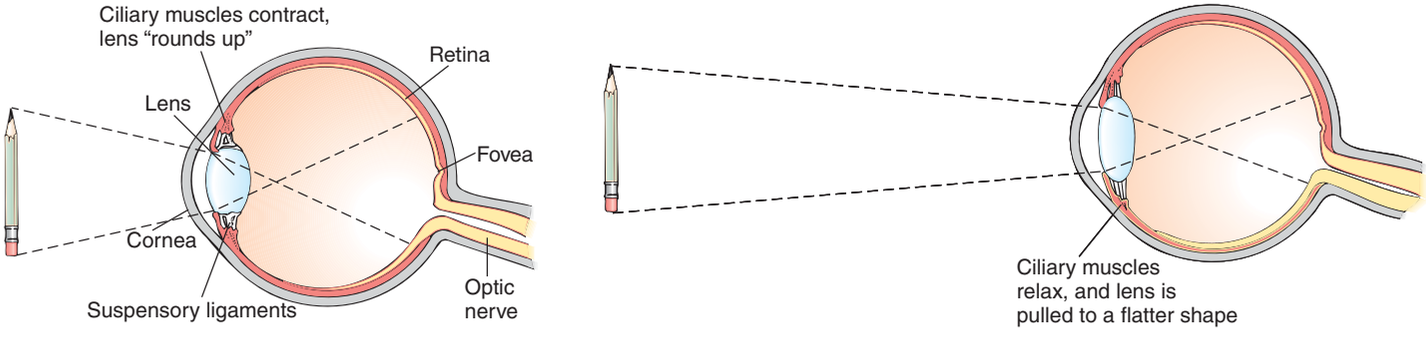
Light passes through the human eye to photoreceptor cells in the retina. In this lateral view, the eye is shown partly sectioned along the sagittal plane to show its internal structures.

brown depending on the amount and nature of pigment present. The iris consists of two mutually antagonistic sets of muscle fibers. One set is arranged circularly and contracts to *decrease* the size of the pupil. The other is arranged radially and contracts to *increase* the size of the pupil.

ACTIVE FIGURE **41-15** **Accomodation.**

How the eye changes focus for **(a)** near and **(b)** distant vision.

BiologyNow™ See how **vision disorders** change the eye by clicking on this figure on your BiologyNow CD-ROM.



(a) Near vision

(b) Distant vision

Each eye has six muscles that extend from the surface of the eyeball to various points in the bony socket. These muscles enable the eye as a whole to move and be oriented in a given direction. Cranial nerves innervate the muscles in such a way that the eyes normally move together and focus on the same area.

The retina contains light-sensitive rods and cones

The light-sensitive structure in the vertebrate eye is the retina, which lines the posterior two thirds of the eyeball, covering the choroid. The retina, which is composed of 10 layers, contains the photoreceptor cells called, according to shape, **rods** and **cones.** In both rod and cone cells, infoldings of the plasma membrane form stacks of membranous discs that contain the photopigments. The discs greatly increase the light-absorbing surface. The human eye has about 125 million rods and 6.5 million cones. Rods function in dim light, letting us detect shape and movement. They are not sensitive to colors. Because the rods are more numerous in the periphery of the retina, you can see an object better in dim light if you look slightly to one side of it (allowing the image to fall on the rods).

Cones respond to light at higher levels of intensity, for example daylight, and they allow us to perceive fine detail. Cones are responsible for color vision; they are differentially sensitive to different wavelengths (colors) of light. In primates and certain hunting birds (such as eagles), the cones are most concentrated in the **fovea,** a small depressed area in the center of the retina. The fovea is the region of sharpest vision because it has the greatest density of receptor cells and because the retina is thinner there.

Light must pass through several layers of connecting neurons in the retina to reach the rods and cones (Fig. 41-16). This arrangement lets the rods and cones contact a layer of pigmented epithelium that provides retinal, a component of rhodopsin. The retina has five main types of neurons: (1) Photoreceptors (rods and cones) synapse on (2) **bipolar cells,** which make synaptic contact with (3) **ganglion cells.** Two types of lateral interneurons are the (4) **horizontal cells,** which receive information from the photoreceptor cells and send it to bipolar cells, and (5) **amacrine cells,** which receive messages from the bipolar

cells and send signals back to the bipolar cells or to ganglion cells (Fig. 41-17). Interestingly, researchers recently reported that one group of ganglion cells project to the suprachiasmatic nucleus, the body's main biological clock. These ganglion cells contain a light-sensitive pigment (melanopsin) that is important in nonvisual responses to light.

The axons of the ganglion cells extend across the surface of the retina and unite to form the **optic nerve.** The area where the optic nerve passes out of the eyeball, the **optic disk,** is known as the "blind spot"; because it lacks rods and cones, images falling on it cannot be perceived. A simplified summary of the visual pathway follows:

Light passes through cornea ⟶ through aqueous fluid ⟶ through lens ⟶ through vitreous body ⟶ image forms on photoreceptor cells in retina ⟶ signal bipolar cells ⟶ signal ganglion cells ⟶ optic nerve transmits signals to thalamus ⟶ integration by visual areas of cerebral cortex

FIGURE **41-16** **Organization of the retina.**

(a) The elaborate interconnections among the various layers of neurons in the retina let them interact and influence one another. The rods and cones are the photoreceptor cells. **(b)** Rods *(red elongated structures)* and two cones *(shorter, thicker, yellow structures)* are seen in this SEM. The elongated rods permit you to see shape and movement, whereas the shorter cones allow you to view the world in color.

KEY CONCEPT: The rods and cones in the retina are the photoreceptors in vertebrates.

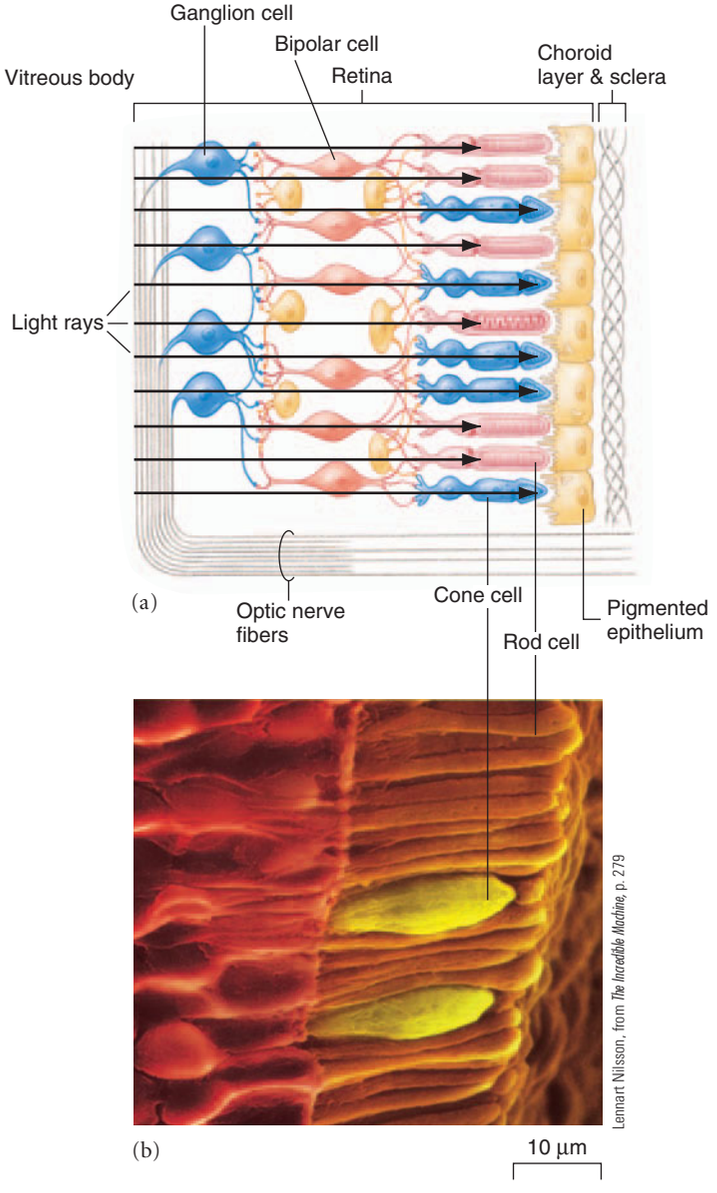


FIGURE **41-17** **Neural pathway in the retina.**

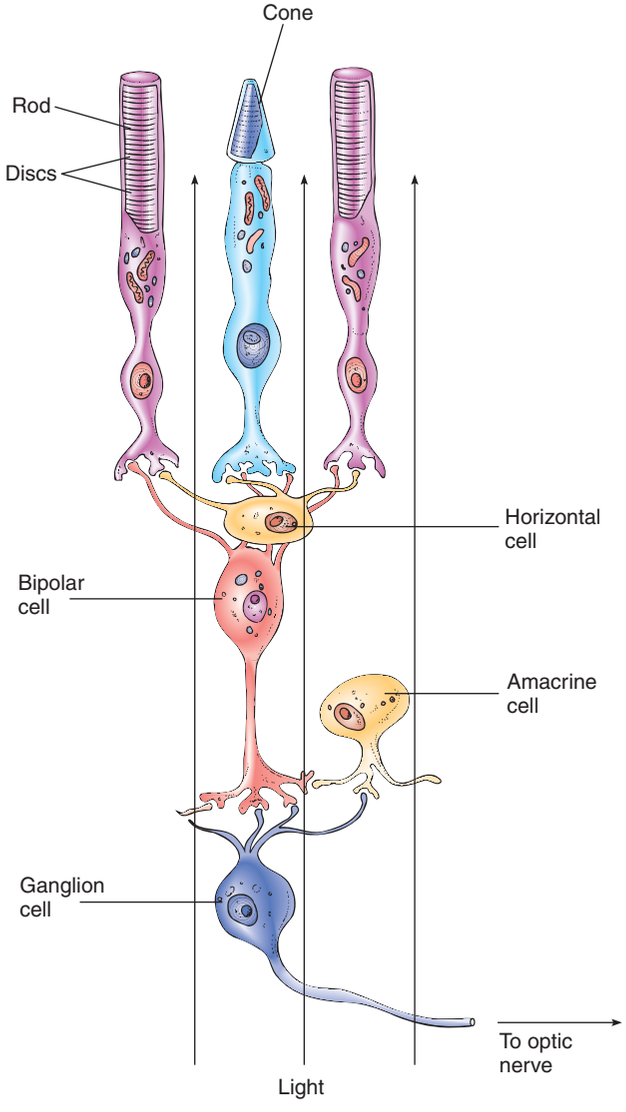
The photoreceptor cells (rods and cones) are located in the back of the retina. They synapse with bipolar and horizontal cells. The bipolar cells synapse with ganglion cells and amacrine cells. Axons of ganglion cells make up the optic nerve.



A chemical change in rhodopsin leads to the response of a rod to light

How is light converted into the neural signals that transmit information about environmental stimuli into pictures in the brain? Rod cells are so sensitive to light that they can respond to a single photon. Rhodopsin in the rod cells and some very closely related photopigments in the cone cells are responsible for the ability to see. Rhodopsin consists of *opsin,* a large protein that is chemically joined with *retinal,* an aldehyde of vitamin A (see Fig. 3-14). Two isomers of retinal exist: the *cis* form, which is folded, and the *trans* form, which is straight.

When it is dark, opsin binds to retinal in the *cis* form. Cyclic GMP (cyclic guanosine monophosphate, a molecule similar to cyclic AMP) opens nonspecific channels that permit passage of Na^+ and other cations into the rod cell (Fig. 41-18). This depolarizes the rod cell, which releases the neurotransmitter glutamate. The glutamate hyperpolarizes the membrane of the bipolar cell so it does not transmit messages. Note that the photoreceptor differs from other neurons in that the ion channels in its membrane are normally open; it is depolarized and continually releases neurotransmitter. The steady flow of ions into the cell when it is dark is called the *dark current.* Another unusual characteristic of photoreceptors, and also bipolar cells, is that they do not produce action potentials. Their release of neurotransmitter is graded, regulated by the extent of depolarization.

When light strikes rhodopsin, light is transduced. This process can be considered in three stages:

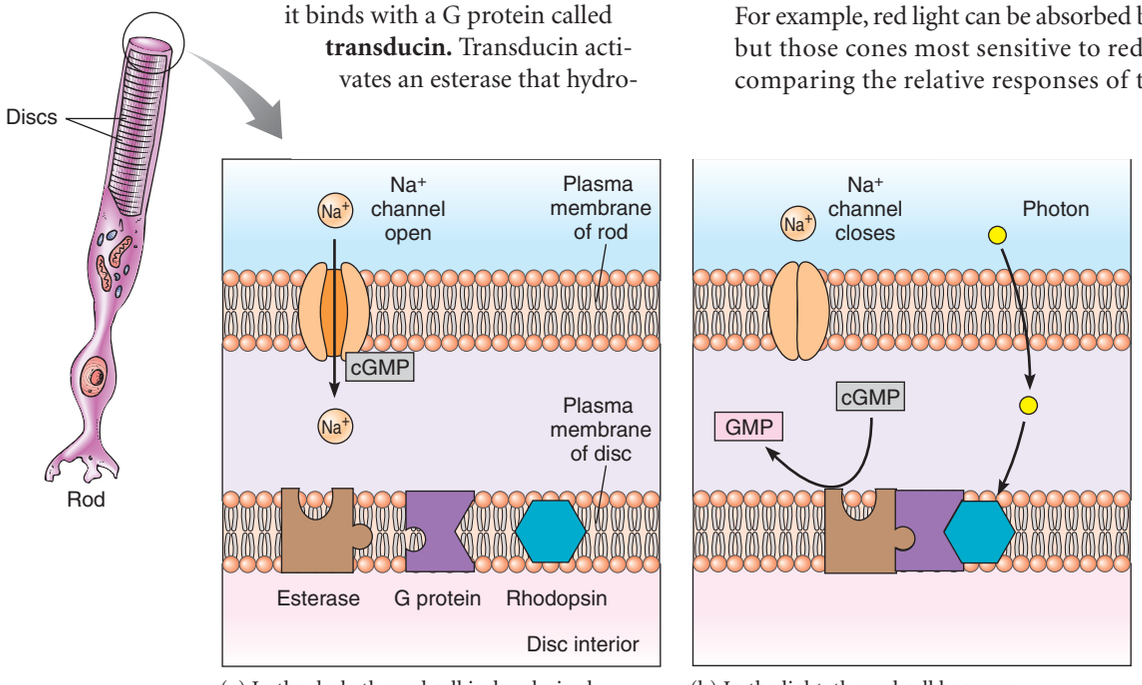
1. Light activates rhodopsin. Light transforms *cis*-retinal to *trans*-retinal. This causes rhodopsin to change shape and to break down into its components, opsin and retinal. This is the light-dependent process in vision.
2. Rhodopsin is part of a signal transduction pathway. When it changes shape, it binds with a G protein called **transducin.** Transducin activates an esterase that hydrolyzes cyclic GMP (cGMP) to GMP, reducing the concentration of cGMP.
3. When the concentration of cGMP in the rod decreases, its Na^+ channels begin to close. Fewer cations pass into the rod cell, and it becomes more negative (hyperpolarized). The rod cell then releases less glutamate. Thus light decreases the number of neural signals from the rod cells.

The release of glutamate normally hyperpolarizes the membrane of the bipolar cell, so a decrease in glutamate release results in its depolarization. The depolarized bipolar cell increases its release of a neurotransmitter, which typically stimulates the ganglion cell.

When you move from bright daylight to a dark room, or from a dimly lit room to bright light, you experience "blindness" for a few moments while your eyes adapt. In dim light, vision depends on the rods. However, exposure to bright light may completely activate rhodopsin in the rods. Dark adaptation occurs as enzymes restore rhodopsin to a form in which it can respond to light.

Color vision depends on three different types of cones

Many invertebrates and at least some animals in each vertebrate class have color vision. Color perception depends on cones. Most mammals have two types of cones, but humans and other primates have three types: blue, green, and red cones. Each contains a slightly different photopigment. Although the retinal portion of the pigment molecule is the same as in rhodopsin, the opsin protein differs slightly in each type of photoreceptor. Each type of cone responds to light within a considerable range of wavelengths but is named for the ability of its pigment to absorb a particular wavelength more strongly than other cones. For example, red light can be absorbed by all three types of cones, but those cones most sensitive to red act as red receptors. By comparing the relative responses of the three types of cones,



(a) In the dark, the rod cell is depolarized

(b) In the light, the rod cell becomes hyperpolarized

FIGURE **41-18**

The biochemistry of vision.

(a) In the dark, sodium channels are open and the rod cell is depolarized. It releases the neurotransmitter glutamate. **(b)** Light makes rhodopsin change shape, activating a signal transduction pathway. The activation of a G protein leads to hyperpolarization and a decrease in signals from the rod cell. The discs are infoldings of the plasma membrane.

the brain can detect colors of intermediate wavelengths. Color blindness occurs when there is a deficiency of one or more of the three types of cones. This is usually an inherited X-linked condition (see Chapter 10, Fig. 10-16).

Integration of visual information begins in the retina

The size, intensity, and location of light stimuli determine initial processing in the retina. Rods and cones send signals directly to bipolar cells, and bipolar cells send signals directly to ganglion cells. However, as illustrated in Figure 41-17, photoreceptor cells can also transmit signals to horizontal cells, and bipolar cells can transmit signals to amacrine cells. Ganglion cells are inhibited by amacrine cells and can be inhibited indirectly by horizontal cells, by their action on bipolar cells. Thus the horizontal and amacrine cells integrate signals laterally.

Bipolar, horizontal, and amacrine cells combine signals from several photoreceptors. Each ganglion cell has a **receptive field,** a specific group of photoreceptors that light must strike for the ganglion cell to be stimulated. Ganglion cells are activated or inhibited, depending on which photoreceptor cells have been stimulated.

The pattern of neuron firing in the retina is very important. The signals sent to ganglion cells depend on spatial patterns and timing of the light striking the retina. Ganglion cells receive signals about specific types of visual stimuli such as color, brightness, and motion and transmit this information about the characteristics of a visual image. Ganglion cells produce action potentials, in contrast with rods and cones and most other neurons of the retina, which produce only graded potentials.

The retina begins the construction of visual images, but those images are interpreted in the brain. Axons of more than a million ganglion cells form the **optic nerves** that transmit information to the brain by complex, encoded signals. The optic nerves cross in the floor of the hypothalamus, forming an X-shaped structure, the **optic chiasm** (Fig. 41-19). Some of the axons of the optic nerves cross over and then extend to the opposite side of the brain. Axons of the optic nerves end in the **lateral geniculate nuclei** of the thalamus. From there, neurons send signals to the **primary visual cortex** in the occipital lobe of the cerebrum. The lateral geniculate nucleus controls which information is sent to the visual cortex. Neurons in the reticular activating system are involved in this integration. Information is transmitted from the primary visual cortex to other cortical areas for further processing.

Different types of ganglion cells receive information about different aspects of a visual stimulus. As a result, information from each point in the retina is transmitted in parallel by several different types of ganglion cells. These cells project to different kinds of neurons in the lateral geniculate nucleus and primary visual cortex.

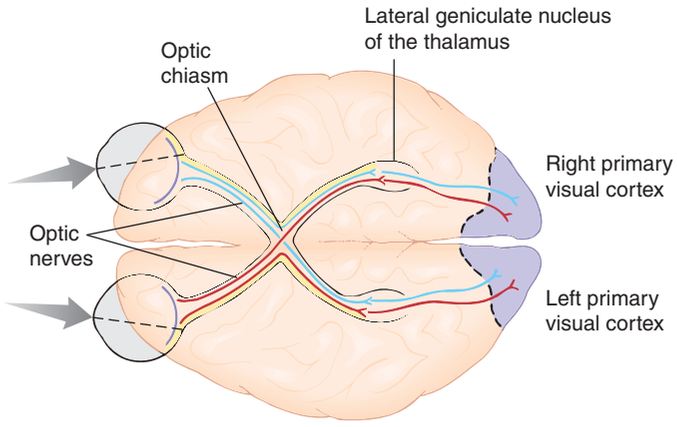


FIGURE **41-19** **Neural pathway for transmission of visual information.**

Axons of ganglion cells form the optic nerves. The optic nerves cross, forming the optic chiasm. Many optic nerve fibers end in the lateral geniculate nuclei of the thalamus. From there, signals are sent to the visual cortex.

Neurobiologists have not yet discovered all the mechanisms by which the brain makes sense out of the visual information it receives. We know that a large part of the association areas of the cerebrum are involved in integrating visual input. The neurons of the visual cortex are organized as a map of the external visual field. They are also organized into columns. Each column of neurons receives signals originating from light entering either the right or left eye. Columns are also organized by orientation of light. Neurons in a column receive signals originally triggered by light with the same orientation. However, these signals originate from different locations in the retina.

Review

- How does the insect's compound eye compare with the vertebrate eye?
- What happens when light strikes rhodopsin? (Include a description of the signal transduction pathway in your answer.)
- What is the sequence of neural signaling in the retina?
- What is meant by the statement "Vision happens mainly in the brain?"

BiologyNow™ Assess your understanding of **photoreceptors** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Distinguish among five kinds of sensory receptors according to the types of energy they transduce.

- **Sensory receptors** are neuron endings or specialized receptor cells in close contact with neurons. **Sense organs** consist of sensory receptors and accessory cells.
- **Mechanoreceptors** transduce mechanical energy, permitting animals to feel, hear, and maintain balance.
- **Chemoreceptors** transduce certain kinds of chemical compounds, allowing taste and olfaction.
- **Thermoreceptors** transduce thermal energy. In endothermic animals, thermoreceptors provide cues about body temperature; some invertebrates use thermoreceptors to locate endothermic prey.
- **Electroreceptors,** used by predatory fishes to detect prey, respond to electrical stimuli.

- **Photoreceptors** transduce light energy and serve as the sensory receptors in eyespots and eyes.

2 Describe how a sensory receptor functions; define *energy transduction*, receptor potential, and *sensory adaptation* as part of your answer.

- Receptor cells absorb energy, transduce that energy—**energy transduction**—into electrical energy, and produce **receptor potentials,** which are depolarizations or hyperpolarizations of the membrane. Receptor potentials are **graded responses.**
- The ability to experience sensation depends on sensory receptors transmitting coded signals and on the brain interpreting those signals.
- **Sensory adaptation,** the decrease in frequency of action potentials in a sensory neuron even when the stimlulus is maintained, decreases response to that stimulus.

3 Describe the following mechanoreceptors: tactile receptors, nociceptors, proprioceptors, statocysts, hair cells, and lateral line organs.

- Mechanoreceptors respond to touch, pressure, gravity, stretch, or movement. They are activated when they change shape as a result of being mechanically pushed or pulled.
- **Tactile receptors** in the skin respond to mechanical displacement of hairs or to displacement of the receptor cells themselves. For example, the **Pacinian corpuscle** is a tactile receptor that responds to touch and pressure.
- **Nociceptors** are pain receptors; they are free nerve endings of certain sensory neurons that respond to strong tactile stimuli, temperature extremes, and certain chemicals.
- **Proprioceptors** enable the animal to perceive orientation of the body and the positions of its parts. **Muscle spindles, Golgi tendon organs,** and **joint receptors** are proprioceptors that continually respond to tension and movement.
- **Statocysts** are gravity receptors found in many invertebrates.
- Vertebrate **hair cells** detect movement; they are found in the lateral line of fishes, the vestibular apparatus, semicircular canals, and cochlea. Each hair cell has a single **kinocilium,** which is a true cilium, and **stereocilia,** which are microvilli that contain actin filaments.
- **Lateral line organs** supplement vision in fish and some amphibians by informing the animal of moving objects or objects in its path.

4 Compare the function of the saccule and utricle with that of the semicircular canals in maintaining equilibrium.

- The vertebrate **inner ear** consists of a **labyrinth** of fluid-filled chambers and canals that help maintain equilibrium. The **vestibular apparatus** in the upper part of the labyrinth consists of the **saccule, utricle,** and **semicircular canals.**
- The saccule and utricle contain **otoliths** that change position when the head is tilted or when the body is moving in a straight line. The otoliths stimulate hair cells that send signals to the brain, enabling the animal to perceive the direction of gravity.
- The semicircular canals inform the brain about turning movements. Clumps of hair cells, called **cristae,** are located within each bulblike enlargement, an **ampulla. Cristae** are stimulated by movements of the **endolymph,** a fluid that fills each canal.

5 Trace the path taken by sound waves through the structures of the ear, and explain how the organ of Corti functions as an auditory receptor.

- In birds and mammals, the **organ of Corti** within the **cochlea** contains auditory receptors.
- Sound waves pass through the **external auditory canal** and cause the **tympanic membrane** (eardrum) to vibrate. The ear bones—**malleus, incus,** and **stapes**—transmit and amplify the vibrations through the middle ear.
- Vibrations pass through the **oval window** to fluid within the vestibular duct. Pressure waves press on the membranes that separate the three ducts of the cochlea.
- The bulging of the **round window** serves as an escape valve for the pressure. The pressure waves cause movements of the **basilar membrane.** These movements stimulate the hair cells of the organ of Corti by rubbing them against the overlying **tectorial membrane.**
- Neural impulses are initiated in the dendrites of neurons that lie at the base of each hair cell, and are transmitted by the **cochlear nerve** to the brain.

6 Compare the structure and function of the receptors of taste and smell.

- The receptors for taste and smell are chemoreceptors. Taste receptor cells are specialized epithelial cells in **taste buds.** The **olfactory epithelium** contains specialized olfactory cells with axons that extend to the brain as fibers of the **olfactory nerves.**
- When a molecule binds with a receptor on a taste receptor cell or an olfactory receptor cell, a signal transduction process involving a G protein is initiated.

7 Contrast simple eyes, compound eyes, and vertebrate eyes.

- **Eyespots,** or **ocelli,** found in cnidarians and flatworms, detect light but do not form images.
- The **compound eye** of insects and crustaceans consists of visual units called **ommatidia,** which collectively produce a **mosaic** image. Each ommatidium has a transparent **lens** and a **crystalline cone** that focus light onto receptor cells called **retinular cells.**
- The vertebrate eye can be compared to a camera.

8 Describe the functions of each structure of the vertebrate eye.

- In the human eye, light enters through the **cornea,** is focused by the lens, and produces an image on the **retina.** The **iris** regulates the amount of light that can enter.

9 Describe the events that take place in human vision; compare the two types of photoreceptors and describe the signal transduction pathway as part of your explanation.

- The retina contains the photoreceptor cells: **rods,** which function in dim light and form images in black and white; and **cones,** which function in bright light and permit color vision.
- The retina also contains **bipolar cells** that send signals to **ganglion cells.** Two types of lateral interneurons integrate information: **Horizontal cells** receive signals from the rods and cones and send signals to bipolar cells, and **amacrine cells** receive signals from bipolar cells and send signals back to bipolar cells and to ganglion cells.
- When the environment is dark, ion channels in the plasma membranes of rod cells are open and the cells are depolarized; they release glutamate, which hyperpolarizes the membranes of bipolar cells so they do not send signals.
- When light strikes the photopigment **rhodopsin** in the rod cells, its retinal portion changes shape and initiates a signal transduc-

SUMMARY WITH KEY TERMS *(continued)*

tion process that involves **transducin.** This G protein activates an esterase that hydrolyzes cGMP, reducing its concentration. As a result, ion channels close and the membrane becomes hyperpolarized. The rod cells release less glutamate, and fewer signals are transmitted. As a result, bipolar cells become depolarized, and release neurotransmitter that stimulates ganglion cells.

- Axons of the ganglion cells make up the **optic nerves.** The optic nerves transmit information to the **lateral geniculate nuclei** in the thalamus. From there neurons project to the **primary visual cortex** and then to integration centers in the cerebral cortex.

POST-TEST

1. Which of the following is *not* true of a sensory receptor? (a) detects a stimulus in the environment (b) converts energy of the stimulus into electrical energy (c) produces a receptor potential (d) produces a graded response (e) interprets sensory stimuli
2. A sensory receptor absorbs energy from some stimulus. The next step is (a) release of neurotransmitter (b) transmission of an action potential (c) energy transduction (d) transmission of a receptor potential (e) sensory adaptation
3. Interoceptors (a) help maintain homeostasis (b) are located in the skin (c) are photoreceptors (d) adapt rapidly (e) convert absorbed energy directly into action potentials
4. Which of the following are *not* correctly matched? (a) mechanoreceptors—touch, pressure (b) electroreceptors—voltage (c) photoreceptors—light (d) chemoreceptors—gravity (e) nociceptors—extreme temperature
5. A Pacinian corpuscle (a) is a mechanoreceptor (b) responds to heat (c) responds to pressure (d) answers a, b, and c are correct (e) answers a and c only
6. Which of the following is *not* located in the vertebrate inner ear? (a) vestibular apparatus (b) cochlea (c) malleus (d) organ of Corti (e) utricle
7. The auditory receptors are located in the (a) utricles (b) organs of Corti (c) vestibular apparati (d) saccule (e) semicircular canals
8. Which of the following is/are associated with informing the brain about turning movements? (a) semicircular canals (b) saccule (c) lymph (d) otoliths (e) utricle
9. Which of the following receptors do *not* have hair cells? (a) lateral line organ (b) saccule (c) utricle (d) semicircular canals (e) rods
10. In the process of hearing, the basilar membrane vibrates. Which event occurs next? (a) tympanic membrane vibrates (b) bones in middle ear amplify and conduct vibrations (c) cochlear nerve transmits impulses to organ of Corti (d) hair cells in organ of Corti are stimulated (e) vibrations conducted to chemoreceptors
11. In olfaction, (a) pheromones stimulate the taste buds (b) the number of odorous molecules determines the magnitude of the receptor potential (c) chemical signals are converted directly into electrical signals (d) a G protein is activated and leads to the closing of gated channels (e) the concentration of cyclic AMP increases, leading to hyperpolarization of the receptor
12. The vomeronasal organ (a) detects pheromones (b) is located at the back of the tongue (c) sends signals directly to the thalamus (d) releases pheromones (e) detects signals from predators
13. Mechanical stimulation of stereocilia (a) produces action potentials (b) inhibits glutamate secretion (c) causes voltage changes (d) degrades opiates (e) causes rhodopsin release
14. In the human visual pathway, after light passes through the cornea, it (a) stimulates ganglion cells (b) passes through the lens (c) sends signals through the optic nerve (d) depolarizes horizontal cells (e) hyperpolarizes rod cells
15. Cones (a) are most concentrated in the ganglion area (b) are more numerous than rods (c) are responsible for vision in bright light (d) are found in all animals with photoreceptors (e) are a type of bipolar cell
16. Rhodopsin (a) is concentrated in bipolar cells (b) binds with a G protein (c) changes shape when the membrane of the cone is depolarized (d) sends signals to the lateral geniculate nuclei (e) activates substance P

CRITICAL THINKING

1. If all neurons transmit the same type of message, how do you know the difference between sound and light? How are you able to distinguish between an intense pain and a mild one? How are these discriminations adaptive?
2. Connoisseurs can recognize many varieties of cheese or wine by "tasting." How can this be, when there are only a few types of taste receptors? How might it be adaptive for organisms to have only four or five basic tastes?
3. Design a synaptic mechanism by which the same neurotransmitter has an excitatory effect on one bipolar cell and an inhibitory effect on another.

PET scan visualizing the left ventricle of the human heart. The scan measures metabolic activity based on glucose levels in the cardiac muscle tissue, providing information about the condition of the heart. (The color progression from least to most active is blue, green, yellow, red.)

CHAPTER OUTLINE

- Types of Circulatory Systems
- Vertebrate Blood
- Vertebrate Blood Vessels
- Evolution of the Vertebrate Cardiovascular System
- The Human Heart
- Blood Pressure
- The Pattern of Circulation
- The Lymphatic System

Most cells need a continuous supply of nutrients and oxygen and the removal of waste products. In very small animals, these metabolic needs are met by simple **diffusion,** the net movement of particles from a region of higher concentration to a region of lower concentration, resulting from random motion. A molecule can diffuse 1 micrometer (μm) in less than 1 millisecond (msec), so diffusion is adequate over microscopic distances. In invertebrates that are only a few cells thick, diffusion is an effective mechanism for distributing materials to and from their cells. No specialized circulatory structures are present in sponges, cnidarians (such as jellyfish), ctenophores (comb jellies), flatworms, or nematodes (roundworms). As in all animals, the fluid between the cells, called **interstitial fluid,** or tissue fluid, bathes the cells and provides a medium for diffusion of oxygen, nutrients, and wastes.

How much time diffusion requires increases with the square of the distance over which diffusion occurs. A cell that is 10 μm away from its oxygen (or nutrient) supply can receive oxygen by diffusion in about 50 msec, but a cell that is 1000 μm (1 mm) away from its oxygen supply would have to wait several minutes and couldn't survive if it had to depend on diffusion alone. In animals that are many cells thick, specialized **circulatory systems** transport oxygen, nutrients, hormones, and other materials to the interstitial fluid surrounding all the cells and remove metabolic wastes. A circulatory system reduces the diffusion distance that needed materials must travel. In most animals, a circulatory system interacts with every other organ system in the body.

A circulatory system typically has the following: (1) **blood,** a connective tissue consisting of cells and cell fragments dispersed in fluid known as *plasma;* (2) a pumping organ, generally a **heart;** and (3) a system of **blood vessels** or spaces through which blood circulates.

The human circulatory system, known as the **cardiovascular system,** is the focus of extensive research because cardiovascular disease is the leading cause of death in the United States and most other industrial societies. The positron emission tomography (PET) scan shown here visualizes the left ventricle of the

human heart. A major risk factor for cardiovascular disease is elevated levels of cholesterol and low-density lipoprotein (LDL) in the blood. In contrast, high-density lipoprotein (HDL) seems to play a protective role, removing excess cholesterol from the blood and tissues. Cells in the liver and certain other organs bind with the HDL, remove the cholesterol, and use it in synthesizing needed compounds.

Researchers have identified a gene in mice that codes for an HDL receptor. When investigators knock out this gene, cholesterol levels more than double. As new receptors and mechanisms involved in lipid transport and metabolism are discovered, they serve as targets for new drugs and other treatments for cardiovascular disease. ■

TYPES OF CIRCULATORY SYSTEMS

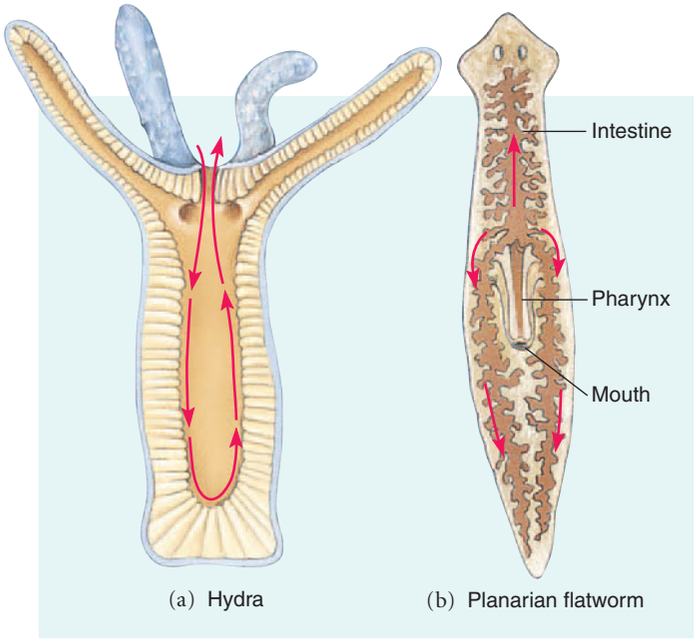
Learning Objective

1 Compare and contrast internal transport in animals with no circulatory system, those with an open circulatory system, and those with a closed circulatory system.

As indicated, many small, aquatic invertebrates have no circulatory system. In cnidarians, the central gastrovascular cavity serves as a circulatory organ as well as a digestive organ (Fig. 42-1a).

FIGURE **42-1** **Invertebrates with no circulatory system.**

(a) In *Hydra* and other cnidarians, oxygen and nutrients circulate through the gastrovascular cavity and come in contact with the inner layer of body cells. These materials diffuse the short distance to the outer layer of cells. **(b)** In planarian flatworms, the branched intestine circulates nutrients and oxygen within close proximity to the body cells.



As the animal stretches and contracts, body movements stir up the contents of the gastrovascular cavity and help distribute nutrients.

The flattened body of the flatworm permits effective gas exchange by diffusion (Fig. 42-1b). Its branched intestine brings nutrients close to all the cells. As in cnidarians, circulation is aided by contractions of the body wall muscles, which agitate the intestinal fluid and the tissue fluid. The branching excretory system of planarians provides for internal transport of metabolic wastes that are then expelled from the body.

Fluid in the body cavity of nematodes and other pseudocoelomate animals helps circulate materials. Nutrients, oxygen, and wastes dissolve in this fluid and diffuse through it to and from the cells. Body movements of the animal move the fluid, distributing these materials.

Many invertebrates have an open circulatory system

Arthropods and most mollusks have an **open circulatory system,** in which the heart pumps blood into vessels that have open ends. Their blood and interstitial fluid are indistinguishable and are collectively referred to as **hemolymph.** Hemolymph spills out of the open ends of the blood vessels, filling large spaces, called *sinuses.* The sinuses make up the **hemocoel** (blood cavity), which is not part of the coelom. (In arthropods and mollusks, the coelom is reduced.) The hemolymph bathes the cells of the body directly. Blood re-enters the circulatory system through openings in the heart (in arthropods) or through open-ended vessels that lead to the gills (in mollusks).

In the open circulatory system of most mollusks, the heart typically has three chambers (Fig. 42-2a). The two atria receive hemolymph from the gills. Then the single ventricle pumps oxygen-rich hemolymph into blood vessels that conduct it into the large sinuses of the hemocoel. After bathing the body cells, the hemolymph passes into vessels that lead to the gills, where it is recharged with oxygen. The hemolymph then returns to the heart.

Some mollusks, as well as arthropods, have a hemolymph pigment, **hemocyanin,** containing copper that binds with oxygen. When oxygenated, hemocyanin is blue and imparts a bluish color to the hemolymph of these animals (the original blue bloods!).

In arthropods, a tubular heart pumps hemolymph into blood vessels (arteries) that deliver it to the sinuses of the hemocoel (Fig. 42-2b). Hemolymph then circulates through the hemocoel, eventually returning to the pericardial cavity surrounding the heart. Hemolymph enters the heart through tiny openings (*ostia*) equipped with valves to prevent backflow. The rate of hemolymph circulation increases when the insect moves. Thus, when an animal is active and most needs nutrients for fuel, its own movement ensures effective circulation.

An open circulatory system cannot provide enough oxygen to maintain the active lifestyle of insects. Indeed, insect hemolymph mainly distributes nutrients and hormones. Oxygen diffuses directly to the cells through a system of air tubes (tracheae) that make up the respiratory system (see Figure 44-2). In cray-

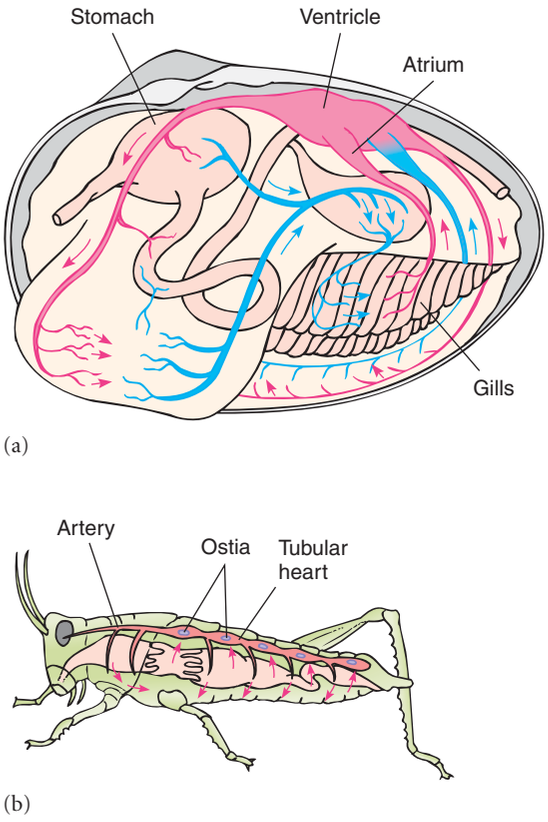


FIGURE **42-2** **Open circulatory systems.**

In mollusks and arthropods, a heart pumps the blood into arteries that end in sinuses of the hemocoel. Hemolymph circulates through the hemocoel. **(a)** In most mollusks, hemolymph enters vessels that conduct it to the gills, where it is recharged with oxygen. Blood then returns to the heart. **(b)** In arthropods, a tubular heart pumps hemolymph into arteries that deliver it to the sinuses of the hemocoel. After circulating, hemolymph re-enters the heart through ostia in the heart wall.

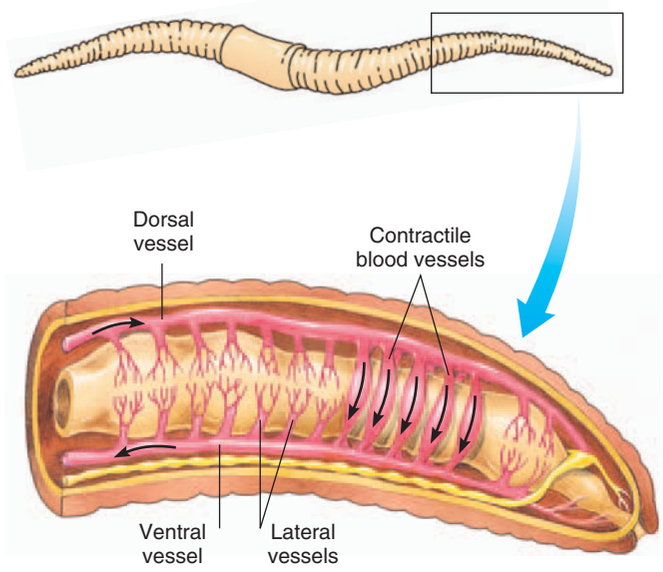

FIGURE **42-3** **Closed circulatory system of the earthworm.**

Blood circulates through a continuous system of blood vessels. Five pairs of contractile blood vessels deliver blood from the dorsal vessel to the ventral vessel.

fish and other crustaceans, gas exchange takes place as hemolymph circulates through the gills.

Some invertebrates have a closed circulatory system

Annelids, some mollusks (cephalopods), and echinoderms have a **closed circulatory system.** In them, blood flows through a continuous circuit of blood vessels. The walls of the smallest blood vessels, the **capillaries,** are thin enough to permit diffusion of gases, nutrients, and wastes between blood in the vessels and the interstitial fluid that bathes the cells.

A rudimentary closed circulatory system characterizes proboscis worms (phylum Nemertea). This system consists of a complete network of blood vessels but no heart. Blood flow depends on movements of the animal and on contractions in the walls of large blood vessels.

Earthworms and other annelids have a complex, closed circulatory system (Fig. 42-3). Two main blood vessels extend lengthwise in the body. The ventral vessel conducts blood posteriorly, and the dorsal vessel conducts blood anteriorly. Dorsal and ventral vessels are connected by lateral vessels in every segment. Branches of the lateral vessels deliver blood to the surface, where it is oxygenated. In the anterior part of the worm, five pairs of contractile blood vessels (sometimes called "hearts") connect dorsal and ventral vessels. Contractions of these paired vessels and of the dorsal vessel, as well as contraction of the body wall muscles, circulate the blood. Earthworms have **hemoglobin,** the same red pigment that transports oxygen in vertebrate blood. However, their hemoglobin is not contained within red blood cells but is dissolved in the blood plasma.

Although other mollusks have an open circulatory system, the fast-moving cephalopods, such as the squid and octopus, require a more efficient means of internal transport. They have a closed system made even more effective by accessory "hearts" at the base of the gills, which speed passage of blood through the gills.

All vertebrates have a closed circulatory system

The circulatory system is basically similar in all vertebrates, from fishes, frogs, and reptiles to birds and mammals. The system consists of heart, blood vessels, blood, lymph, lymph vessels, and associated organs such as the thymus, spleen, and liver. All vertebrates have a ventral, muscular heart that pumps blood into a closed system of blood vessels. Capillaries, the tiniest blood vessels, have very thin walls that permit exchange of materials between blood and interstitial fluid.

The vertebrate circulatory system performs several functions:

1. Transports nutrients from the digestive system and from storage depots to each cell
2. Transports oxygen from respiratory structures (gills or lungs) to the cells
3. Transports metabolic wastes from each cell to organs that excrete them
4. Transports hormones from endocrine glands to target tissues
5. Helps maintain fluid balance
6. Defends the body against invading microorganisms
7. Helps distribute metabolic heat within the body, which helps maintain a constant body temperature in endothermic animals
8. Helps maintain appropriate pH

Review

- How are nutrients and oxygen transported to the body cells in a hydra, flatworm, earthworm, insect, and frog?
- How does an open circulatory system differ from a closed circulatory system?

VERTEBRATE BLOOD

Learning Objectives

2 Compare the structure and function of red blood cells, white blood cells, and platelets.

3 Summarize the sequence of events involved in blood clotting.

In vertebrates, blood consists of a pale yellowish fluid called **plasma,** in which red blood cells, white blood cells, and platelets are suspended (Fig. 42-4; Table 42-1). In humans the total circulating blood volume is about 8% of the body weight—5.6 L (6 qt) in a 70-kg (154-lb) person. About 55% of the blood volume is plasma. The remaining 45% is made up of blood cells and platelets. Because cells and platelets are heavier than plasma, they can be separated from it by centrifugation. Plasma does not separate from blood cells in the body, because the blood is constantly mixed as it circulates in the blood vessels.

Plasma is the fluid component of blood

Plasma consists of water (about 92%), proteins (about 7%), salts, and a variety of materials being transported, such as dissolved gases, nutrients, wastes, and hormones. Plasma is in dynamic equilibrium with the interstitial fluid bathing the cells and with the intracellular fluid. As blood passes through the capillaries, substances continuously move into and out of the plasma. Changes in its composition signal one or more organs of the body to restore homeostasis.

Plasma contains several kinds of **plasma proteins,** each with specific properties and functions: **fibrinogen;** alpha, beta, and gamma **globulins;** and **albumin.** Fibrinogen is one of the proteins involved in the clotting process. When the proteins involved in blood clotting have been removed from the plasma, the remaining liquid is called **serum.** Alpha globulins include certain hormones and proteins that transport hormones; prothrombin, a protein involved in blood clotting; and high-density lipoproteins (HDL), which transport fats and cholesterol. Beta globulins include other lipoproteins that transport fats and cholesterol, as well as proteins that transport certain vitamins and minerals. The **gamma globulin** fraction contains many types of antibodies that provide immunity to diseases such as measles and infectious hepatitis. Purified human gamma globulin is

TABLE **42-1** Cell Components of Blood

	Normal Range	Function	Pathology
Red Blood Cells (RBCs)	Male: 4.2–5.4 million/μL Female: 3.6–5.0 million/μL	Oxygen transport; carbon dioxide transport	Too few: anemia Too many: polycythemia
Platelets	150,000–400,000/μL	Essential for clotting	Clotting malfunctions; bleeding; easy bruising
White Blood Cells (WBCs)	5000–10,000/μL		
Neutrophils	About 60% of WBCs	Phagocytosis	Too many: may be due to bacterial infection, inflammation, myelogenous leukemia
Eosinophils	1%–3% of WBCs	Play some role in allergic response	Too many: may result from allergic reaction, parasitic infestation
Basophils	1% of WBCs	May play role in prevention of inappropriate clotting	
Lymphocytes	25%–35% of WBCs	Produce antibodies; destroy foreign cells	Atypical lymphocytes present in infectious mononucleosis; too many may be due to lymphocytic leukemia, certain viral infections
Monocytes	6% of WBCs	Differentiate to form macrophages	May increase in monocytic leukemia and fungal infections

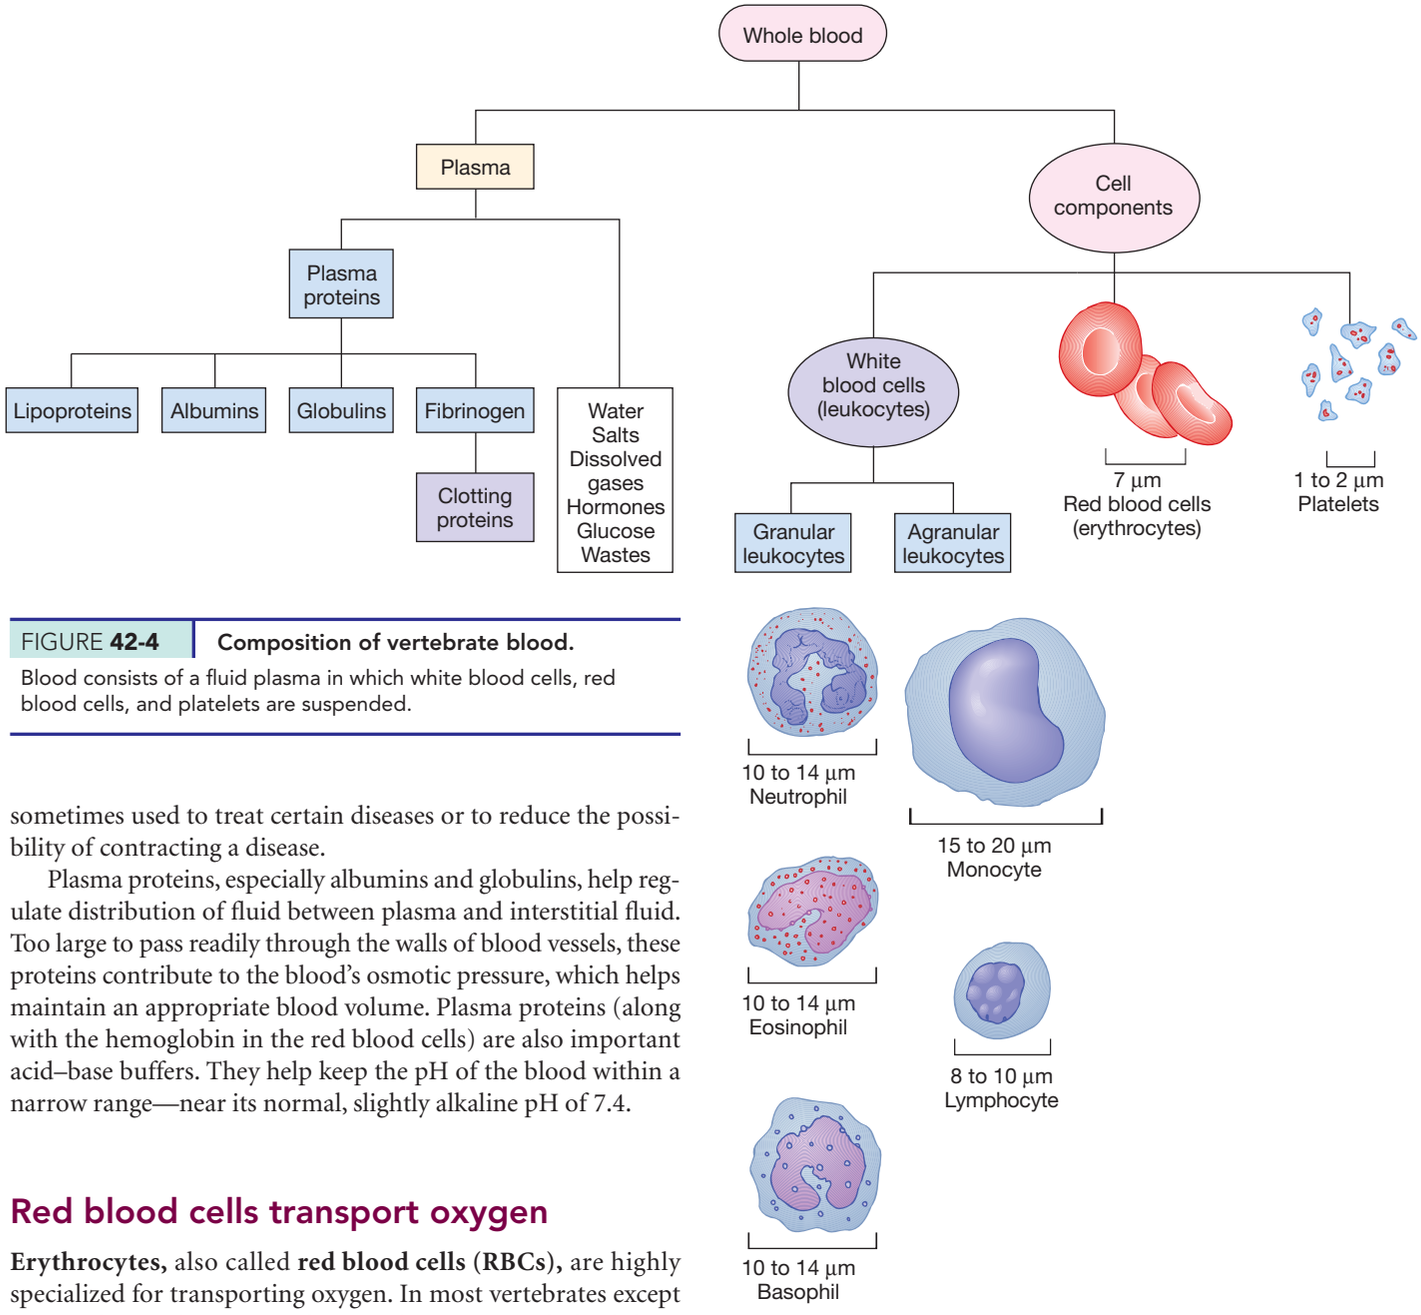

FIGURE **42-4** **Composition of vertebrate blood.**

Blood consists of a fluid plasma in which white blood cells, red blood cells, and platelets are suspended.

sometimes used to treat certain diseases or to reduce the possibility of contracting a disease.

Plasma proteins, especially albumins and globulins, help regulate distribution of fluid between plasma and interstitial fluid. Too large to pass readily through the walls of blood vessels, these proteins contribute to the blood's osmotic pressure, which helps maintain an appropriate blood volume. Plasma proteins (along with the hemoglobin in the red blood cells) are also important acid–base buffers. They help keep the pH of the blood within a narrow range—near its normal, slightly alkaline pH of 7.4.

Red blood cells transport oxygen

Erythrocytes, also called **red blood cells (RBCs),** are highly specialized for transporting oxygen. In most vertebrates except mammals, circulating RBCs have nuclei. For example, birds have large, oval, nucleated RBCs. In mammals, the nucleus is ejected from the RBC as the cell develops. Each mammalian RBC is a flexible, biconcave disc, 7 to 8 µm in diameter and 1 to 2 µm thick. An internal elastic framework maintains the disc shape and permits the cell to bend and twist as it passes through blood vessels even smaller than its own diameter. Its biconcave shape provides a high ratio of surface area to volume, allowing efficient diffusion of oxygen and carbon dioxide into and out of the cell. In an adult human, about 30 trillion RBCs circulate in the blood, approximately 5 million per µL.

Erythrocytes are produced within the red bone marrow of certain bones: vertebrae, ribs, breastbone, skull bones, and long bones. As an RBC develops, it produces great quantities of hemoglobin, the oxygen-transporting pigment that gives vertebrate blood its red color. (Oxygen transport is discussed in Chapter 44.) The life span of a human RBC is about 120 days. As blood circulates through the liver and spleen, phagocytic cells remove worn-out RBCs from the circulation. These RBCs are then disassembled, and some of their components are recycled. In the human body, more than 2.4 million RBCs are destroyed every second, so an equal number must be produced in the bone marrow to replace them. Red blood cell production is regulated by the hormone **erythropoietin,** which the kidneys release in response to a decrease in oxygen.

Anemia is a deficiency in hemoglobin (often accompanied by a decrease in the number of RBCs). When hemoglobin is insufficient, the amount of oxygen transported is inadequate to supply the body's needs. An anemic person may complain of feeling weak and may become easily fatigued. Three general causes

of anemia are (1) loss of blood from hemorrhage or internal bleeding; (2) decreased production of hemoglobin or red blood cells as in iron-deficiency anemia or pernicious anemia (which can be caused by vitamin B_{12} deficiency); and (3) increased rate of RBC destruction—the **hemolytic anemias,** such as sickle cell anemia (see Chapter 15).

White blood cells defend the body against disease organisms

The **leukocytes,** or **white blood cells (WBCs),** are specialized to defend the body against harmful bacteria and other microorganisms. Leukocytes are amoeba-like cells capable of independent movement. Some types routinely slip through the walls of blood vessels and enter the tissues. Human blood contains five kinds of leukocytes, classified as either granular or agranular (see Fig. 42-4). Both types are manufactured in the red bone marrow.

The **granular leukocytes** are characterized by large, lobed nuclei and distinctive granules in their cytoplasm. The three varieties of granular leukocytes are the neutrophils, eosinophils, and basophils. **Neutrophils,** the principal phagocytic cells in the blood, are especially adept at seeking out and ingesting bacteria. They also phagocytize dead cells, a cleanup task especially demanding after injury or infection. Most granules in neutrophils contain enzymes that digest ingested material.

Eosinophils have large granules that stain bright red with eosin, an acidic dye. The lysosomes of these WBCs contain enzymes such as oxidases and peroxidases, suggesting that they function in detoxifying foreign proteins and other substances. Eosinophils increase in number during allergic reactions and during parasitic (for example, tapeworm) infestations. **Basophils** exhibit deep blue granules when stained with basic dyes. Like eosinophils, these cells play a role in allergic reactions. Basophils do not contain lysosomes. Granules in their cytoplasm contain **histamine,** a substance that dilates blood vessels and makes capillaries more permeable. Basophils release histamine in injured tissues and in allergic responses. Other basophil granules contain **heparin,** an anticoagulant that helps prevent blood from clotting inappropriately within the blood vessels.

Agranular leukocytes lack large, distinctive granules, and their nuclei are rounded or kidney-shaped. Two types of agranular leukocytes are lymphocytes and monocytes. Some **lymphocytes** are specialized to produce antibodies, whereas others directly attack foreign invaders such as bacteria or viruses. Just how they manage these feats is discussed in Chapter 43.

Monocytes are the largest WBCs, reaching 20 μm in diameter. After circulating in the blood for about 24 hours, a monocyte leaves the circulation and completes its development in the tissues. The monocyte greatly enlarges and becomes a **macrophage,** a giant scavenger cell. All macrophages found in the tissues develop this way. Macrophages voraciously engulf bacteria, dead cells, and debris.

Human blood normally has about 7000 WBCs per μL of blood (only 1 for every 700 RBCs). During bacterial infections the number may rise sharply, so a WBC count is useful in diagnosis. The proportion of each kind of WBC is determined by a differential WBC count. The normal distribution of leukocytes is indicated in Table 42-1.

Leukemia is a form of cancer in which any one of the various kinds of WBCs multiplies rapidly within the bone marrow. Many of these cells do not mature, and their large numbers crowd out developing RBCs and platelets, leading to anemia and impaired clotting. A common cause of death from leukemia is internal hemorrhaging, especially in the brain. Another frequent cause of death is infection; although the WBC count may rise dramatically, the cells are immature and abnormal and cannot defend the body against disease organisms.

Platelets function in blood clotting

In most vertebrates other than mammals, the blood contains small, oval cells called **thrombocytes,** which have nuclei. In mammals, thrombocytes are tiny spherical or disc-shaped bits of cytoplasm that lack nuclei. They are usually called **platelets.** About 300,000 platelets per μL are present in human blood. Platelets are pinched off from very large cells in the bone marrow. Thus, a platelet is not a whole cell but a fragment of cytoplasm enclosed by a membrane.

When a blood vessel is cut, it constricts, reducing blood loss. Platelets stick to the rough, cut edges of the vessel, physically patching the break. As platelets begin to gather, they release substances that attract other platelets. The platelets become sticky and adhere to collagen fibers in the blood vessel wall. Within about 5 minutes after injury, they form a platelet plug, or temporary clot.

At the same time the temporary clot forms, a stronger, more permanent clot begins to develop. More than 30 different chemical substances interact in this very complex process. The series of reactions that leads to clotting is triggered when one of the clotting factors in the blood is activated by contact with the injured tissue. In **hemophilia,** one clotting factor is absent, as a result of an inherited genetic mutation (see Chapter 15).

Prothrombin, a plasma protein manufactured in the liver, requires vitamin K for its production. In the presence of clotting factors, calcium ions, and compounds released from platelets, prothrombin is converted to **thrombin.** Then thrombin catalyzes the conversion of the soluble plasma protein **fibrinogen** to an insoluble protein, **fibrin.** Once formed, fibrin polymerizes, producing long threads that stick to the damaged surface of the blood vessel and form the webbing of the clot. These threads trap blood cells and platelets, which help strengthen the clot. The clotting process is summarized in Figure 42-5.

Review

- What are the functions of the main groups of plasma proteins?
- What is the function of red blood cells? Of neutrophils?
- What are the major steps in blood clotting?

VERTEBRATE BLOOD VESSELS

Learning Objective

4 Compare the structure and function of different types of blood vessels, including arteries, arterioles, capillaries, and veins.

The vertebrate circulatory system includes three main types of blood vessels: arteries, capillaries, and veins (Fig. 42-6). An **artery** carries blood away from a heart chamber, toward other tissues. When an artery enters an organ, it divides into many smaller branches called **arterioles.** The arterioles deliver blood into the microscopic capillaries. After blood circulates through an organ, capillaries merge to form **veins** that channel the blood back toward the heart.

The wall of an artery or vein has three layers (Fig. 42-6b). The innermost layer, which lines the blood vessel, consists mainly of **endothelium,** a tissue that resembles squamous epithelium (see Chapter 37). The middle layer is connective tissue and smooth muscle cells, and the outer coat is connective tissue rich in elastic and collagen fibers.

The thick walls of arteries and veins prevent gases and nutrients from passing through. Materials are exchanged between the blood and interstitial fluid bathing the cells through the capillary walls, which are only one cell thick. Capillary networks in the body are so extensive that at least one of these tiny vessels is located close to every cell in the body. The total length of all capillaries in the body has been estimated to be over 96,000 km!

Smooth muscle in the arteriole wall can constrict (**vasoconstriction**) or relax (**vasodilation**), changing the radius of the arteriole. Such changes help maintain appropriate blood pressure and help control the volume of blood passing to a particular tissue. Changes in blood flow are regulated by the nervous system in response to the metabolic needs of the tissue, as well as by the demands of the body as a whole. For example, when a tissue is metabolizing rapidly, it needs more nutrients and oxygen. During exercise, arterioles within skeletal muscles dilate, increasing by more than 10-fold the amount of blood flowing to these muscle tissues.

If all your blood vessels dilated at the same time, you would not have enough blood to fill them completely. Normally your liver, kidneys, and brain receive the lion's share of blood. However, if an emergency suddenly occurred requiring rapid action, your blood would be rerouted quickly in favor of heart and muscles. At such a time the digestive system and kidneys can do with less blood, because they are not crucial in responding to the crisis.

The small vessels that directly link arterioles with venules (small veins) are **metarterioles.** The true capillaries branch off from the metarterioles and then rejoin them (Fig. 42-7). True capillaries also interconnect with one another. Wherever a capillary branches from a metarteriole, a smooth muscle cell called a *precapillary sphincter* is present. Precapillary sphincters open and close continuously, directing blood first to one and then to another section of tissue. These sphincters (along with the smooth muscle in the walls of arteries and arterioles) regulate the blood supply to each organ and its subdivisions.

Review

- Compare the functions of arteries, capillaries, and veins.
- How do arterioles function in maintaining homeostasis?

Biology Now™ Assess your understanding of **vertebrate blood vessels** by taking the pretest on your BiologyNow CD-ROM.

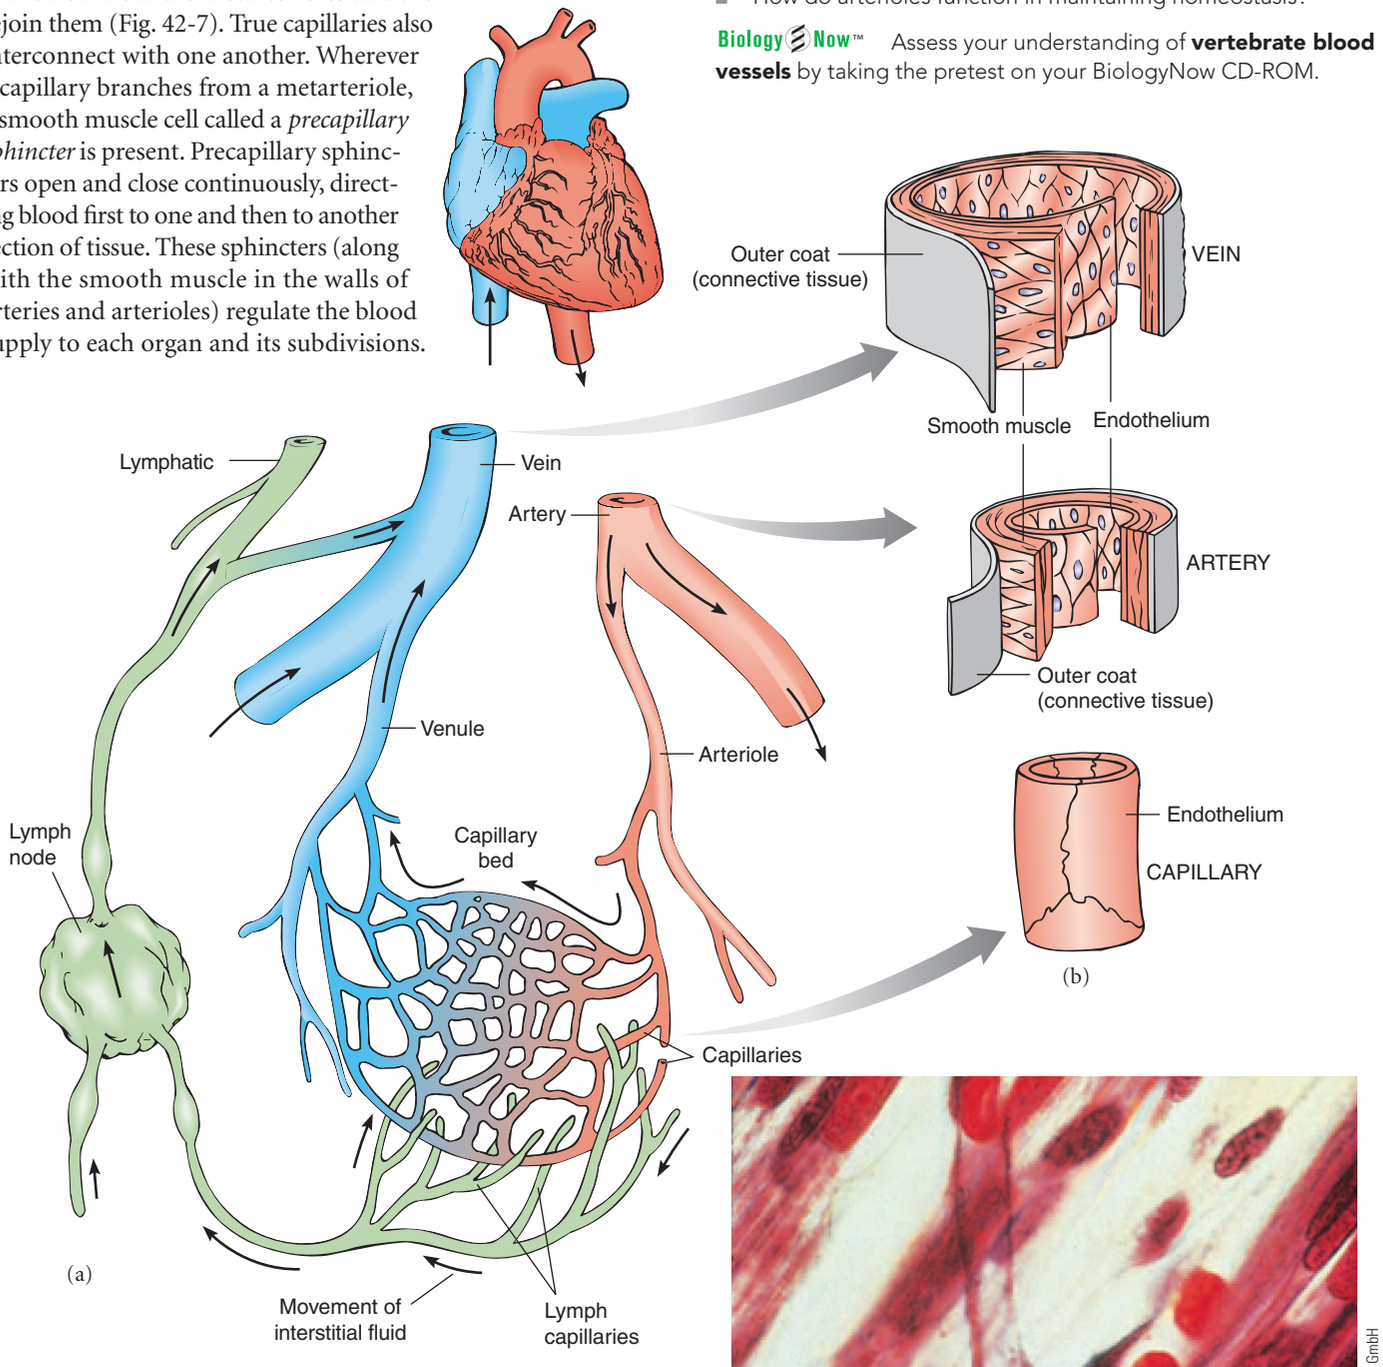

FIGURE **42-6** **Blood flow through blood and lymphatic vessels.**

(a) The heart pumps blood into arteries. Blood then flows through arterioles, capillaries, and veins, which return it to the heart. Some plasma leaves the capillaries and becomes interstitial fluid. Lymphatic vessels return excess interstitial fluid to the blood by way of ducts that lead into large veins in the shoulder region. Blood vessels with oxygen-rich blood are shown in red. Those with oxygen-poor blood are shown in blue. **(b)** Comparison of the walls of an artery, vein, and capillary. All three vessels are lined with endothelium. The capillary wall is only one cell thick, allowing exchange of materials. **(c)** LM of red blood cells passing through capillaries almost in single file.

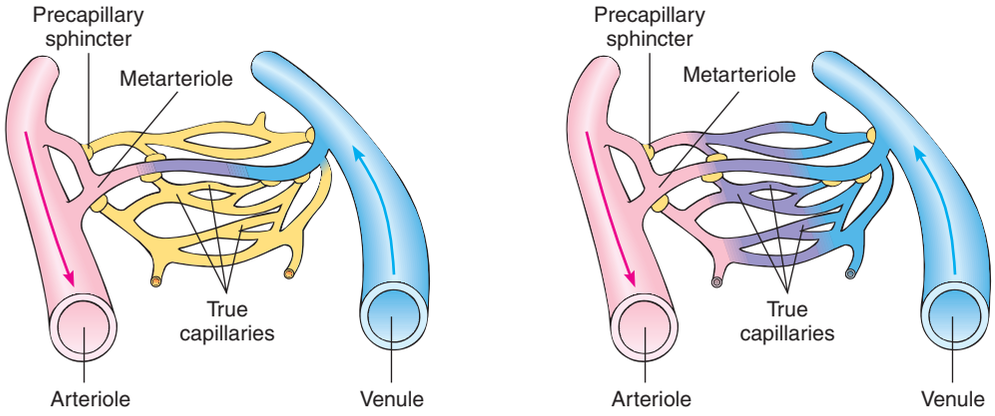

FIGURE **42-7**

Blood flow through a capillary network.

As a tissue becomes active, the pattern of blood flow through its capillary networks changes. **(a)** When a tissue is inactive, only its metarterioles are open. **(b)** When the tissue becomes active, decreased oxygen tension in the tissue relaxes the precapillary sphincters, and the capillaries open. This increases the blood supply and thus the delivery of nutrients and oxygen to the active tissue.

EVOLUTION OF THE VERTEBRATE CARDIOVASCULAR SYSTEM

Learning Objective

5 Trace the evolution of the vertebrate cardiovascular system from fish to mammal.

The vertebrate cardiovascular system became modified in the course of evolution, as the site of gas exchange shifted from gills to lungs and as certain vertebrates became active, endothermic animals with higher metabolic rates. The vertebrate heart has one or two **atria** (sing., *atrium*), chambers that receive blood returning from the tissues, and one or two **ventricles** that pump blood into the arteries (Fig. 42-8). Some vertebrate classes have additional chambers.

The fish heart has one atrium and one ventricle. The atrium pumps blood into the ventricle, which pumps blood into a single circuit of blood vessels. Blood is oxygenated as it passes through capillaries in the gills. After blood circulates through the gill capillaries, its pressure is low, so blood passes very slowly to the other organs. The fish's swimming movements facilitate circulation. Blood returning to the heart has a low oxygen content. A thin-walled *sinus venosus* receives blood returning from the tissues and pumps it into the atrium.

In amphibians, blood flows through a double circuit: the **pulmonary circulation** and the **systemic circulation.** Oxygen-rich and oxygen-poor blood are kept somewhat separate. The amphibian heart has two atria and one ventricle. A *sinus venosus* collects oxygen-poor blood returning from the veins and pumps it into the right atrium. Blood returning from the lungs passes directly into the left atrium. Both atria pump into the single ventricle, but oxygen-poor blood is pumped out of the ventricle before oxygen-rich blood enters it. Blood passes into an artery, the *conus arteriosus,* equipped with a fold that helps keep the blood separate. Much of the oxygen-poor blood is directed into the pulmonary circulation, which delivers it to the lungs and skin where it is recharged with oxygen. The systemic circulation delivers oxygen-rich blood into arteries that conduct it to the various tissues of the body.

Most reptiles also have a double circuit of blood flow, made more efficient by a wall that partly divides the ventricle. Mixing of oxygen-rich and oxygen-poor blood is minimized by the timing of contractions of the left and right sides of the heart and by pressure differences. In crocodilians (crocodiles and alligators), the wall between the ventricles is complete, so the heart consists of two atria and two ventricles. Thus a four-chambered heart first evolved among the reptiles.

Unlike birds and mammals, amphibians and reptiles do not ventilate their lungs continuously. Therefore, it would be inefficient to pump blood through the pulmonary circulation continuously. The shunts between the two sides of the heart allow blood to be distributed to the lungs as needed.

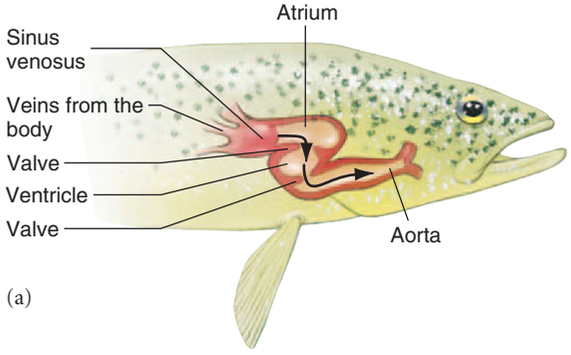
In all birds and mammals (and in crocodilians), the septum (wall) between the ventricles is complete. Biologists hypothesize that the completely divided heart evolved twice during the course of vertebrate evolution; first in the crocodilian-bird clade and then independently in mammals The interventricular septum prevents oxygen-rich blood in the left chamber from mixing with oxygen-poor blood in the right chamber. The conus arteriosus has split and become the base of the **aorta** (the largest artery) and the pulmonary artery. No sinus venosus is present as a separate chamber, but a vestige remains as the *sinoatrial node* (the pacemaker).

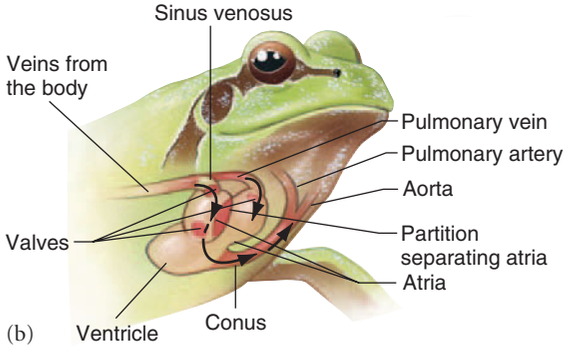
Complete separation of the right and left sides of the heart requires blood to pass through the heart twice each time it tours the body. The complete double circuit allows birds and mammals to maintain higher blood pressures in the systemic circulation and modest pressures in the pulmonary circulation. This system delivers materials to the tissues rapidly and efficiently. Because their blood contains more oxygen per unit volume and circulates more rapidly than in other vertebrates, the tissues of birds and mammals receive more oxygen. As a result, these animals can maintain a higher metabolic rate and a constant, high body temperature even in cold surroundings.

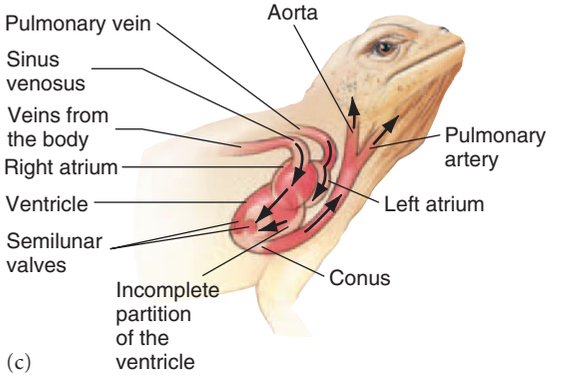
The pattern of blood circulation in birds and mammals can be summarized as follows:

Veins (conduct blood from organs) ⟶ right atrium ⟶right ventricle ⟶ pulmonary arteries ⟶ capillaries in the lungs ⟶ pulmonary veins ⟶ left atrium ⟶ left ventricle ⟶ aorta ⟶ arteries (conduct blood to organs) ⟶ arterioles ⟶ capillaries

KEY CONCEPT: The adaptations of the cardiovascular system reflect the evolution of vertebrates as they became terrestrial, active, endothermic animals.







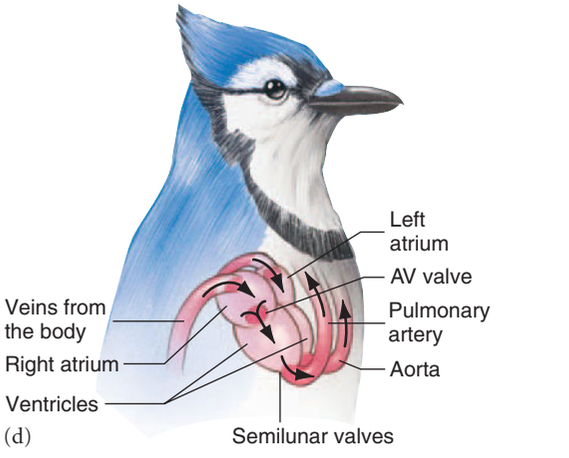


FIGURE **42-8** **Evolution of the vertebrate cardiovascular system.**

(a) The single atrium and ventricle of the fish heart are part of a single circuit of blood flow. **(b)** In amphibians blood flows through a double circuit and the heart consists of two atria and one ventricle. **(c)** The reptilian heart has two atria and two ventricles; in all but the crocodiles and alligators, the wall separating the ventricles is incomplete so blood from the right and left chambers mixes to some extent. **(d)** Birds and mammals have two atria and two ventricles, and blood rich in oxygen is kept completely separate from oxygen-poor blood.

THE HUMAN HEART

Learning Objectives

6 Describe the structure and function of the human heart. (Include the heart's conduction system in your answer.)

7 Trace the events of the cardiac cycle, and relate normal heart sounds to these events.

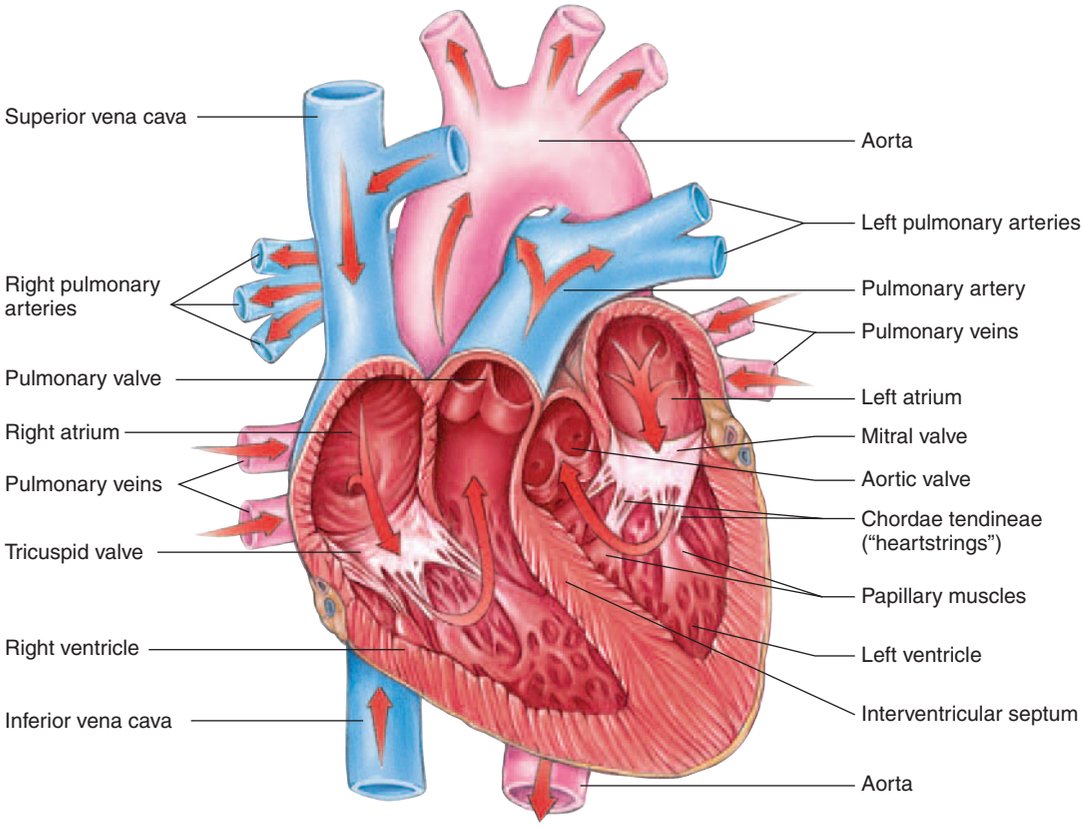
8 Define *cardiac output,* describe how it is regulated, and identify factors that affect it.

Not much bigger than a fist and weighing less than a pound, the human **heart** is a remarkable organ that beats about 2.5 billion times in an average lifetime, pumping about 300 million L (80 million gal) of blood. To meet the body's changing needs, the heart can vary its output from 5 to more than 20 L of blood per minute.

Your heart is a hollow, muscular organ located in the chest cavity directly under the breastbone. Enclosing it is a tough connective tissue sac, the **pericardium.** A smooth layer of endothelium covers the inner surface of the pericardium and the outer surface of the heart. Between these two surfaces is a small **pericardial cavity** filled with fluid, which reduces friction to a minimum as the heart beats. The wall of the heart is mainly cardiac muscle attached to a framework of collagen fibers.

The right atrium and ventricle are separated from the left atrium and ventricle by a wall, or **septum.** Between the atria the wall is known as the **interatrial septum;** between the ventricles, it is the **interventricular septum.** A shallow depression, the **fossa ovalis,** on the interatrial septum marks the place where an opening, the **foramen ovale,** was located in the fetal heart. In the fetus, the foramen ovale lets the blood flow directly from right to left atrium, so very little passes to the nonfunctional lungs. At the upper surface of each atrium lies a small muscular pouch, the **auricle.**

To keep blood from flowing backward, the heart has valves that close automatically (Fig. 42-9). The valve between the right atrium and right ventricle is called the **right atrioventricular (AV) valve,** or **tricuspid valve.** The **left AV valve** (between



ACTIVE FIGURE **42-9**

Note the right and left atria, which receive blood, and the right and left ventricles, which pump blood into the arteries. Arrows indicate the pattern of blood flow.

BiologyNow™ Learn more about **heart anatomy** by clicking on this figure on your BiologyNow CD-ROM.

the left atrium and left ventricle) is the **mitral valve,** or **bicuspid valve.** The AV valves are held in place by stout cords, or "heart-strings," the **chordae tendineae.** These cords attach the valves to the papillary muscles that project from the walls of the ventricles.

When blood returning from the tissues fills the atria, blood pressure on the AV valves forces them to open into the ventricles, which then fill with blood. As the ventricles contract, blood is forced back against the AV valves, pushing them closed. Contraction of the papillary muscles and tensing of the chordae tendineae prevent the valves from opening backward into the atria. These valves are like swinging doors that open in only one direction.

Semilunar valves (named for their flaps, which are shaped like half-moons) guard the exits from the heart. The semilunar valve between the left ventricle and the aorta is the **aortic valve,** and the one between the right ventricle and the pulmonary artery is the **pulmonary valve.** When blood passes out of the ventricles, the flaps of the semilunar valves are pushed aside and offer no resistance to blood flow. But when the ventricles are relaxing and filling with blood from the atria, blood pressure in the arteries is higher than in the ventricles. Blood then fills the pouches of the valves, stretching them across the artery so blood cannot flow back into the ventricle.

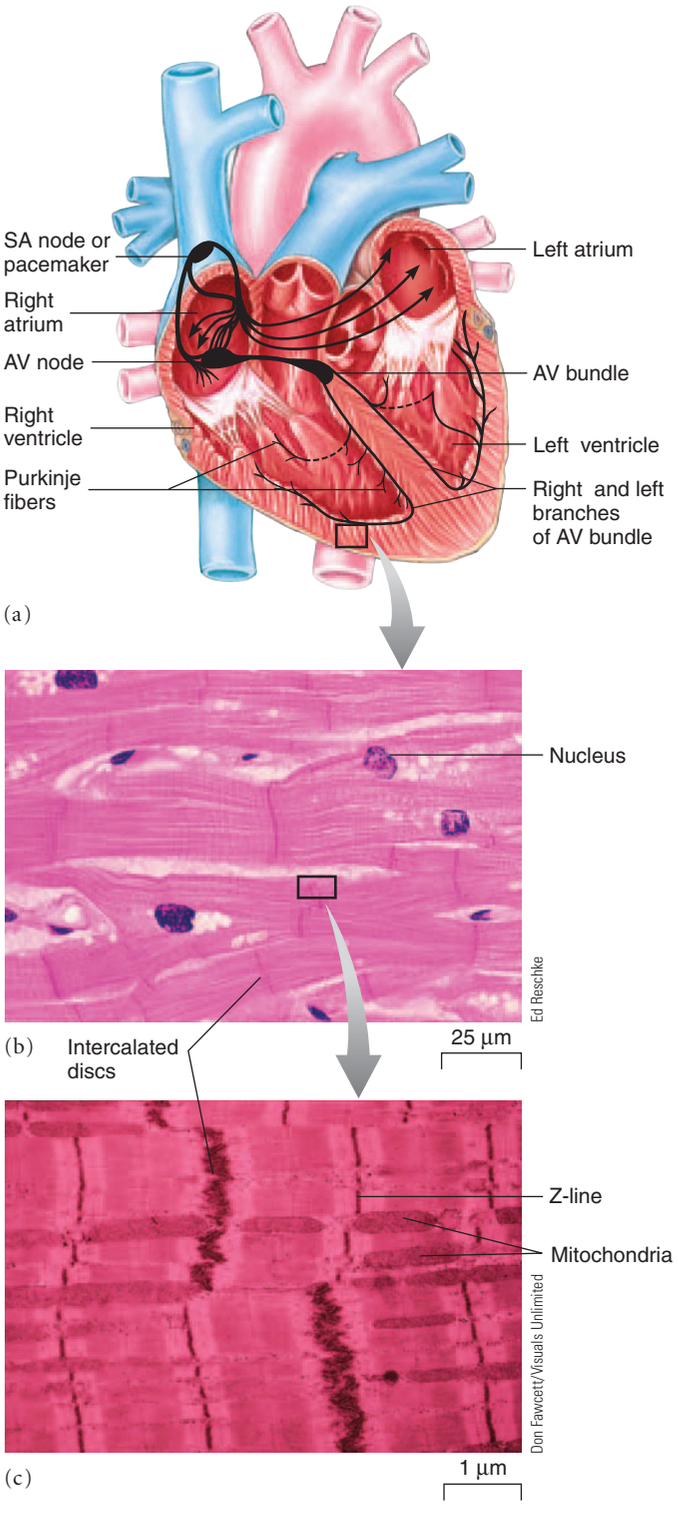
Each heartbeat is initiated by a pacemaker

Horror films sometimes feature a scene in which a heart cut out of a human body continues to beat. Scriptwriters of these tales actually have some factual basis for their gruesome fantasies, because a heart carefully removed from the body does continue to beat for many hours if kept in a nutritive, oxygenated fluid. This is possible because the contractions of cardiac muscle begin within the muscle itself and can occur independently of any nerve supply (Fig. 42-10).

At their ends cardiac muscle cells are joined by dense bands called **intercalated discs** (Fig. 42-10b, c). Each disc is a type of *gap junction* (see Chapter 5) in which two cells connect through pores. This type of junction is of great physiological importance, because it offers very little resistance to the passage of an action potential. Ions move easily through the gap junctions, allowing the entire atrial (or ventricular) muscle mass to contract as one giant cell.

Compared with skeletal muscle that has action potentials typically lasting 1 to 2 msec, the action potentials of cardiac muscle are much longer, several hundred milliseconds. Voltage-activated calcium ion channels open during depolarization of cardiac muscle fibers. Entry of Ca^{2+} contributes to the longer depolarization time. Another factor is a type of potassium channel that stays open when the cell is at its resting potential but closes during depolarization, lengthening depolarization time by decreasing the permeability of the membrane to K^+. From patch-clamp experiments (see Chapter 5) on isolated cardiac muscle fibers, investigators have found that spontaneous contraction results from the combination of a slow decrease in potassium permeability and a slow increase in sodium and calcium permeability.

A specialized conduction system ensures that the heart beats in a regular and effective rhythm. Each beat is initiated by the



ACTIVE FIGURE **42-10** **Conduction system of the heart.**

(a) The sinoatrial (SA) node initiates each heartbeat. The action potential spreads through the muscle fibers of the atria, producing atrial contraction. Transmission is briefly delayed at the atrioventricular (AV) node before the action potential spreads through specialized muscle fibers into the ventricles. **(b)** LM of cardiac muscle. **(c)** TEM of cardiac muscle.

BiologyNow™ See **cardiac conduction** in action by clicking on this figure on your BiologyNow CD-ROM.

pacemaker, also called the **sinoatrial (SA) node.** The SA node is a small mass of specialized cardiac muscle in the posterior wall of the right atrium near the opening of a large vein, the superior vena cava. The action potential in the SA node is triggered mainly by the opening of Ca^{2+} channels. Ends of the SA node fibers fuse with surrounding ordinary atrial muscle fibers so each action potential spreads through both atria, producing atrial contraction.

One group of atrial muscle fibers conducts the action potential directly to the **atrioventricular (AV) node,** located in the right atrium along the lower part of the septum. Here transmission is delayed briefly, letting the atria finish contracting before the ventricles begin to contract. From the AV node the action potential spreads into specialized muscle fibers called **Purkinje fibers.** These large fibers make up the **AV bundle.** The AV bundle divides, sending branches into each ventricle. When an impulse reaches the ends of the Purkinje fibers, it spreads through the ordinary cardiac muscle fibers of the ventricles.

SA node ⟶ atrial muscle fibers (atria contract) ⟶ AV node ⟶ AV bundle (Purkinje fibers) ⟶right and left branches (Purkinje fibers) ⟶ ventricular muscle fibers (ventricles contract)

As each wave of contraction spreads through the heart, electrical currents flow into the tissues surrounding the heart and onto the body surface. By placing electrodes on the body surface on opposite sides of the heart, the electrical activity can be amplified and recorded either by an oscilloscope or an electrocardiograph. The graph produced is called an **electrocardiogram** (**ECG** or **EKG**). Abnormalities in the EKG indicate disorders in the heart or its rhythm. For example, in **heart block** impulse transmission is delayed or blocked at some point in the conduction system. **Artificial pacemakers** can help patients with severe heart block. The pacemaker is implanted beneath the skin, and its electrodes connected to the heart. This device provides continuous rhythmic impulses that avoid the block and drive the heartbeat.

Each minute the heart beats about 70 times. One complete heartbeat takes about 0.8 second and is referred to as a **cardiac cycle.** That portion of the cycle in which contraction occurs is known as **systole;** the period of relaxation is **diastole.** Figure 42-11 shows the sequence of events that occur during one cardiac cycle.

You can measure your heart rate by placing a finger over the radial artery in your wrist or the carotid artery in your neck and counting the pulsations for 1 minute. **Arterial pulse** is the alternate expansion and recoil of an artery. Each time the left ventricle pumps blood into the aorta, the elastic wall of the aorta expands to accommodate the blood. This expansion moves in a wave down the aorta and the arteries that branch from it. When this pressure wave passes, the elastic arterial wall snaps back to its normal size.

When you listen to the heartbeat with a stethoscope, you can hear two main heart sounds, "lub-dup," which repeat rhythmically. These sounds result from the heart valves closing. When the valves close, they cause turbulence in blood flow that sets up vibrations in the walls of the heart chambers. The first heart sound, "lub," is low-pitched, not very loud, and fairly long-

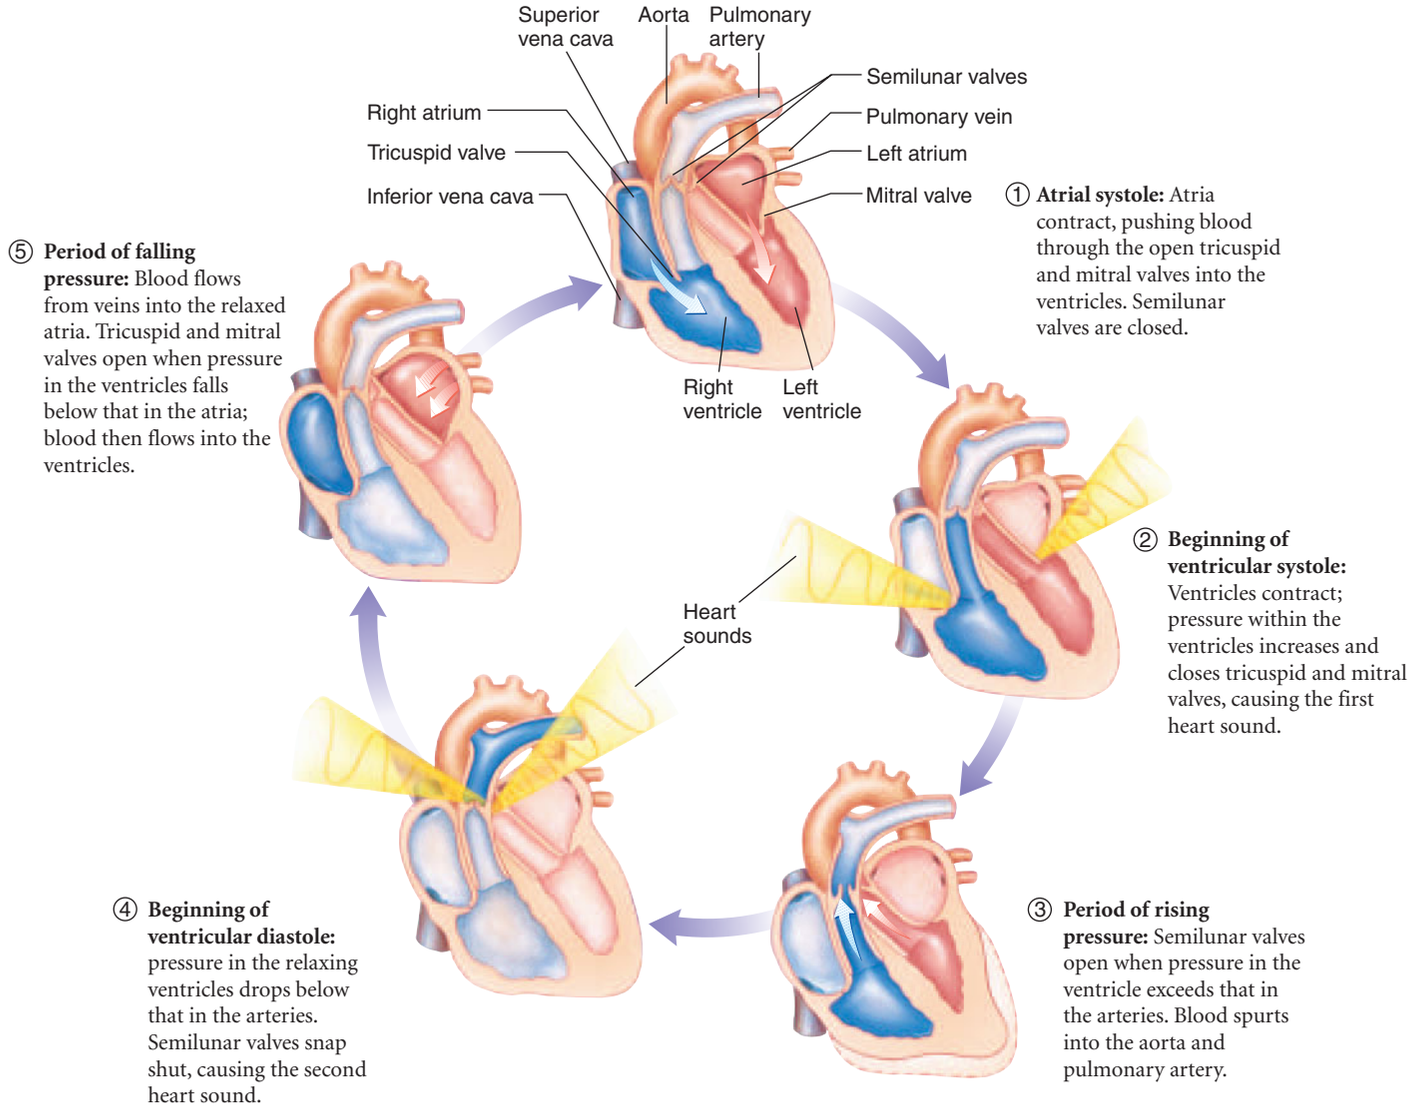


FIGURE **42-11** **The cardiac cycle.**

The cycle comprises contraction of both atria followed by both ventricles. White arrows indicate the direction of blood flow; dotted lines indicate the change in size as contraction occurs.

lasting. It is caused mainly by the closing of the AV (mitral and tricuspid) valves and marks the beginning of ventricular systole. The "lub" sound is quickly followed by the higher-pitched, louder, sharper, and shorter "dup" sound. Heard almost as a quick snap, the "dup" marks the closing of the semilunar valves and the beginning of ventricular diastole.

The quality of these sounds tells a discerning physician much about the state of the valves. For example, when a valve doesn't close tightly blood may flow backward, causing a **heart murmur.** When the semilunar valves are injured, a soft, hissing noise ("lub-shhh") is heard in place of the normal sound. Valve deformities are sometimes present at birth, or they may result from certain diseases such as rheumatic fever or syphilis. Diseased or deformed valves can be surgically repaired or replaced with artificial valves.

The nervous system regulates heart rate

Although the heart can beat independently, its rate is, in fact, carefully regulated by the nervous system and endocrine system (Fig. 42-12). Sensory receptors in the walls of certain blood vessels and heart chambers are sensitive to changes in blood pressure. When stimulated, they send messages to **cardiac centers** in the medulla of the brain. These cardiac centers govern two sets of autonomic nerves that pass to the SA node: parasympathetic and sympathetic nerves.

Parasympathetic and sympathetic nerves have opposite effects on heart rate (see Fig. 40-15). Parasympathetic nerves release the neurotransmitter *acetylcholine,* which slows the heart. Acetylcholine slows the rate of depolarization by increasing the membrane's permeability to potassium (Fig. 42-13a). Sympathetic nerves release norepinephrine, which speeds the heart rate and increases the strength of contraction. Norepinephrine stimulates calcium ion channel opening during depolarization (Fig. 42-13b). Both norepinephrine and acetylcholine act indirectly on ion channels. They activate a *signal transduction* process involving a G protein. Norepinephrine binds to *beta-adrenergic receptors,* one of the two main types of adren-

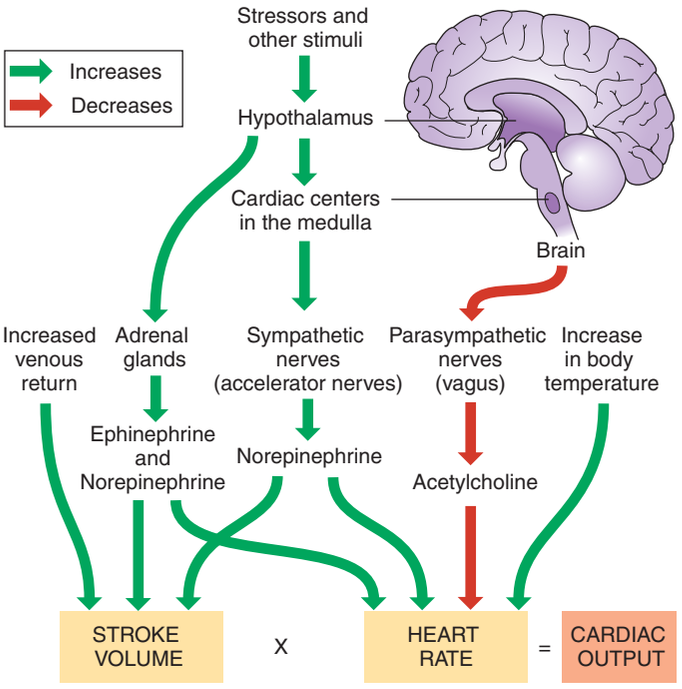

FIGURE **42-12** **Some factors that influence cardiac output.**

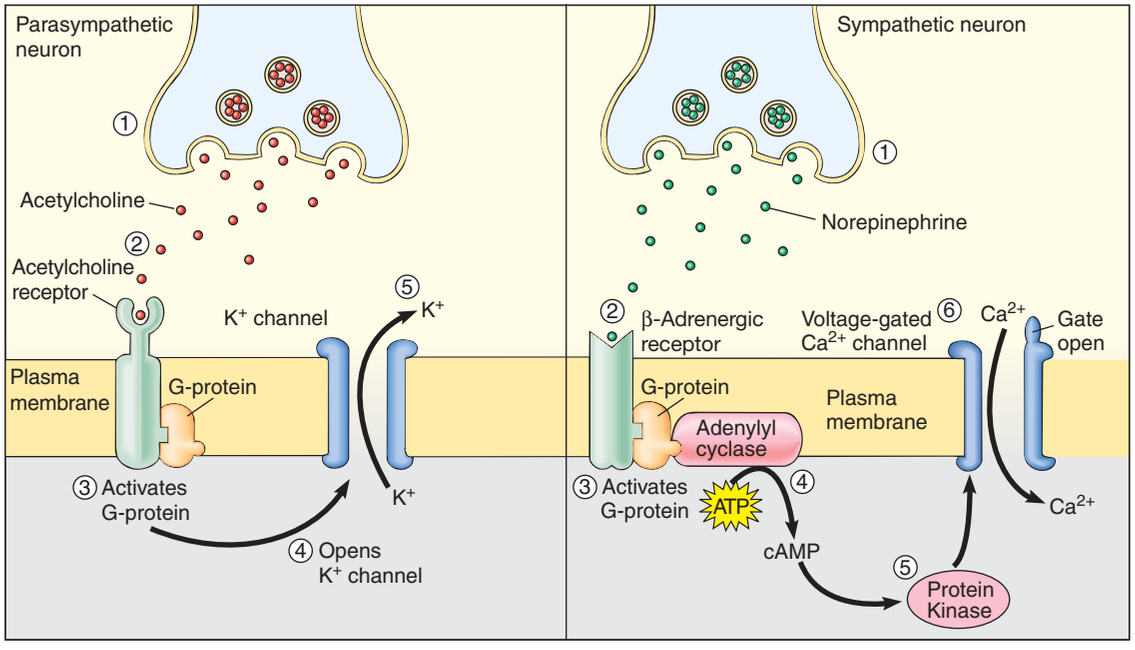
ergic receptors. These receptors are targeted by *beta blockers*, drugs that block the actions of norepinephrine on the heart and are used clinically in treating hypertension and other types of heart disease.

In response to physical and emotional stressors, the adrenal glands release epinephrine and norepinephrine, which speed the heart. An elevated body temperature also increases heart rate. During fever, the heart may beat more than 100 times per minute. As you might expect, heart rate decreases when body temperature is lowered. This is why physicians may deliberately lower a patient's temperature during heart surgery.

Stroke volume depends on venous return

The volume of blood one ventricle pumps during one beat is the **stroke volume.** Stroke volume depends mainly on **venous return,** the amount of blood the veins deliver to the heart. According to **Starling's law of the heart,** if the veins deliver more blood to the heart, the heart pumps more blood (within physiological limits). When extra amounts of blood fill the heart chambers, the cardiac muscle fibers stretch more and contract with greater force, pumping a larger volume of blood into the arteries. Norepinephrine released by sympathetic nerves and



(a) Parasympathetic action on cardiac muscle (b) Sympathetic action on cardiac muscle

FIGURE **42-13** **Actions of sympathetic and parasympathetic neurons on cardiac muscle cells.**

Neurotransmitters released by sympathetic and parasympathetic neurons initiate a signal transduction process. **(a)** ① Parasympathetic neurons release acetylcholine which ② binds with receptors on the plasma membrane of cardiac muscle. ③ The receptor activates a G protein, which ④ binds with a K^+ channel, causing the channel to open. ⑤ K^+ leaves the cell, causing the membrane to become hyperpolarized. The rate of action potentials slows.

(b) ① Sympathetic neurons release norepinephrine, which ② binds with receptors on the plasma membrane of cardiac muscle. ③ The receptor then activates a G protein, which ④ activates the enzyme (adenylyl cyclase) that converts ATP to cyclic AMP. ⑤ Cyclic AMP activates a protein kinase. ⑥ The protein kinase phosphorylates calcium ion channels so that they open more easily when the neuron is depolarized. Action potentials occur more rapidly.

epinephrine released by the adrenal glands during stress also increase the force of contraction of cardiac muscle fibers.

Cardiac output varies with the body's need

By multiplying the stroke volume by the number of times the left ventricle beats per minute, we can compute the **cardiac output (CO).** The CO is the volume of blood pumped by the left ventricle into the aorta in 1 minute. For example, in a resting adult the heart may beat about 72 times per minute and pump about 70 mL of blood with each contraction.

$$\begin{aligned} CO &= \text{stroke volume} \times \text{heart rate (number of ventricular contractions per minute)} \\ &= 70 \text{ mL/stroke} \times 72 \text{ strokes/min} \\ &= 5040 \text{ mL/min (about 5 L/min)} \end{aligned}$$

Cardiac output varies with changes in either stroke volume or heart rate (see Fig. 42-12). When stroke volume increases, CO increases. The CO varies dramatically with the changing needs of the body. During stress or heavy exercise, the normal heart can increase its CO fourfold to fivefold, so that it pumps 20 to 30 L of blood per minute.

Review

- What factors influence cardiac output?
- What sequence of events occurs during cardiac conduction?

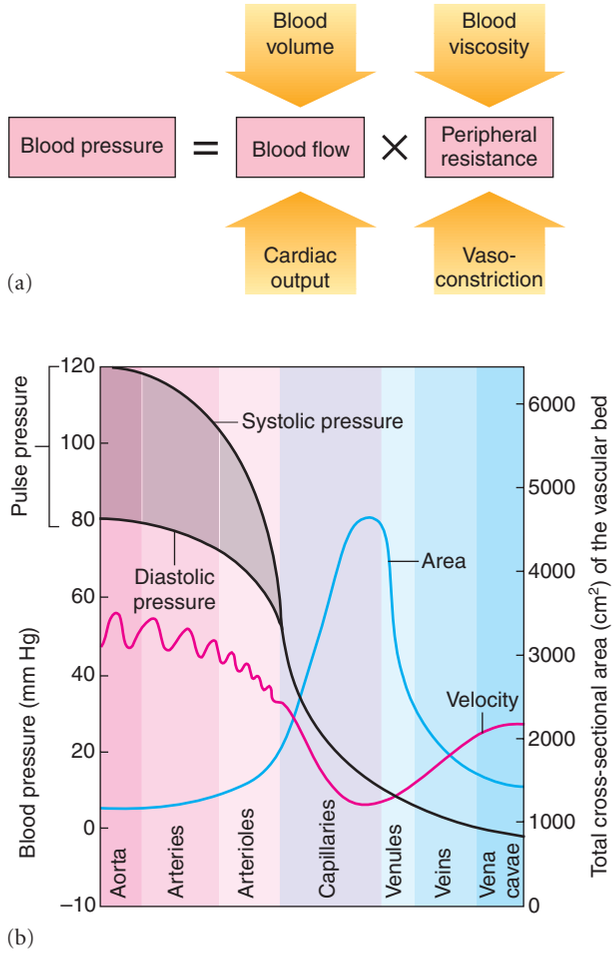
BLOOD PRESSURE

Learning Objective

9 Identify factors that determine and regulate blood pressure, and compare blood pressure in different types of blood vessels.



ACTIVE FIGURE **42-14** **Blood pressure.**

(a) Blood pressure depends on blood flow and resistance to that flow. A variety of factors affect blood flow and resistance. **(b)** Blood pressure in different types of blood vessels. Systolic and diastolic variations in arterial blood pressures are shown. Note that the venous pressure drops below zero (below atmospheric pressure) near the heart.

BiologyNow™ Learn more about **determining blood pressure** by clicking on this figure on your BiologyNow CD-ROM.

Blood pressure is the force exerted by the blood against the inner walls of the blood vessels. It is determined by CO, blood volume, and the resistance to blood flow (Fig. 42-14a). When CO increases, blood flow increases, causing a rise in blood pressure. When CO decreases, blood flow decreases, causing a fall in blood pressure. If the volume of blood is reduced by hemorrhage or by chronic bleeding, the blood pressure drops. In contrast, an increase in blood volume results in an increase in blood pressure. For example, a high dietary intake of salt causes water retention. This increases blood volume and raises blood pressure.

Blood flow is impeded by resistance; when the resistance to flow increases, blood pressure rises. **Peripheral resistance** is the resistance to blood flow caused by blood viscosity and by friction between blood and the blood vessel wall. In the blood of a healthy person, viscosity remains fairly constant and is only a minor influence on changes in blood pressure. More important is the friction between blood and the blood vessel wall. The length and diameter of a blood vessel determine the amount of surface area in contact with the blood. Blood vessel length does not change, but the diameter, especially of an arteriole, does. A small change in blood vessel diameter causes a big change in blood pressure. Constriction of blood vessels raises blood pressure; dilation lowers blood pressure.

Blood pressure in arteries rises during systole and falls during diastole. In 2003 the National Institutes of Health revised its guidelines for prevention and treatment of **hypertension,** or high blood pressure. It included a new guideline for normal blood pressure, defining it as a systolic pressure of less than 120 and a diastolic pressure of less than 80. An example of a normal blood pressure, measured in the upper arm with a sphygmomanometer, is 110/73 mm of mercury, abbreviated mm Hg. Systolic pressure is indicated by the first number, diastolic by

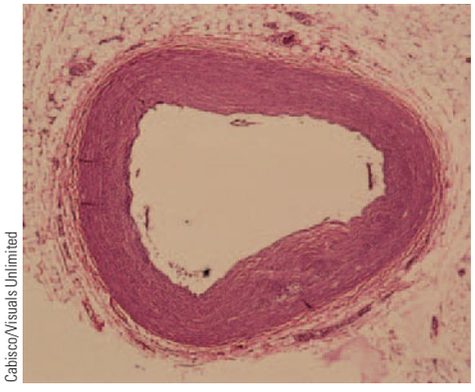
Cardiovascular disease is the number one cause of death in the United States and in most other industrial countries. Most often death results from some complication of **atherosclerosis,** a disease in which the arteries are damaged, inflamed, and narrow as a result of lipid deposits in their walls. Although it can affect almost any artery, the disease most often develops in the aorta and in the coronary and cerebral arteries. When it occurs in the cerebral arteries, less blood is delivered to the brain. This condition can lead to a **cerebrovascular accident (CVA),** commonly referred to as a stroke.

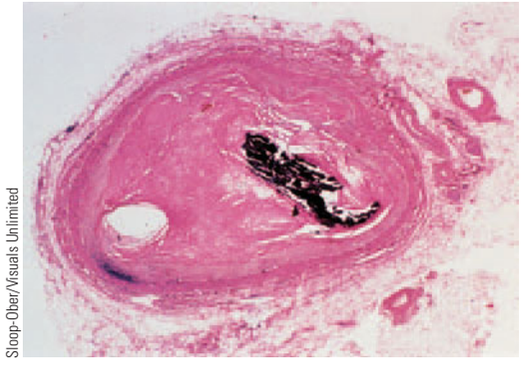
Atherosclerosis develops when excess low-density lipoprotein (LDL), known as "bad" cholesterol, in the blood triggers inflammation in the wall of arteries. (Inflammation, discussed in Chapter 43, is one of the body's most important responses to infection or injury.) The LDLs become oxidized and adhere to the wall of the blood vessel. They stimulate a complex series of events that promote inflammation. Underlying smooth muscle fibers then migrate to the inner lining of the artery and produce components of the extracellular matrix. The muscle fibers and extracellular matrix components form a fibrous cap of tissue over the injured area of the artery.

As atherosclerotic plaque develops, arteries lose their ability to stretch when filled with blood, and they gradually become occluded (blocked), as shown in the figure. The occluded vessels deliver less blood to the tissues, which then become **ischemic** (lacking in blood). Now the tissue is deprived of an adequate oxygen and nutrient supply.

In **ischemic heart disease,** the increased need for oxygen during exercise or emotional stress results in the pain characteristic of **angina pectoris.** Nitroglycerin pills or a nitroglycerin patch dilate veins, decreasing venous return. Cardiac output is lowered so the heart is working less hard and requires less oxygen. Nitroglycerin also dilates the coronary arteries slightly, allowing more blood to reach the heart muscle. *Calcium ion channel blockers* are drugs that slow the heart by inhibiting the passage of calcium into cardiac muscle fibers. They also dilate the coronary arteries.

Myocardial infarction (MI), or heart attack, is a very serious, often fatal, consequence of cardiovascular disease. MI often results from a sudden decrease in coronary blood supply. The part of





Progression of atherosclerosis. LMs of cross sections through two arteries showing changes that take place in atherosclerosis. **(a)** Normal coronary artery. **(b)** This artery is almost completely blocked with atherosclerotic plaque.

the second. If you have a blood pressure of 120 to 139 systolic over 80 to 89 diastolic, you are considered *prehypertensive,* and you need to modify your lifestyle to prevent cardiovascular disease and stroke. Lifestyle changes that will reduce your risk include: exercise, lose excess weight, follow a heart-healthy diet, reduce salt intake, limit alcohol, and don't smoke.

If your systolic pressure consistently measures 140 mm Hg or higher or your diastolic pressure measures 90 mm Hg or higher, you have hypertension. Hypertension is a risk factor for atherosclerosis and other cardiovascular disease (see *Focus On: Cardiovascular Disease*). In hypertension, there is usually increased vascular resistance, especially in the arterioles and small arteries. The heart's workload increases because it must pump against this greater resistance. If this condition persists, the left ventricle enlarges and may deteriorate in function. Heredity, aging, and ethnicity contribute to the development of hypertension.

Blood pressure is highest in arteries

As you might guess, blood pressure is greatest in the large arteries, decreasing as blood flows away from the heart and through the smaller arteries and capillaries (Fig. 42-14b). By the time blood enters the veins, its pressure is very low, even approaching zero. Flow rate can be maintained in veins at low pressure, because they are low-resistance vessels. Their diameter is larger than that of corresponding arteries, and their walls have little smooth muscle. Flow of blood through veins depends on several factors, including skeletal muscle movement, which compresses veins. Most veins larger than 2 mm (0.08 in) in diameter that conduct blood against the force of gravity are equipped with valves to prevent backflow (Fig. 42-15). Such valves usually consist of two cusps formed by inward extensions of the vein wall.

cardiac muscle deprived of oxygen dies within a few minutes and is then referred to as an **infarct.** MI is the leading cause of death and disability in the United States. The sudden decrease in blood supply most often occurs when inflammation causes the fibrous cap over the atherosclerotic plaque to break open. Platelets adhere to the roughened arterial wall and initiate clotting.

A **thrombus,** a clot that forms within a blood vessel or within the heart, can block a sizable branch of a coronary artery. Blood flow to a portion of heart muscle is impeded or completely halted. When such blockage, referred to as a *coronary occlusion,* prevents blood flow to a large region of cardiac muscle, the heart may stop beating; that is, **cardiac arrest** occurs, and death can follow within moments. If only a small part of the heart is affected, however, the heart may continue to function. Cells in the region deprived of oxygen die and are replaced by scar tissue.

An episode of ischemia may trigger a fatal arrhythmia such as **ventricular fibrillation,** a condition in which the ventricles contract very rapidly without actually pumping blood. The pulse may stop, and blood pressure may fall precipitously. Ventricular fibrillation has been linked with about 65% of cardiac arrests. The only effective treatment for fibrillation is **defibrillation** with electric shock. The shock appears to depolarize every muscle fiber in the heart so that its timing mechanism can reset.

Patients with progressive cardiovascular disease can be treated with *coronary bypass surgery* in which veins from another location in the patient's body are grafted around occluded coronary arteries. The newly positioned blood vessels restore adequate blood flow to the affected area. Another procedure, *coronary angioplasty,* involves inserting a small balloon into an occluded coronary artery. Inflating the balloon breaks up the plaque in the arterial wall, widening the vessel.

Approaches to preventing and treating cardiovascular disease include use of anti-inflammatory agents and statins, medications that lower cholesterol level. A molecular marker of inflammation called C-reactive protein (CRP) is used to assess the risk of heart disease. Several major modifiable risk factors for cardiovascular disease have been identified:

1. **Elevated LDL-cholesterol levels** in the blood, associated with diets rich in total calories, total fats, saturated fats, and cholesterol.
2. **Hypertension.** The higher the blood pressure, the greater the risk. The hormone angiotensin II, which at abnormally high levels is thought to contribute to hypertension, also stimulates inflammation.
3. **Cigarette smoking.** The risk of developing atherosclerosis is two to six times greater in smokers than in nonsmokers and is directly proportional to the number of cigarettes smoked daily. Components of cigarette smoke cause oxidants to form, which may contribute to the inflammation by increasing oxidation of the altered LDL in the arterial wall.
4. **Diabetes mellitus,** an endocrine disorder in which glucose is not metabolized normally. The body shifts to fat metabolism, and there is a marked increase in circulating lipids, leading to atherosclerosis.
5. **Physical inactivity.** One in four adults in the United States has a sedentary lifestyle and does not engage in regular exercise. Physical inactivity contributes to more than one third of the approximately 500,000 deaths related to heart disease in the United States each year. Exercise reduces the concentrations of triacylglycerols (triglycerides) and cholesterol in the blood (these lipids have been associated with heart disease). At the same time, exercise increases the concentration of high-density lipoproteins (HDLs), which protect against heart disease.
6. **Obesity** can affect cholesterol levels and increase the risk of hypertension and diabetes.

The risk of developing cardiovascular disease also increases with age. Other probable risk factors currently being studied are hereditary predisposition, hormone levels, stress and behavior patterns, and dietary factors.

When a person stands perfectly still for a long time, as when a soldier stands at attention or a store clerk stands at a cash register, blood tends to pool in the veins. When fully distended, veins can accept no more blood from the capillaries. Pressure in the capillaries increases, and large amounts of plasma are forced out of the circulation through the thin capillary walls. Within just a few minutes, as much as 20% of the blood volume is lost from the circulation—with drastic effect. Arterial blood pressure

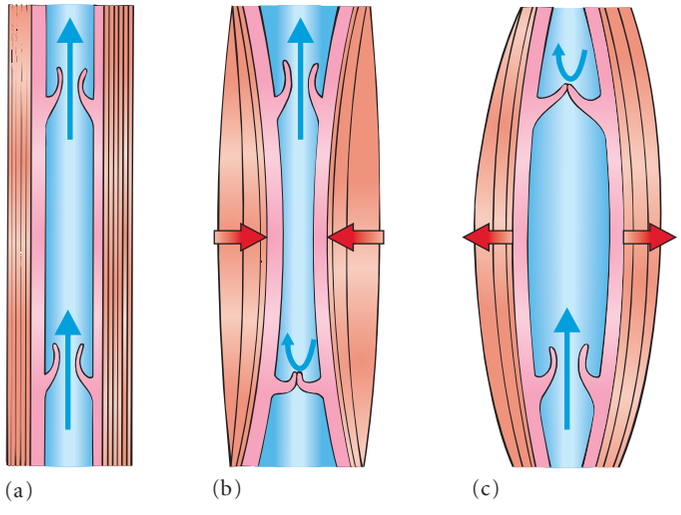


FIGURE **42-15** **Venous blood flow.**

Contraction of skeletal muscles helps move blood through the veins. **(a)** Resting condition. **(b)** Muscles contract and bulge, compressing veins and forcing blood toward the heart. falls dramatically, reducing blood flow to the brain. Sometimes the resulting lack of oxygen in the brain causes fainting, a protective response. Lying in a prone position increases blood supply to the brain. In fact, lifting a person who has fainted to an upright position can result in circulatory shock and even death.

Blood pressure is carefully regulated

Each time you get up from a horizontal position, your blood pressure changes. Several complex mechanisms interact to maintain normal blood pressure so that you do not faint when you get out of bed each morning or change position during the day. When blood pressure falls, sympathetic nerves to the blood vessels stimulate vasoconstriction, causing the pressure to rise again.

The **baroreceptors** present in the walls of certain arteries and in the heart wall are sensitive to changes in blood pressure. When an increase in blood pressure stretches the baroreceptors, messages are sent to the cardiac and vasomotor centers in the medulla of the brain. The cardiac center stimulates parasympathetic nerves that slow the heart, lowering blood pressure. The vasomotor center inhibits sympathetic nerves that constrict arterioles; this action causes vasodilation, which also lowers blood pressure. These neural reflexes continuously work in a complementary way to maintain blood pressure within normal limits.

Hormones are also involved in regulating blood pressure. In response to low blood pressure, the kidneys release **renin,** which activates the **renin-angiotensin-aldosterone pathway** (discussed in Chapter 46). Renin acts on a plasma protein (angiotensinogen), triggering a cascade of reactions that produces the hormone **angiotensin II,** a powerful vasoconstrictor. Angiotensin II also acts indirectly to maintain blood pressure by increasing the synthesis and release of the hormone **aldosterone** by the adrenal glands. Aldosterone increases retention of sodium ions by the kidneys, resulting in greater fluid retention and increased blood volume.

THE PATTERN OF CIRCULATION

Learning Objective

10 Trace a drop of blood through the pulmonary and systemic circulations, naming in sequence each structure through which it passes.

Most vertebrates other than fish have a double circuit of blood vessels: (1) the pulmonary circulation connects the heart and lungs; and (2) the systemic circulation connects the heart with all the body tissues. You can trace this general pattern of circulation in Figure 42-16.

KEY CONCEPT: The left side of the heart pumps oxygen-rich blood into the systemic circulation. The right side of the heart receives oxygen-poor blood and pumps it into the pulmonary circulation.

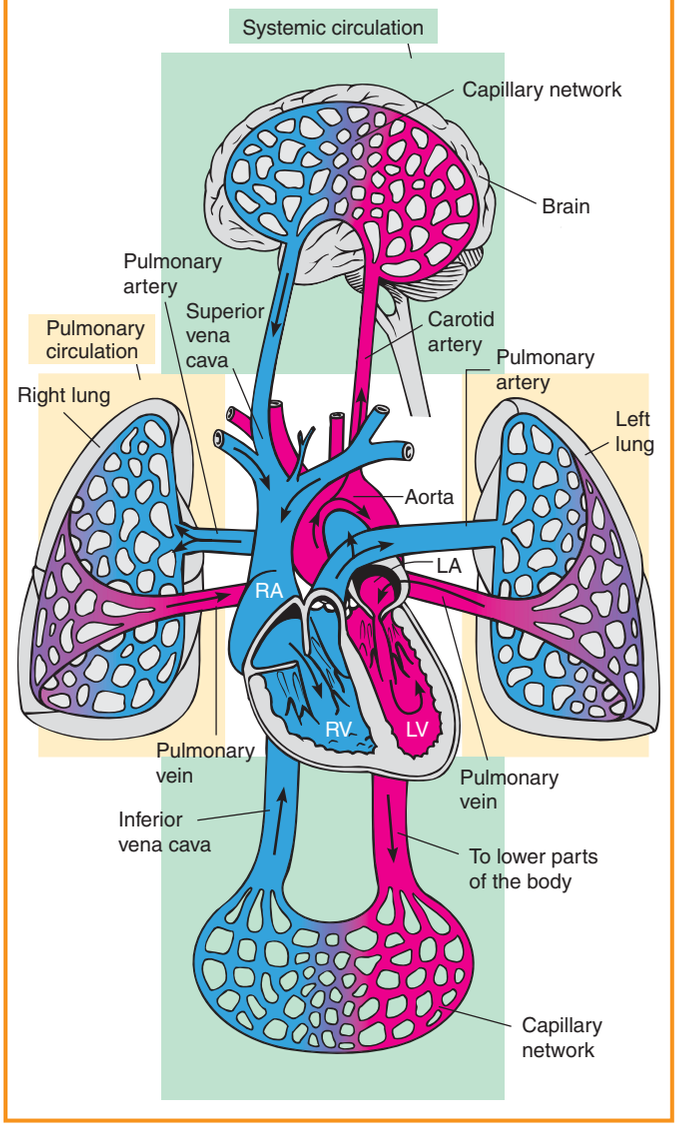

FIGURE **42-16** **Systemic and pulmonary circulation.**
In this highly simplified diagram, red represents oxygen-rich blood; blue represents oxygen-poor blood. Green screen highlights systemic circulation. Yellow screen highlights pulmonary circulation.

The pulmonary circulation oxygenates the blood

Blood from the tissues returns to the right atrium of the heart. This oxygen-poor blood, loaded with carbon dioxide, is pumped by the right ventricle into the pulmonary circulation. As it emerges from the heart, the large pulmonary trunk branches to form the two **pulmonary arteries,** one going to each lung. These are the only arteries that carry oxygen-poor blood.

In the lungs the pulmonary arteries branch into smaller and smaller vessels, which finally give rise to extensive networks of pulmonary capillaries that surround the air sacs of the lungs. As blood circulates through the pulmonary capillaries, carbon dioxide diffuses out of the blood and into the air sacs. Oxygen from the air sacs diffuses into the blood so that by the time it enters the **pulmonary veins** leading back to the left atrium of the heart, the blood is charged with oxygen. Pulmonary veins are the only veins in the body that carry blood rich in oxygen.

In summary, blood flows through the pulmonary circulation in the following sequence:

Right atrium ⟶ right ventricle ⟶ pulmonary arteries ⟶ pulmonary capillaries (in lungs) ⟶ pulmonary veins ⟶ left atrium

The systemic circulation delivers blood to the tissues

Blood entering the systemic circulation is pumped by the left ventricle into the **aorta,** the largest artery. Arteries that branch off from the aorta conduct blood to all regions of the body. Some of the principal branches include the **coronary arteries** to the heart wall itself, the **carotid arteries** to the brain, the **subclavian arteries** to the shoulder region, the **mesenteric artery** to the intestine, the **renal arteries** to the kidneys, and the **iliac arteries** to the legs (Fig. 42-17). Each of these arteries gives rise to smaller and smaller vessels, somewhat like branches of a tree that divide until they form tiny twigs. Eventually blood flows into the capillary network within each tissue or organ.

Blood returning from the capillary networks within the brain passes through the **jugular veins.** Blood from the shoulders and arms drains into the **subclavian veins.** These veins and others returning blood from the upper portion of the body merge to form a very large vein that empties blood into the right atrium. In humans this vein is called the **superior vena cava.** The **renal veins** from the kidneys, **iliac veins** from the lower limbs, **hepatic veins** from the liver, and other veins from the lower portion of the body return blood to the **inferior vena cava,** which delivers blood to the right atrium.

As an example of blood circulation through the systemic circuit, let us trace a drop of blood from the heart to the right leg and back to the heart:

Left atrium ⟶ left ventricle ⟶ aorta ⟶ right common iliac artery ⟶ smaller arteries in leg ⟶ capillaries in leg ⟶ small veins in leg ⟶ common iliac vein ⟶ inferior vena cava ⟶ right atrium

In most fishes, amphibians, and reptiles, the heart muscle is spongy and receives oxygen directly from the blood as it passes through the heart chambers. However, in birds and mammals

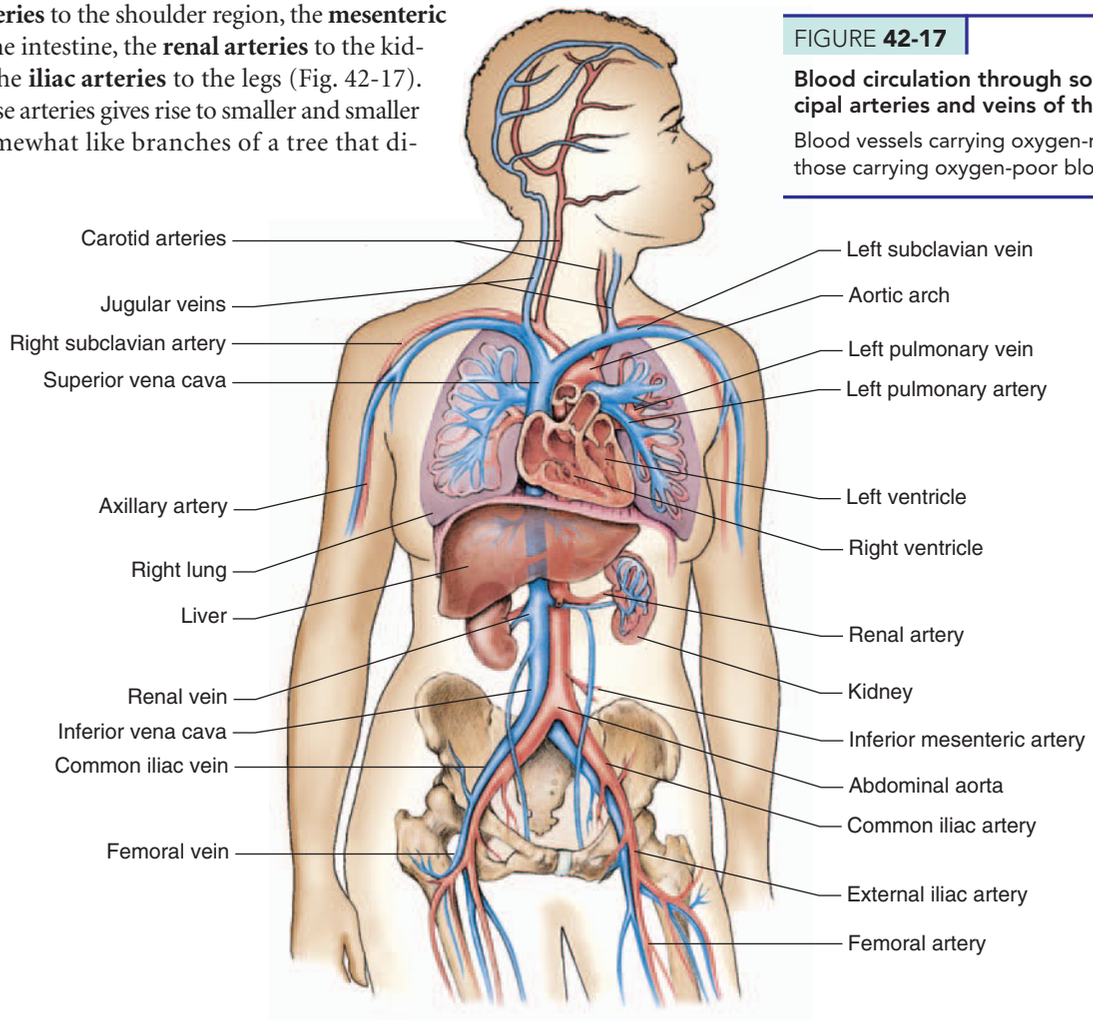

FIGURE **42-17**

Blood circulation through some of the principal arteries and veins of the human body.

Blood vessels carrying oxygen-rich blood are red; those carrying oxygen-poor blood are blue.

the walls of the heart are too thick for nutrients and oxygen to diffuse through them to reach all the muscle fibers. Instead, the cardiac muscle has its own system of blood vessels. In humans, **coronary arteries** give rise to a network of capillaries within the heart wall. The **coronary veins** join to form a large vein, the **coronary sinus** that empties directly into the right atrium.

Blood almost always travels from artery to capillary to vein to the heart. An exception occurs in the **hepatic portal system.** Instead of leading directly back to the heart (as most veins do), the hepatic portal vein delivers nutrients from the intestine to the liver. Within the liver, the hepatic portal vein gives rise to an extensive network of tiny blood sinuses. As blood courses through the hepatic sinuses, liver cells remove nutrients and store them. Eventually liver sinuses merge to form hepatic veins, which deliver blood to the inferior vena cava.

Review

- What sequence of blood vessels and heart chambers would a red blood cell pass through on its way (a) from the inferior vena cava to the aorta; and (b) from the renal vein to the renal artery?
- What is the function of the hepatic portal system? How does its sequence of blood vessels differ from that in most other circulatory routes?

BiologyNow™ Assess your understanding of **the pattern of circulation** by taking the pretest on your BiologyNow CD-ROM.

THE LYMPHATIC SYSTEM

Learning Objective

11 Describe the structure and functions of the lymphatic system.

In addition to the blood circulatory system, vertebrates have an accessory circulatory system, the **lymphatic system** (Fig. 42-18), which has three important functions: (1) to collect and return interstitial fluid to the blood; (2) to launch immune responses that defend the body against disease organisms; and (3) to absorb lipids from the digestive tract. In this section we focus on the first function. We discuss immunity in Chapter 43, and lipid absorption in Chapter 45.

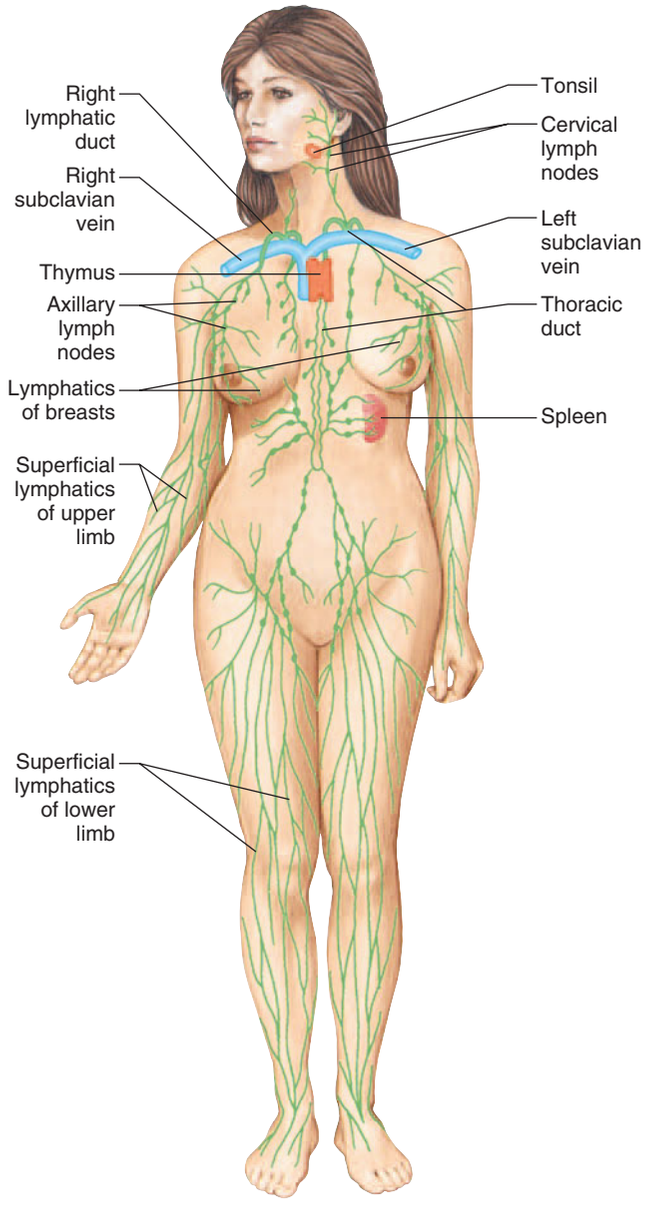

FIGURE **42-18** **Human lymphatic system.**

Note that while the lymphatic vessels extend into most tissues of the body, the lymph nodes are clustered in certain regions. The right lymphatic duct drains lymph from the upper right quadrant of the body. The thoracic duct drains lymph from other regions of the body.

The lymphatic system consists of lymphatic vessels and lymph tissue

The lymphatic system consists of (1) an extensive network of **lymphatic vessels,** or simply **lymphatics,** that conduct **lymph,** the clear, watery fluid formed from interstitial fluid, and (2) **lymph tissue,** a type of connective tissue with large numbers of lymphocytes. Lymph tissue is organized into small masses of tissue called **lymph nodes** and **lymph nodules.** The tonsils, thymus gland, and spleen, which consist mainly of lymph tissue, are also part of the lymphatic system.

Tiny "dead-end" capillaries of the lymphatic system extend into almost all body tissues (Fig. 42-19). Lymph capillaries join to form larger lymphatics (which you can think of as lymph veins). There are no lymph arteries.

Interstitial fluid enters lymph capillaries, becoming lymph. The lymph is conveyed into lymphatics, which at certain locations empty into lymph nodes. As lymph circulates through the lymph nodes, phagocytes filter out bacteria and other harmful materials. The lymph then flows into lymphatics that conduct it away from the lymph node. Lymphatics from all over the body conduct lymph toward the shoulder region. These vessels join the circulatory system at the base of the subclavian veins by way of ducts: the **thoracic duct** on the left side and the **right lymphatic duct** on the right.

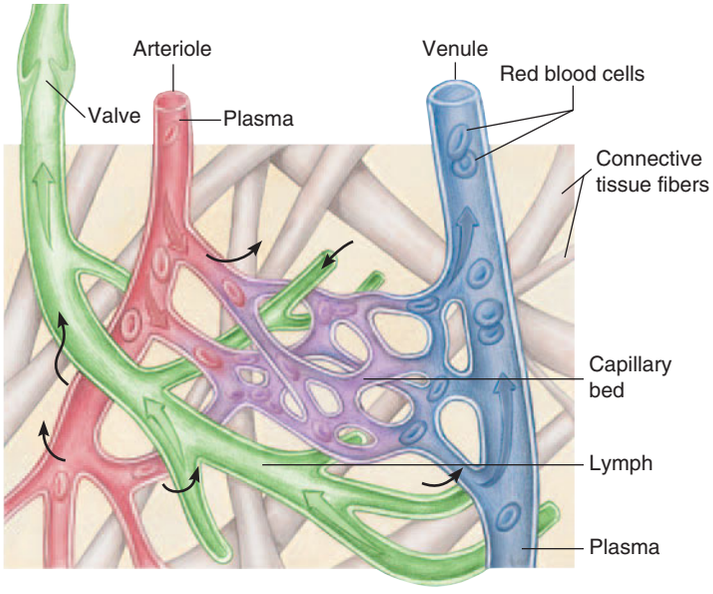

FIGURE **42-19** **Lymph capillaries.**

Lymph capillaries drain excess interstitial fluid from the tissues. Note that blood capillaries are connected to vessels at both ends, whereas lymph capillaries, shown in green, are "dead-end streets." The arrows indicate direction of flow.

Tonsils are masses of lymph tissue under the lining of the oral cavity and throat. (When enlarged, the pharyngeal tonsils in back of the nose are called **adenoids.**) Tonsils help protect the respiratory system from infection by destroying bacteria and other foreign matter that enter the body through the mouth or nose. Unfortunately, tonsils are sometimes overcome by invading bacteria and become the site of frequent infection themselves.

Some nonmammalian vertebrates, such as frogs, have lymph "hearts," which pulsate and squeeze lymph along. However, in mammals the walls of lymphatic vessels themselves pulsate. Valves within the lymphatics prevent the lymph from flowing backward. When muscles contract or when arteries pulsate, pressure on the lymphatic vessels increases lymph flow. The rate at which lymph flows is slow and variable, and the total lymph flow is about 100 mL per hour—far slower than the 5 L per min of blood flowing in the vascular system.

The lymphatic system plays an important role in fluid homeostasis

When blood enters a capillary network, it is under rather high pressure, so some plasma is forced out of the capillaries and into the tissues. Once it leaves the blood vessels, this fluid is called **interstitial fluid,** or tissue fluid. It contains no red blood cells or platelets and only a few white blood cells. Its protein content is about one fourth that found in plasma, because proteins are too large to pass easily through capillary walls. However, smaller molecules dissolved in the plasma do pass out with the fluid leaving the blood vessels. Thus interstitial fluid contains glucose, amino acids, other nutrients, and oxygen, as well as a variety of salts. This nourishing fluid bathes all the cells.

The main force *(filtration pressure)* pushing plasma out of the blood is hydrostatic pressure, that is, the blood pressure against the capillary wall (Fig. 42-20). The osmotic pressure of the interstitial fluid adds to the filtration pressure. The principal opposing force is the osmotic pressure of the blood which restrains fluid loss from the capillary.

At the venous ends of the capillaries the blood pressure is much lower, and the osmotic pressure of the blood draws fluid back into the capillary. However, not as much fluid is absorbed back into the circulation as is filtered out. Furthermore, protein does not return effectively into the venous capillaries and instead tends to accumulate in the interstitial fluid. These potential problems are so serious that without the lymphatic system, fluid balance in the body would be significantly disturbed within a few hours, and death would occur within about 24 hours. The lymphatic system preserves fluid balance by collecting some of

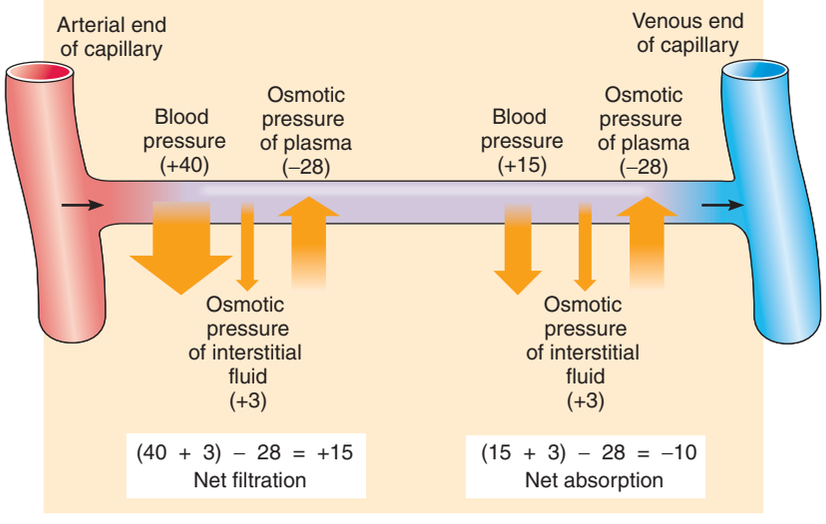

FIGURE **42-20** **Fluid movement between blood and interstitial fluid.**

Blood pressure and osmotic pressures are responsible for fluid movement, and, thus, exchange of dissolved materials, between blood and interstitial fluid. At the arterial end of a capillary, blood pressure forces plasma out of the capillary. The osmotic pressure of the blood is an opposing force acting to draw fluid into the blood. Osmotic pressure of the interstitial fluid contributes to the net filtration pressure but does not change much between arterial and venous ends of the capillary. At the venous end of the capillary, fluid enters the blood because blood pressure is much lower. However, more fluid leaves the blood than returns, and the lymphatic system collects the excess interstitial fluid. The numbers given are hypothetical and represent millimeters of mercury. Net filtration is the total pressure moving fluid out of the capillary. Net absorption is the total pressure drawing fluid into the capillary.

the interstitial fluid (about 10%), including the protein that accumulates in it, and returning it to the circulation.

The walls of the lymph capillaries consist of endothelial cells that overlap slightly. When interstitial fluid accumulates, it presses against these cells, pushing them inward like tiny swinging doors that swing in only one direction. As fluid accumulates within the lymph capillary, these cell doors are pushed closed.

Obstruction of the lymphatic vessels causes **edema,** swelling from excessive accumulation of interstitial fluid. Lymphatic vessels can be blocked as a result of injury, inflammation, surgery, or parasitic infection. For example, when a breast is removed (mastectomy) because of cancer, lymph nodes in the underarm region may also be removed, to prevent the spread of cancer cells. The disrupted lymph circulation makes the patient's arm swell. New lymphatic vessels develop within a few months, and the swelling slowly subsides.

Review

- What are the relationships among plasma, interstitial fluid, and lymph?
- How does the lymphatic system help maintain fluid balance?

BiologyNow™ Assess your understanding of **the lymphatic system** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Compare and contrast internal transport in animals with no circulatory system, those with an open circulatory system, and those with a closed circulatory system.

- Small, simple invertebrates, such as sponges, cnidarians, and flatworms, depend on **diffusion** for internal transport. Larger animals require a specialized **circulatory system,** which typically consists of **blood,** a **heart,** and a system of blood vessels or spaces through which blood circulates. In all animals, **interstitial fluid,** the tissue fluid between cells, brings oxygen and nutrients into contact with cells.
- Arthropods and most mollusks have an **open circulatory system** in which blood flows into a **hemocoel,** bathing the tissues directly.
- Some invertebrates and all vertebrates have a **closed circulatory system** in which blood flows through a continuous circuit of blood vessels.
- The vertebrate circulatory system consists of a muscular heart that pumps blood into a system of **arteries, capillaries,** and **veins.** This system transports nutrients, oxygen, wastes, and hormones; helps maintain fluid balance, appropriate pH, and body temperature; and defends the body against disease.

2 Compare the structure and function of plasma, red blood cells, white blood cells, and platelets.

- **Plasma** consists of water, salts, substances in transport, and **plasma proteins,** including albumins, globulins, and fibrinogen.
- **Red blood cells,** also called **erythrocytes,** transport oxygen and carbon dioxide. Red blood cells produce large quantities of **hemoglobin,** a red pigment that binds with oxygen.
- **White blood cells,** also called **leukocytes,** defend the body against disease organisms. **Lymphocytes** and **monocytes** are agranular white blood cells; **neutrophils, eosinophils,** and **basophils** are granular white blood cells.
- **Platelets** patch damaged blood vessels and release substances essential for blood clotting.

3 Summarize the sequence of events involved in blood clotting.

- Damaged cells and platelets release substances that activate clotting factors. Prothrombin is converted to **thrombin,** which catalyzes the conversion of **fibrinogen** to an insoluble protein, **fibrin.** Fibrin forms long threads that form the webbing of the clot.

4 Compare the structure and function of different types of blood vessels, including arteries, arterioles, capillaries, and veins.

- Arteries carry blood away from the heart; veins return blood to the heart.
- **Arterioles** constrict (**vasoconstriction**) and dilate (**vasodilation**) to regulate blood pressure and distribution of blood to the tissues.
- Capillaries are the thin-walled exchange vessels through which blood and tissues exchange materials.

5 Trace the evolution of the vertebrate heart from fish to mammal.

- The vertebrate heart has one or two **atria,** which receive blood, and one or two **ventricles,** which pump blood into the arteries.
- The fish heart consists of a single atrium and ventricle that are part of a single circuit of blood flow.
- In terrestrial vertebrates, complex circulatory systems separate oxygen-rich from oxygen-poor blood; this allows the higher metabolic rate needed to support an active terrestrial lifestyle.
- Amphibians have two atria and a ventricle, and blood flows through a double circuit so that oxygen-rich blood is partly separated from oxygen-poor blood. Most reptiles have a wall that partly divides the ventricles, minimizing the mixing of oxygen-rich and oxygen-poor blood.
- The four-chambered hearts of birds and mammals separate oxygen-rich blood from oxygen-poor blood.

6 Describe the structure and function of the human heart. (Include the heart's conduction system in your answer.)

- The heart is enclosed by a **pericardium** and has valves that prevent backflow of blood. The valve between right atrium and ventricle is the **right atrioventricular (AV) valve,** or **tricuspid valve.** The valve between left atrium and ventricle is the **mitral valve. Semilunar valves** guard the exits from the heart. Cardiac muscle fibers are joined by **intercalated discs.**
- The **sinoatrial (SA) node,** or **pacemaker,** initiates each heartbeat. A specialized electrical conduction system coordinates heartbeats.

7 Trace the events of the cardiac cycle, and relate normal heart sounds to these events.

- One complete heartbeat makes up a **cardiac cycle.** Contraction occurs during **systole.** The period of relaxation is **diastole.** At

SUMMARY WITH KEY TERMS *(continued)*

the beginning of ventricular systole, the closing of the AV valves, makes a low-pitched "lub" sound. The closing of the semilunar valves, the beginning of ventricular diastole, makes a short, loud, sharp "dup" sound.

8 Define *cardiac output,* describe how it is regulated, and identify factors that affect it.

- **Cardiac output (CO)** equals **stroke volume** times heart rate. Stroke volume depends on **venous return** and on neural messages and hormones, especially epinephrine and norepinephrine.
- According to **Starling's law of the heart,** the more blood delivered to the heart by the veins, the more blood the heart pumps.
- Heart rate is regulated mainly by the nervous system and is influenced by hormones and body temperature.

9 Identify factors that determine and regulate blood pressure, and compare blood pressure in different types of blood vessels.

- **Blood pressure** is the force blood exerts against the inner walls of the blood vessel. Blood pressure is greatest in the arteries and decreases as blood flows through the capillaries.
- Blood pressure depends on cardiac output, blood volume, and resistance to blood flow. **Peripheral resistance** is the resistance to blood flow caused by blood viscosity and by friction between blood and blood vessel wall.
- **Baroreceptors** sensitive to blood pressure changes send messages to the cardiac and vasomotor centers in the medulla of the brain. When informed of an increase in blood pressure, the cardiac center stimulates parasympathetic nerves that slow heart rate, and the vasomotor center inhibits sympathetic nerves that constrict blood vessels. These actions reduce blood pressure.
- **Angiotensin II** is a hormone that raises blood pressure. **Aldosterone** helps regulate salt excretion, which affects blood volume and blood pressure.

10 Trace a drop of blood through the pulmonary and systemic circulations, naming in sequence each structure through which it passes.

- The **pulmonary circulation** connects heart and lungs; the **systemic circulation** connects the heart and the tissues.
- In the pulmonary circulation, the right ventricle pumps blood into the **pulmonary arteries,** one going to each lung. Blood circulates through pulmonary capillaries in the lung and then is conducted to the left atrium by a **pulmonary vein.**
- In the systemic circulation, the left ventricle pumps blood into the **aorta,** which branches into arteries leading to the body organs. After flowing through capillary networks within various organs, blood flows into veins that conduct it to the **superior vena cava** or **inferior vena cava** which returns blood to the right atrium.
- The **coronary arteries** supply the heart muscle with blood.
- The **hepatic portal system** circulates nutrient-rich blood through the liver.

11 Describe the structure and functions of the lymphatic system.

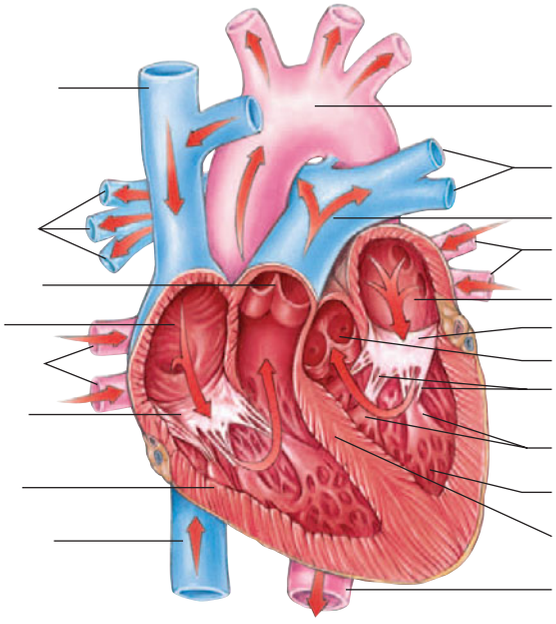
- The **lymphatic system** collects interstitial fluid, and returns it to the blood. It plays an important role in homeostasis of fluids. The lymph system also defends the body against disease and absorbs lipids from the digestive tract.
- **Lymphatic vessels** conduct **lymph,** a clear fluid formed from interstitial fluid, to the **thoracic duct** and **right lymphatic duct** in the shoulder region; these ducts return lymph to the blood circulatory system.
- **Lymph nodes** are small masses of tissue that filter bacteria and harmful materials out of lymph.

POST-TEST

1. An open circulatory system (a) is found in flatworms (b) typically includes a hemocoel (c) has a continuous circuit of vessels with openings in the capillaries (d) is characteristic of vertebrates (e) is typically found in animals with a two-chambered heart
2. Which of the following is *not* a function of the vertebrate circulatory system? (a) helps maintain appropriate pH (b) transports nutrients, oxygen, and metabolic wastes (c) helps maintain fluid balance (d) produces hemocyanin (e) provides internal defense
3. Lipoproteins (a) are mainly transported in granular leukocytes (b) transport cholesterol (c) have been linked to clotting disorders (d) are associated with platelets (e) are stored in red blood cells
4. Which of the following are most closely associated with oxygen transport? (a) red blood cells (b) platelets (c) neutrophils (d) basophils (e) lymphocytes
5. Which of the following are most closely associated with blood clotting? (a) red blood cells (b) platelets (c) neutrophils (d) basophils (e) lymphocytes
6. In blood clotting (a) thrombin ⟶ prothrombin; fibrinogen ⟶ fibrin (b) prothrombin ⟶ thrombin; fibrin ⟶ fibrinogen (c) prothrombin ⟶ thrombin; fibrinogen ⟶ fibrin (d) clotting factors ⟶ platelets; thrombin ⟶ fibrinogen (e) prothrombin ⟶ thrombin; fibrinogen ⟶ platelets
7. Blood vessels that carry blood away from the heart are (a) arteries (b) sinuses (c) veins (d) capillaries (e) arterioles and venules
8. Arterioles (a) help regulate blood pressure (b) help regulate distribution of blood to the tissues (c) deliver blood to arteries (d) answers a, b, and c are correct (e) answers a and b only
9. Which choice most accurately describes one sequence of blood flow? (a) right atrium ⟶ right ventricle ⟶ pulmonary artery (b) right atrium ⟶ left atrium ⟶ left ventricle ⟶ aorta (c) left atrium ⟶ left ventricle ⟶ pulmonary artery (d) left ventricle ⟶ left atrium ⟶ aorta (e) right atrium ⟶ right ventricle ⟶ aorta
10. Which choice most accurately describes one sequence of blood flow? (a) pulmonary vein ⟶ pulmonary artery ⟶ right atrium (b) pulmonary artery ⟶ left atrium ⟶ left ventricle (c) pulmonary artery ⟶ pulmonary capillaries ⟶ pulmonary vein ⟶ left atrium (d) left ventricle ⟶ aorta ⟶ pulmonary artery (e) pulmonary artery ⟶ pulmonary capillaries ⟶ pulmonary vein ⟶ right atrium

POST-TEST *(continued)*

11. A cardiac cycle (a) consists of one ventricular heartbeat (b) includes a systole (c) equals stroke volume times heart rate (d) includes a diastole (e) includes a systole and a diastole
12. Blood pressure is determined by (a) cardiac output (b) peripheral resistance (c) blood volume (d) answers a, b, and c are correct (e) answers b and c only
13. Lymph forms from (a) interstitial fluid (b) blood serum (c) plasma combined with protein (d) fluid released by lymph nodes (e) angiotensins
14. The valve between the right atrium and right ventricle is the (a) mitral valve (b) semilunar valve (c) tricuspid valve (d) pulmonary valve (e) aortic valve
15. Norepinephrine (a) slows heart rate (b) is released in cardiac muscle by parasympathetic nerves (c) causes potassium channels in cardiac muscle to open (d) decreases stroke volume (e) causes calcium channels in cardiac muscle to open
16. Baroreceptors (a) stimulate renin release (b) activate the renninangiotensin-aldosterone pathway (c) stimulate sympathetic nerves (d) are stimulated by increased blood pressure (e) send messages to cardiac centers that increase blood pressure
17. Atherosclerosis (a) is associated with thickening of arteries and veins (b) is associated with high concentrations of low-density lipoprotein (c) can lead to ischemic heart disease (d) answers a, b, and c are correct (e) answers b and c only
18. Label the diagram. See Figure 42-9 to check your answers.



CRITICAL THINKING

1. How is the heart of the fish specifically adapted to its lifestyle?
2. When the nerves to the heart are cut, the heart rate increases to about 100 contractions per minute. What does this indicate about the regulation of the heart rate?
3. List five modifiable risk factors associated with the development of cardiovascular disease. Describe the disease process in atherosclerosis, and explain the association between atherosclerosis and ischemic heart disease. What happens in myocardial infarction?

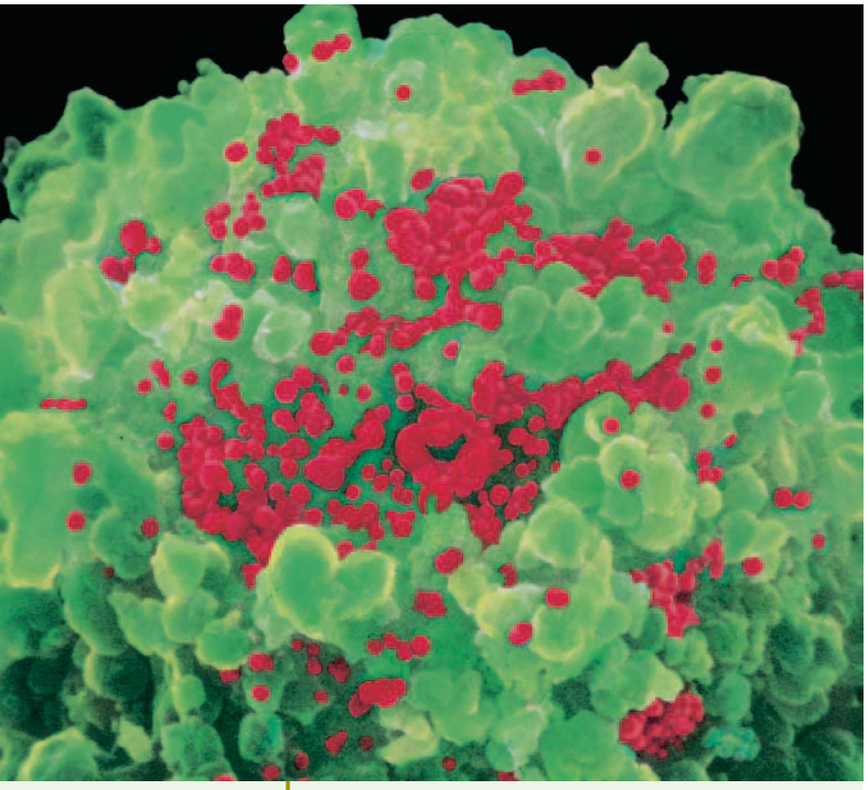
The Immune System: Internal Defense



NIBSC/Science Photo Library/Photo Researchers, Inc.

A T cell infected with HIV. In this colorized SEM, an immune system T cell *(green)* is infected by HIV viruses *(red)*.

CHAPTER OUTLINE

- Nonspecific and Specific Immunity: An Overview
- Nonspecific Immune Responses
- Specific Immune Responses
- Cell-Mediated Immunity
- Antibody-Mediated Immunity
- Immunological Memory
- The Immune System and Disease
- Harmful Immune Responses

The **immune system,** our internal defense system, protects the body against disease-causing organisms and certain toxins. Disease-causing organisms, or **pathogens,** include certain viruses, bacteria, fungi, and protozoa. Pathogens enter the body with air, food, and water; during copulation; and through wounds in the skin. The immune system recognizes pathogens and toxins and responds to eliminate them. Derived from the Latin for "safe," the word *immune* refers to the early observation that when a person recovered from smallpox and other serious infection, they were safe from contracting the same illnesses again. **Immunology,** the study of internal defense systems of humans and other animals, is one of the most rapidly changing, challenging, and exciting fields of biomedical research today.

For more than 50 years, immunologists based their work on the hypothesis that internal defense depends on the animal's ability to distinguish between *self* and *nonself*. Such recognition is possible because each individual is biochemically unique. Cells have surface proteins different from those on the cells of other species or even other members of the same species. An animal's immune system recognizes its own cells and can identify those of other organisms as foreign. Thus when a pathogen invades an animal, its distinctive macromolecules stimulate the animal's defensive responses. A single bacterium may have from 10 to more than 1000 distinct macromolecules on its surface.

Immunologists are aware of several limitations of the self–nonself hypothesis. For example, the immune system does not typically respond to foreign molecules that are harmless. In 1994, Polly Matzinger, of the U. S. National Institutes of Health, proposed the **danger model,** which hypothesizes that the immune system does more than distinguish between self and nonself. It responds to danger signals from injured tissues, such as proteins released when cell membranes are damaged.

Most immunologists now agree that internal defense relies on a combination of factors, including the ability to identify foreign molecules and to respond to chemical clues from injured tissues. The immune system is a collection of many types of cells

and of tissues scattered throughout the body. Immune responses require communication among cells, or **cell signaling.** Cells of the immune system communicate directly by means of their surface molecules and indirectly by releasing messenger molecules. Understanding the complex signaling systems of the immune system is a major focus of research.

Sometimes pathogens overcome the body's internal defenses, resulting in disease. Some diseases, as well as certain genetic mutations, prevent or compromise immune function. HIV, the retrovirus that causes AIDS, infects T cells, an important component of the immune system (see photograph). The immune system may overfunction, as in allergic reactions, or it may respond in ways that are clinically important, such as in Rh incompatibility or the destruction of the cells of organ transplants. In about 5% of adults in highly developed countries, certain immune responses are directed against self tissues, resulting in autoimmune disease.

Among the greatest accomplishments of immunologists are the development of vaccines that prevent disease, and techniques for successful tissue and organ transplantation. Sophisticated research tools, such as gene transfer, have enabled immunologists to expand their knowledge of the cells and molecules that interact to generate immune responses, and to develop new approaches to the prevention and treatment of disease. Much has been learned, and many challenges lie ahead. ■

NONSPECIFIC AND SPECIFIC IMMUNITY: AN OVERVIEW

Learning Objectives

1. Distinguish between nonspecific and specific immune responses.
2. Compare, in general terms, the immune responses of invertebrates and vertebrates.

An **immune response** is the process of recognizing foreign or dangerous macromolecules and responding to eliminate them. Two main types of immune responses protect the body: nonspecific and specific. **Nonspecific immune responses,** or *innate immunity,* provide general protection against pathogens, parasites, some toxins and drugs, and cancer cells. Nonspecific immune responses prevent most pathogens from entering the body and rapidly destroy those that do penetrate the outer defenses. For example, the cuticle or skin provides a physical barrier to pathogens that come in contact with an animal's body. Phagocytosis, another nonspecific defense, destroys bacteria that invade the body. Some of the molecules important in nonspecific immune responses recognize and attack certain pathogen-associated molecular patterns, which are shared by whole groups of viruses, bacteria, or fungi.

Specific immune responses, also referred to as *adaptive* or *acquired immunity,* are highly specific. Any molecule that cells of the immune system specifically recognize as foreign is called an **antigen.** Proteins are the most powerful antigens, but some polysaccharides and lipids can be antigenic. **Antibodies** are highly specific proteins that recognize and bind to specific antigens. Specific immune responses are directed toward particular antigens and typically include the production of antibodies. In complex animals, an important characteristic of specific immune responses is **immunological memory,** the capacity to respond more effectively the second time foreign molecules invade the body.

Invertebrates launch nonspecific immune responses

All invertebrate species that researchers have studied demonstrate the ability to distinguish between their own cells and those of other species. For example, sponge cells have specific glycoproteins on their surfaces that enable them to recognize their own species. When cells of two different species are mixed together, they reassort according to species. When two different species of sponges are forced to grow in contact with each other, tissue is destroyed along the region of contact. Cnidarians (such as corals), annelids (such as earthworms), arthropods (such as insects), and echinoderms (such as sea stars) reject tissue grafted from other animals, even from the same species.

Invertebrates have very efficient nonspecific immune mechanisms. For example, many invertebrates (cnidarians, annelids, and mollusks) are covered by mucus that traps and kills pathogens. Tough external skeletons, such as shells or cuticles, shield the body of many invertebrates. Most invertebrate coelomates (animals with a coelom) have amoeba-like **phagocytes** that engulf and destroy bacteria and other foreign matter. In mollusks, substances in the hemolymph (blood) enhance phagocytosis.

Researchers have identified **antimicrobial peptides** in all eukaryotes (including plants) that have been studied, suggesting an early common origin of these molecules. More than 800 of these peptides that inactivate or kill pathogens have been described! When researchers inject an antigen into an insect, as many as 15 antimicrobial peptides are produced within a few hours. Antimicrobial peptides are very effective because of their small size (a dozen or fewer amino acids), which facilitates their rapid production and diffusion.

What stimulates an animal to produce antimicrobial peptides and other immune defenses? Animal cells have receptors that recognize certain types of pathogen molecules, and then signal the cell to produce antimicrobial peptides. One important family of these signaling receptors, the *Toll group,* is a focus of current research. Immunologists first identified the Toll group in the fruit fly *Drosophila.* Toll receptors recognize some common molecular features of classes of pathogens called **pathogen-associated molecular patterns,** or **PAMPs.** Examples of PAMPs include the double-stranded RNA of certain viruses and peptidoglycan in Gram-positive bacteria.

Certain cnidarians, arthropods, some echinoderms and simple chordates (such as tunicates) appear to remember antigens for a short period. As mentioned earlier, immunological

memory enables the body to respond more effectively when it encounters the same pathogens again. Although certain invertebrates demonstrate some specificity and memory, their immune responses are primarily nonspecific. Echinoderms and tunicates are the simplest animals known to have differentiated white blood cells that perform limited immune functions.

Vertebrates launch nonspecific and specific immune responses

A specialized lymphatic system, including **lymphocytes,** white blood cells specialized to carry out immune responses, evolved in the vertebrates (see Chapter 42). The lymphatic system performs the sophisticated specific immune responses of vertebrates. In the discussion that follows, we focus on the human immune system, with references to immune mechanisms of other animals (Fig. 43-1).

Review

- What are two key ways in which specific immune responses differ from nonspecific immune responses?
- How do vertebrate immune responses differ from invertebrate responses?

BiologyNow™ Assess your understanding of **nonspecific and specific immunity,** in general by taking the pretest on your BiologyNow CD-ROM.

ACTIVE FIGURE **43-1** **Overview of human immune responses.**

Nonspecific immune responses include physical and chemical barriers that prevent the entrance of pathogens; soluble molecules; phagocytosis; and inflammation. During inflammation, certain cells release cytokines that activate specific immune responses: cell-mediated and antibody-mediated immunity.

BiologyNow™ Watch **the immune system fight a cold** by clicking on this figure on your BiologyNow CD-ROM.

NONSPECIFIC IMMUNE RESPONSES

Learning Objective

3 Describe nonspecific immune responses, including physical and chemical barriers; soluble molecules such as cytokines and the proteins that make up the complement system; phagocytes; natural killer cells; and the inflammatory response.

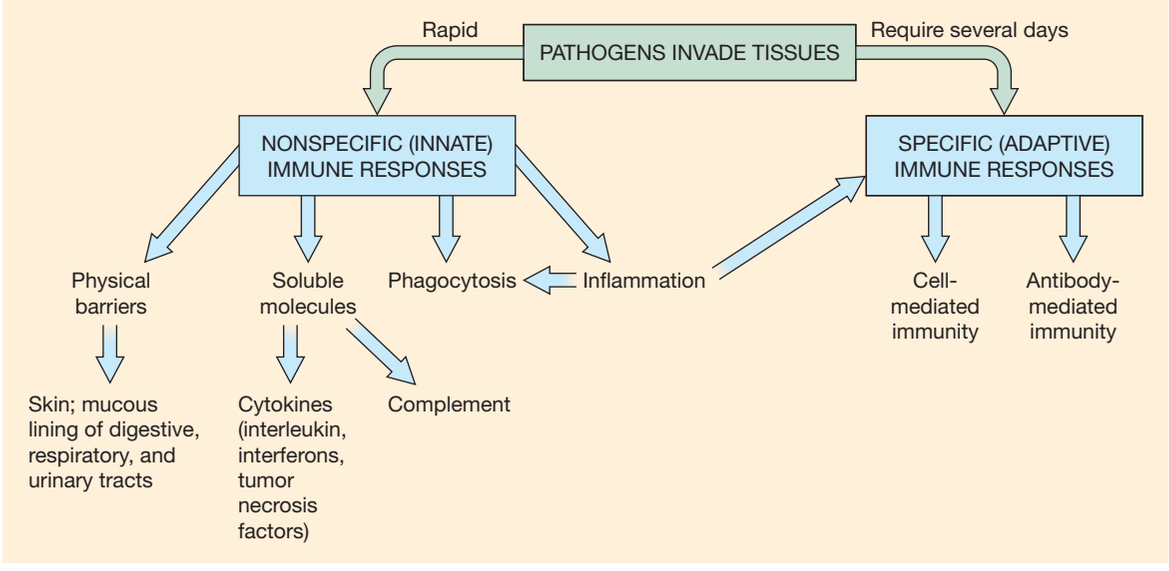
Physical and chemical barriers prevent most pathogens from entering the body. An animal's first line of defense is its outer covering—skin, cuticle, shell, or chitin—which blocks the entry of pathogens. Microorganisms that enter with food are usually destroyed by the acid secretions and enzymes of the stomach, which are effective chemical barriers.

Mucous membranes of the respiratory and reproductive tracts protect passageways that open to the outside of the body. For example, pathogens that enter the body with inhaled air may be filtered out by hairs in the nose or trapped in the sticky mucous lining of the respiratory tract. Once trapped, they are destroyed by phagocytes. Mucus contains a substance called *mucin,* which chemically destroys invaders. **Lysozyme,** an enzyme found in many tissues, as well as in tears and other body fluids, attacks the cell walls of many Gram-positive bacteria.

When pathogens breach the body's outer barriers, their chemical properties activate other nonspecific defense responses, and most invaders are quickly eliminated. In addition to the front-line physical and chemical barriers, nonspecific immune responses involve soluble molecules, phagocytes, and natural killer (NK) cells. The activation and concentration of these molecules and cells produce inflammation, the major nonspecific immune response.

Soluble molecules mediate immune responses

Cells of the immune system secrete a remarkable number of regulatory and antimicrobial peptides and proteins. Two major



groups of soluble molecules in nonspecific defense responses are cytokines and complement.

Cytokines are important signaling molecules

Cytokines are a large group of peptides and proteins (most are glycoproteins) that serve as signals and perform regulatory functions during both nonspecific and specific immune responses. Cytokines help regulate the intensity and duration of immune responses, and they are also important in regulating many other biological processes, such as cell growth, repair, and cell activation. Cytokines can act as *autocrine agents,* affecting the very cells that produce them, or as *paracrine agents* regulating the activity of nearby cells (see Chapter 47). Some cytokines circulate in the blood and affect distant tissues. Biologists name the types of cytokines for their function or origin. We discuss four groups: interferons, interleukins, chemokines, and tumor necrosis factors.

When infected by viruses or other intracellular parasites (some types of bacteria, fungi, and protozoa), cells respond by secreting cytokines called **interferons.** Type I interferons are produced by either macrophages, which are large phagocytic cells, or fibroblasts, cells that produce the fibers of connective tissues. Type I interferons inhibit viral replication and also activate natural killer cells that have antiviral actions. Viruses produced in cells exposed to Type I interferons are not very effective at infecting other cells.

Type II interferons, produced as a specific immune response, also exhibit anti-viral activity, but in addition, they enhance the activities of other immune cells. For example, Type II interferons stimulate macrophages to destroy tumor cells and host cells that have been infected by viruses.

Since their discovery in 1957, interferons have been the focus of a great deal of research. Pharmaceutical companies now use recombinant DNA techniques to produce large quantities of some interferons. The U.S. Food and Drug Administration (FDA) has approved interferons for treating several diseases, including hepatitis B and hepatitis C, genital warts, a type of leukemia, a type of multiple sclerosis, and AIDS-related Kaposi's sarcoma. Researchers are testing interferons in clinical trials for the treatment of HIV infection and several types of cancer.

Interleukins are a diverse group of cytokines secreted mainly by macrophages and lymphocytes. Interleukins are numbered according to their order of discovery. They regulate interactions between lymphocytes and other cells of the body, and some interleukins have widespread effects. For example, during infection *interleukin-1 (IL-1)* can reset the body's thermostat in the hypothalamus, resulting in **fever** and its symptoms. Just as there are overlaps between the functions of nonspecific and specific immune responses, the actions of cytokines of these subsystems also overlap. For example, cytokines produced by nonspecific cells such as macrophages can activate lymphocytes involved in specific immune responses.

Chemokines, a large group of cytokines, are signaling molecules that attract, activate, and direct the movement of various cells of the immune system. Some chemokines are produced in response to infection and are key mediators of the inflammatory response.

Tumor necrosis factors (TNFs) are cytokines secreted by macrophages and by lymphocytes called *T cells.* TNF stimulates immune cells to initiate an inflammatory response. TNF also kills tumor cells, offering promise in terms of immunotherapy for cancer patients. Sometimes infection by Gram-negative bacteria, such as *Salmonella typhi,* results in the release of large amounts of TNF and other cytokines. This results in a cascade of reactions leading to *septic shock,* a potentially fatal condition that may involve high fever and malfunctioning of the circulatory system. Thus cytokines can sometimes have harmful effects.

Complement leads to the destruction of pathogens

Cytokines produced by phagocytes can activate the *complement system.* **Complement,** so named because it "complements" the action of other defensive responses, consists of more than 20 proteins present in plasma and other body fluids. Similarities in complement proteins in many species, including horseshoe crabs, sea urchins, tunicates, and mammals, suggest these molecules evolved millions of years ago and have been conserved.

Normally, complement proteins are inactive until the body is exposed to an antigen. Certain pathogens activate the complement system directly. In other cases, the binding of an antigen and antibody stimulate activation. Complement activation involves a cascade of reactions; each component acts on the next in the series. Proteins of the complement system then work to destroy pathogens.

Complement proteins are activated against many antigens, and their actions are nonspecific: (1) They lyse viruses, bacteria, and other cells; (2) they coat pathogens, making them less "slippery" so that phagocytes (macrophages and neutrophils) phagocytose them more easily; (3) they attract white blood cells to the site of infection (a process called *chemotaxis*); and (4) they bind to specific receptors on cells of the immune system, stimulating specific actions, such as secreting regulatory molecules, and enhancing the inflammatory response.

Phagocytes and natural killer cells destroy pathogens

Neutrophils, the most common type of white blood cell, (see Chapter 42) and macrophages are the main phagocytes in the body. Recall that **phagocytosis** is a type of endocytosis in which cells engulf microorganisms, foreign matter, or other cells (see Fig. 5-18). A neutrophil can phagocytize about 20 bacteria before it becomes inactivated (perhaps by leaking lysosomal enzymes) and dies.

Macrophages are large phagocytes that develop from nongranular white blood cells called *monocytes.* A macrophage can phagocytize about 100 bacteria during its life span. Some macrophages patrol the body's tissues, phagocytizing damaged cells or foreign matter (including bacteria) and, when appropriate, they release antiviral agents (Fig. 43-2). Others stay in one place and destroy bacteria that pass by. For example, air sacs in the lungs contain large numbers of macrophages that destroy foreign matter entering with inhaled air.

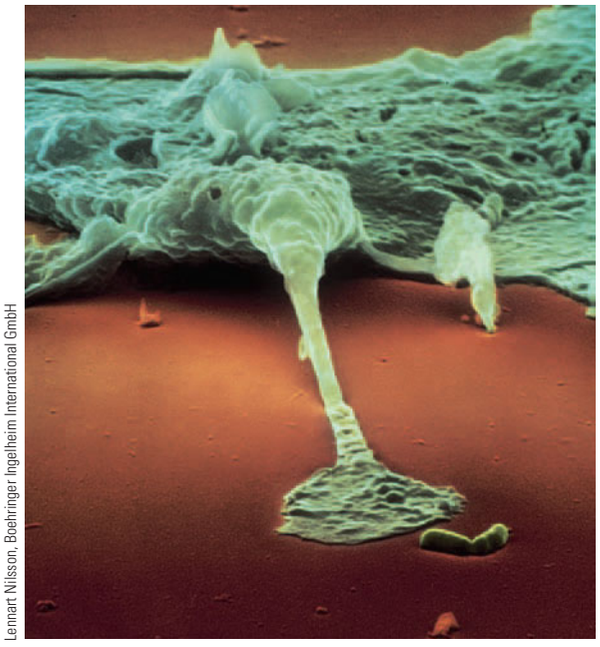


FIGURE **43-2** **Phagocytosis.**

These colorized SEMs show macrophages, which are efficient warriors. **(a)** A macrophage extends a pseudopod toward an invading *E. coli* bacterium that is already multiplying. **(b)** The bacterium is trapped within the engulfing pseudopod. **(c)** The macrophage takes in the trapped bacteria along with its own plasma membrane. The macrophage plasma membrane will seal over the bacteria, and powerful lysosomal enzymes will destroy them.

Vertebrate macrophages have **Toll-like receptors** (a family of receptors related to the Toll receptors of insects) that recognize certain PAMPs and respond by producing cytokines e.g. TNF. For example, when stimulated by a lipopolysaccharide found on Gram-negative bacteria, macrophages release molecules that enhance the inflammatory response.

Can bacteria counteract the phagocyte's attack? Many strategies have evolved in bacteria that protect them from their hosts. *Streptococcus pneumoniae,* for example, has cell walls or capsules that resist the action of the phagocyte's lysosomal enzymes. Other bacteria release enzymes that destroy the lysosomal membranes. The powerful lysosomal enzymes then spill out into the cytoplasm and may destroy the phagocyte. *Listeria monocytogenes* bacteria escape destruction by surviving within phagocytic cells.

Natural killer (NK) cells are large, granular lymphocytes that originate in the bone marrow. They account for about 10% of circulating lymphocytes. NK cells are active against tumor cells and cells infected with some types of viruses. They destroy target cells by both nonspecific and specific (antibody-mediated) processes. NK cells release cytokines, as well as perforins and granzymes, enzymes that destroy target cells. **Perforins** cause pores to form in the plasma membrane of the target cell, allowing granzymes to enter the cell. **Granzymes** then activate a cascade of reactions that cause the cell to self-destruct by **apoptosis,** programmed cell death. Several cytokines stimulate NK cell activity. When NK cell levels are high, resistance to certain cancers may be strengthened. Psychological stressors are thought to decrease NK cell activity and thus enhance tumor growth.

Inflammation is a protective response

The **inflammatory response,** or *inflammation,* begins immediately after pathogen invasion or physical injury (Fig. 43-3). Tissue injury activates a clotting factor in the blood plasma that turns on three different interconnecting molecular cascades in the plasma, including the clotting cascade. The reactions generate molecules—for example, the peptide *bradykinin*—that mediate the inflammatory process. These plasma mediators dilate blood vessels and increase capillary permeability. Inflammation also activates the complement system.

Large numbers of neutrophils migrate into the inflamed tissue within a few hours. These cells secrete cytokines, including chemokines, that are important mediators of the inflammatory response. Macrophages and **mast cells** stationed in the tissues also respond rapidly to damaged tissue or infection. Mast cells release **histamine,** cytokines, and other compounds that dilate blood vessels in the affected area and increase capillary perme-

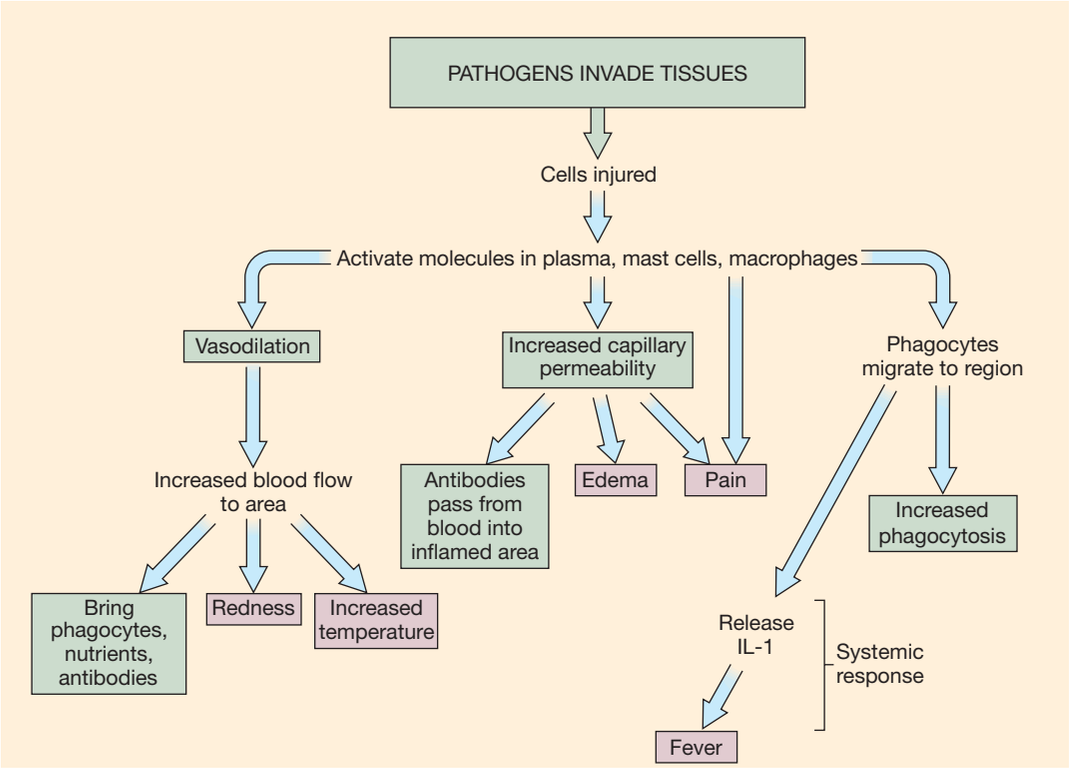

FIGURE **43-3**

The inflammatory response.

ability. Mast cells and macrophages release signaling molecules that attract and activate additional neutrophils. In turn, neutrophils send signals that attract lymphocytes.

The clinical characteristics of inflammation are heat, redness, edema (swelling), and pain. The inflammatory response includes three main processes.

1. *Vasodilation.* Expanded blood vessel diameter brings more blood to the area. The increased blood flow warms the skin and reddens skin that contains little pigment.
2. *Increased capillary permeability.* Fluid and antibodies leave the circulation and enter the tissues. As the volume of interstitial fluid increases, *edema* occurs. The edema, along with the action of certain enzymes in the plasma, cause the pain that characterizes inflammation.
3. *Increased phagocytosis.* Increased blood flow brings large numbers of neutrophils and other phagocytic cells to the infected region. The phagocytes migrate out of the capillaries and into the infected tissues. One of the main functions of inflammation is increased phagocytosis.

Although the inflammatory response begins as a local response, sometimes the entire body becomes involved. Fever, a common clinical symptom of widespread inflammation, helps the body fight infection. Elevated body temperature increases phagocytosis and interferes with the growth and replication of microorganisms. Fever breaks down lysosomes, destroying cells infected by viruses. Fever also promotes the activity of certain lymphocytes. A short-term, low fever speeds recovery.

SPECIFIC IMMUNE RESPONSES

Learning Objectives

4 Distinguish between cell-mediated and antibody-mediated immunity.

5 Describe the principal cells of the immune system, and summarize the function of the major histocompatibility complex.

While nonspecific immune responses are destroying pathogens and preventing the spread of infection, the body is mobilizing its specific immune responses. It takes several days to activate specific immune responses, but once in gear, these mechanisms are extremely effective. As discussed earlier, specific immune responses are precisely targeted to destroy specific antigens, and they have immunological memory. Two types of specific immune responses are cell-mediated and antibody-mediated immunity.

Many types of cells are involved in specific immune responses

The primary types of cells of the immune system are shown in Figure 43-4. Two key cell types that participate in specific immune responses are lymphocytes and antigen-presenting cells. Phagocytes and many other cells important in nonspecific immune responses also participate in specific responses. **Eosinophils**

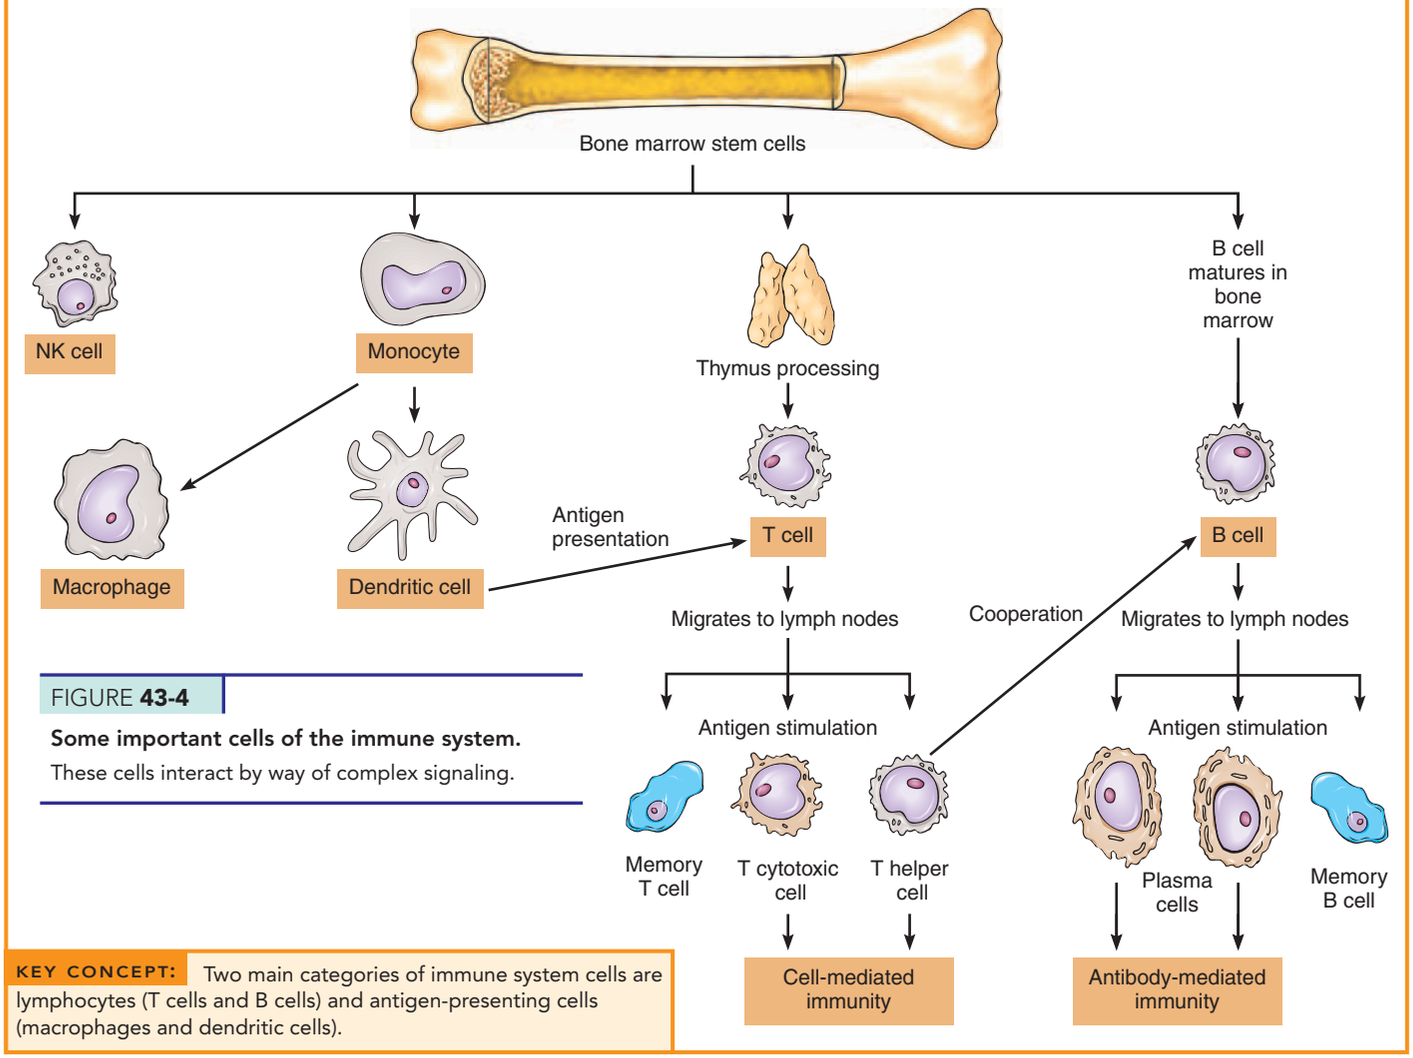

FIGURE **43-4**

Some important cells of the immune system.
These cells interact by way of complex signaling.

KEY CONCEPT: Two main categories of immune system cells are lymphocytes (T cells and B cells) and antigen-presenting cells (macrophages and dendritic cells).

are white blood cells that release toxins from their granules to destroy parasitic worms.

Lymphocytes are the principal warriors in specific immune responses

Three main types of lymphocytes are T lymphocytes, B lymphocytes, and NK cells. As already discussed, NK cells kill virally infected cells and tumor cells. **T lymphocytes,** or **T cells,** are responsible for **cell-mediated immunity.** T cells are the body's cellular soldiers. They travel to the site of infection and attack body cells infected by invading pathogens, as well as foreign cells (such as those introduced in tissue grafts or organ transplants). T cells also destroy cells altered by mutation (cancer cells).

B lymphocytes, or **B cells,** are responsible for **antibody-mediated immunity.** B cells mature into **plasma cells,** which produce specific antibodies. Antibodies bind to specific antigens, neutralizing them or marking them for destruction. Antibody-mediated immunity is one of the body's chief chemical defense strategies.

All lymphocytes develop from stem cells in the bone marrow. B cells complete their development in the adult bone marrow (from which the *B* in their name is derived). T cells mature in the **thymus gland** (from which the *T* in their name derives). Large numbers of mature lymphocytes reside in the secondary lymph organs, including the spleen, lymph nodes, tonsils, and other lymph tissues strategically positioned throughout the body.

Although T and B cells are similar in appearance when viewed with a light microscope, sophisticated techniques such as fluorescence microscopy demonstrate that these cells can be differentiated by their unique cell surface macromolecules. T and B cells have different functions and life histories, and tend to locate in (or "home" to) separate regions of the spleen, lymph nodes, and other lymph tissues.

Millions of B cells are produced in the bone marrow daily. Each B cell is genetically programmed to encode a glycoprotein receptor that binds with a specific type of antigen. When a B cell comes into contact with an antigen that binds to its receptors, it becomes activated. B-cell activation is a complex process that typically requires the participation of a particular type of T cell. Once activated, a B cell divides rapidly, forming a clone of identical cells. The cloned B cells differentiate into plasma cells, which produce antibody, a soluble form of the cell's glycoprotein receptor molecule that can be secreted. A plasma cell can produce more than 10 million molecules of antibody per hour! The antibody binds to the antigen that originally activated the B cells. Some activated

B cells do not become plasma cells, but instead become long-living **memory B cells** that continue to produce small amounts of antibody after the body overcomes an infection.

On their way from the bone marrow to the lymph tissues, T cells are processed in the **thymus gland.** The thymus makes T cells *immunocompetent,* capable of immunological response. As T cells move through the thymus, they divide many times and develop specific surface proteins with distinctive receptor sites. Only the T cells that have specific receptors are selected to divide; this is a form of *positive selection.*

T cells that react to self-antigens undergo apoptosis. This is a form of *negative selection.* Immunologists estimate that more than 90% of developing T cells are negatively selected. The remaining T cells differentiate and leave the thymus to take up residence in other lymph tissues or to launch immune responses in infected tissues. By selecting only appropriate T cells, the thymus gland ensures that T cells can distinguish between the body's own molecules and foreign antigens.

Most T cells in the thymus differentiate just before birth and during the first few months of postnatal life. If the thymus is removed before this processing takes place, an animal does not develop cell-mediated immunity. If the thymus is removed after that time, cell-mediated immunity is less seriously impaired.

T cells are distinguished by the **T-cell receptor (TCR)** which recognizes specific antigens. Two main populations of T cells develop in the thymus: T cytotoxic and T helper cells. **T cytotoxic (T_C) cells** are also known as *CD8 cells* because they have a glycoprotein designated CD8 on their plasma membrane surface. Known less formally as *killer T cells,* T_C cells recognize and destroy cells with foreign antigens on their surfaces. Among their target cells are virus-infected cells, cancer cells, and foreign tissue grafts.

T helper (T_H) cells, also known as *CD4 cells,* have a surface glycoprotein designated CD4. T_H cells are regulatory cells. They secrete cytokines that activate B cells and macrophages. After an infection, both cytotoxic and helper **memory T cells** remain in the body.

Antigen-presenting cells activate T helper cells.

Macrophages, dendritic cells, and B cells function as "professional" **antigen-presenting cells (APCs)** that display foreign antigens as well as their own surface proteins. APCs are inactive until their pattern recognition receptors recognize PAMPs on pathogens. Once activated, an APC ingests the pathogen and lysosomal enzymes degrade most, but not all, of the bacterial antigens. The APC displays fragments of the foreign antigens on its cell surface in association with a type of self-molecule (class II MHC, discussed later). The activated APC expresses additional signaling molecules, called **co-stimulatory molecules,** along with the displayed antigen. APCs present displayed antigens to T cells.

Macrophages secrete more than 100 different compounds, including cytokines and enzymes that destroy bacteria. Macrophages stimulated by bacteria secrete interleukins that activate B cells and certain T cells. Interleukins also promote nonspecific immune responses, such as fever.

Although biologists first identified **dendritic cells** in 1868 and then rediscovered them in 1973, their small numbers made them hard to study until sophisticated techniques became available in the 1990s. Their name derives from their long cytoplasmic extensions known as *dendrites* (not to be confused with the dendrites of neurons). Like macrophages, they develop from monocytes. Dendritic cells are strategically stationed in all tissues of the body that come into contact with the environment—the skin and the linings of the digestive, respiratory, urinary, and vaginal passageways.

When pathogens infect a tissue, dendritic cells are activated by PAMPs and capture the pathogens (or their products) by phagocytosis or by receptor-mediated endocytosis (see Chapter 5). Guided by chemokines expressed in the lymph nodes and lymph vessels, dendritic cells make their way to the lymph nodes. As they migrate, they mature. Mature dendritic cells break down antigens and display the fragments on their cell surface. Co-stimulatory molecules, along with the displayed antigen, attract and activate specific T cells capable of responding to the antigen. Thus dendritic cells are specialized to process, transport, and present antigens to T cells.

The major histocompatibility complex is responsible for recognition of self

The ability of the vertebrate immune system to distinguish self from nonself depends largely on a cluster of closely linked genes known as the **major histocompatibility complex (MHC).** In humans, the MHC is also called the **HLA (human leukocyte antigen) complex.** The MHC genes are polymorphic (variable). Within the population there are multiple alleles, more than 40 for each locus. As a result, the cell surface proteins for which they code are generally different in each individual. With so many possible combinations, no two people, except identical twins, are likely to have all the same MHC proteins on their cells. The more closely related two individuals are, the more MHC genes they have in common. Thus, a person's MHC proteins serve as a biochemical "fingerprint."

The MHC genes encode **MHC antigens,** or self-antigens, that differ in chemical structure, function, and tissue distribution. Class I MHC genes encode glycoproteins expressed on the surface of most nucleated cells. These antigens bind with foreign antigens from viruses or other pathogens within the cell, forming a foreign antigen–class I MHC glycoprotein complex. The cell displays this complex on its surface, and presents it to T_C cells. Thus any infected cell can function as an antigen-presenting cell and can activate certain T_C cells.

Class II MHC genes encode glycoproteins expressed primarily on "professional" APCs—dendritic cells, macrophages, and B cells. These MHC antigens combine with foreign antigen from bacteria, and the cell presents the complex to T_H cells. Class III MHC genes encode many secreted proteins, including components of the complement system and TNFs.

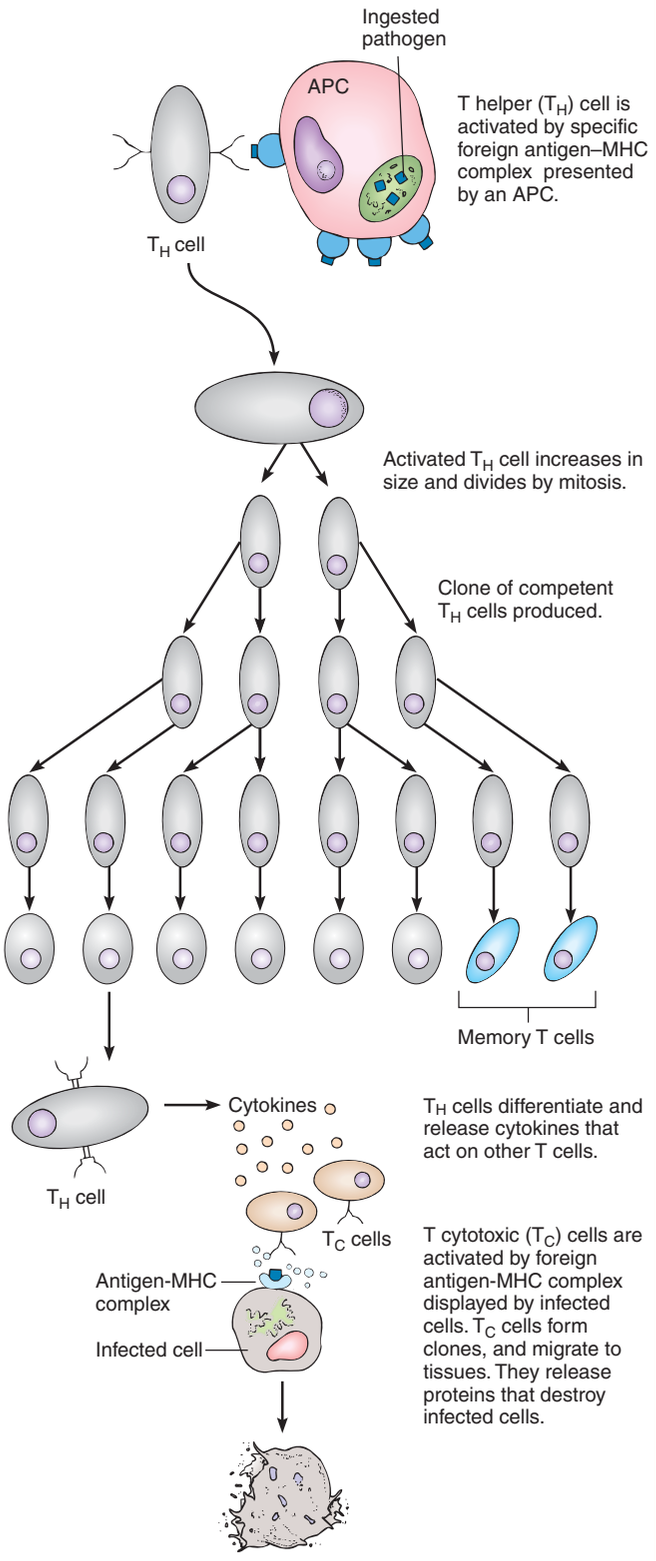
KEY CONCEPT: T cells and APCs are responsible for cell-mediated immunity.



CELL-MEDIATED IMMUNITY

Learning Objective

6 Describe the sequence of events in cell-mediated immunity.

T cells and APCs (mainly dendritic cells and macrophages) are responsible for cell-mediated immunity (Fig. 43-5). T cells destroy cells infected with viruses and cells that have been altered in some way, such as cancer cells. They also destroy the cells of foreign grafts such as a transplanted kidney. There are thousands of different populations of T cells. Each T_C cell expresses the CD8 molecule on its surface, as well as more than 50,000 identical T cell receptors (TCRs) that bind to one specific type of antigen.

How do T cells know which cells to target? T cells do not recognize antigens unless they are presented properly. When a virus (or other pathogen) infects a cell, some of the viral protein is broken down to peptides and displayed with class I MHC molecules on the cell surface. Only T_C cells with receptors that bind to the specific antigen–MHC class I complex become activated. Generally, fewer than 1 in 10,000 T cells have the same antigen specificity and can respond. T_C cell activation requires at least two signals in addition to the presented antigen: a co-stimulatory signal and an interleukin signal.

Once activated, a T_C cell increases in size and gives rise to a clone. Activated T_C cells are the effector cells that make up the cell infantry. They leave the lymph nodes and make their way to the infected area, where they destroy target cells within seconds after contact. When a T_C cell combines with antigen on the surface of the target cell, it destroys it in much the same way that NK cells destroy their target cells. The T_C secretes perforins and granzymes that perforate the plasma membrane of the target cell and induce it to kill itself by apoptosis. After releasing cytotoxic substances, the T cell disengages itself from its victim cell and seeks out a new target. This sequence is summarized as follows:

Virus invades body cell ⟶ infected cell displays foreign antigen–MHC class I antigen complex ⟶ specific T_C cell activated by this complex ⟶ clone of T_C cells produced ⟶ T_C cells migrate to area of infection ⟶ T_C cells release proteins that stimulate destruction of target cells

T_H cells are activated by the foreign antigen–MHC class II antigen complex displayed on the surface of APCs. Once activated, a T_H cell gives rise to a clone of T_H cells. Some T_H cells attract macrophages to the site of infection and promote the destruction of intracellular pathogens. Others function mainly in antibody-mediated immunity.

FIGURE **43-5** **Cell-mediated immunity.**

When activated by a foreign antigen–MHC complex presented by an APC, and by cytokines, a T helper (T_H) cell divides, giving rise to a clone of cells. T cytotoxic (T_C) cells are activated by antigens presented on the surfaces of infected cells. T_C cells also form a clone. Both types of T cells migrate to the site of infection, and T_C cells release proteins that destroy invading pathogens.

ANTIBODY-MEDIATED IMMUNITY

Learning Objectives

7 Summarize the sequence of events in antibody-mediated immunity, including the effects of antigen-antibody complexes on pathogens.

8 Describe the basic structure and function of an antibody, and explain the basis of antibody diversity.

B cells are responsible for antibody-mediated immunity (also called *humoral immunity*). A given B cell can produce many copies of one specific antibody. Antibody molecules serve as cell surface receptors that combine with antigens. Only a B cell displaying a matching receptor on its surface can bind a particular antigen. Inside the B cell, the antigen is degraded into peptide fragments. The B cell then displays the peptide fragments together with MHC protein class II on its surface.

In most cases, the activation of B cells is a complex process that involves APCs and T_H cells (Fig. 43-6). T_H cells stimulate B cells to divide and produce antibodies. However, the T_H cell itself must first be activated. T_H cells do not recognize an antigen that is presented alone. The antigen must be presented as part of a foreign antigen–class II MHC complex on the surface of an APC. When an APC displaying a foreign antigen–MHC complex contacts a T_H cell with complementary T cell receptors, a complicated interaction occurs. Multiple chemical signals are sent back and forth between cells. For example, the APC secretes interleukins, such as IL-1, that activate T_H cells.

B cells serve as APCs to T cells. An activated T_H cell binds with the foreign antigen–MHC complex on the B cell. The T_H cell then releases interleukins, which, together with antigen, activate the B cell.

Once activated, a B cell increases in size, and then divides by mitosis, giving rise to a clone of identical cells (Fig. 43-7). This cell division in response to a specific antigen is known as *clonal selection* (discussed later). The cloned B cells mature into plasma cells that secrete antibodies specific to the antigen that activated the original B cell. It is important to remember that the specificity of the clone is determined *before* the B cell encounters the antigen.

Unlike T cells, most plasma cells do not leave the lymph nodes. Only the antibodies they secrete pass out of the lymph tissues and make their way via the lymph and blood to the infected area. This sequence can be summarized as follows:

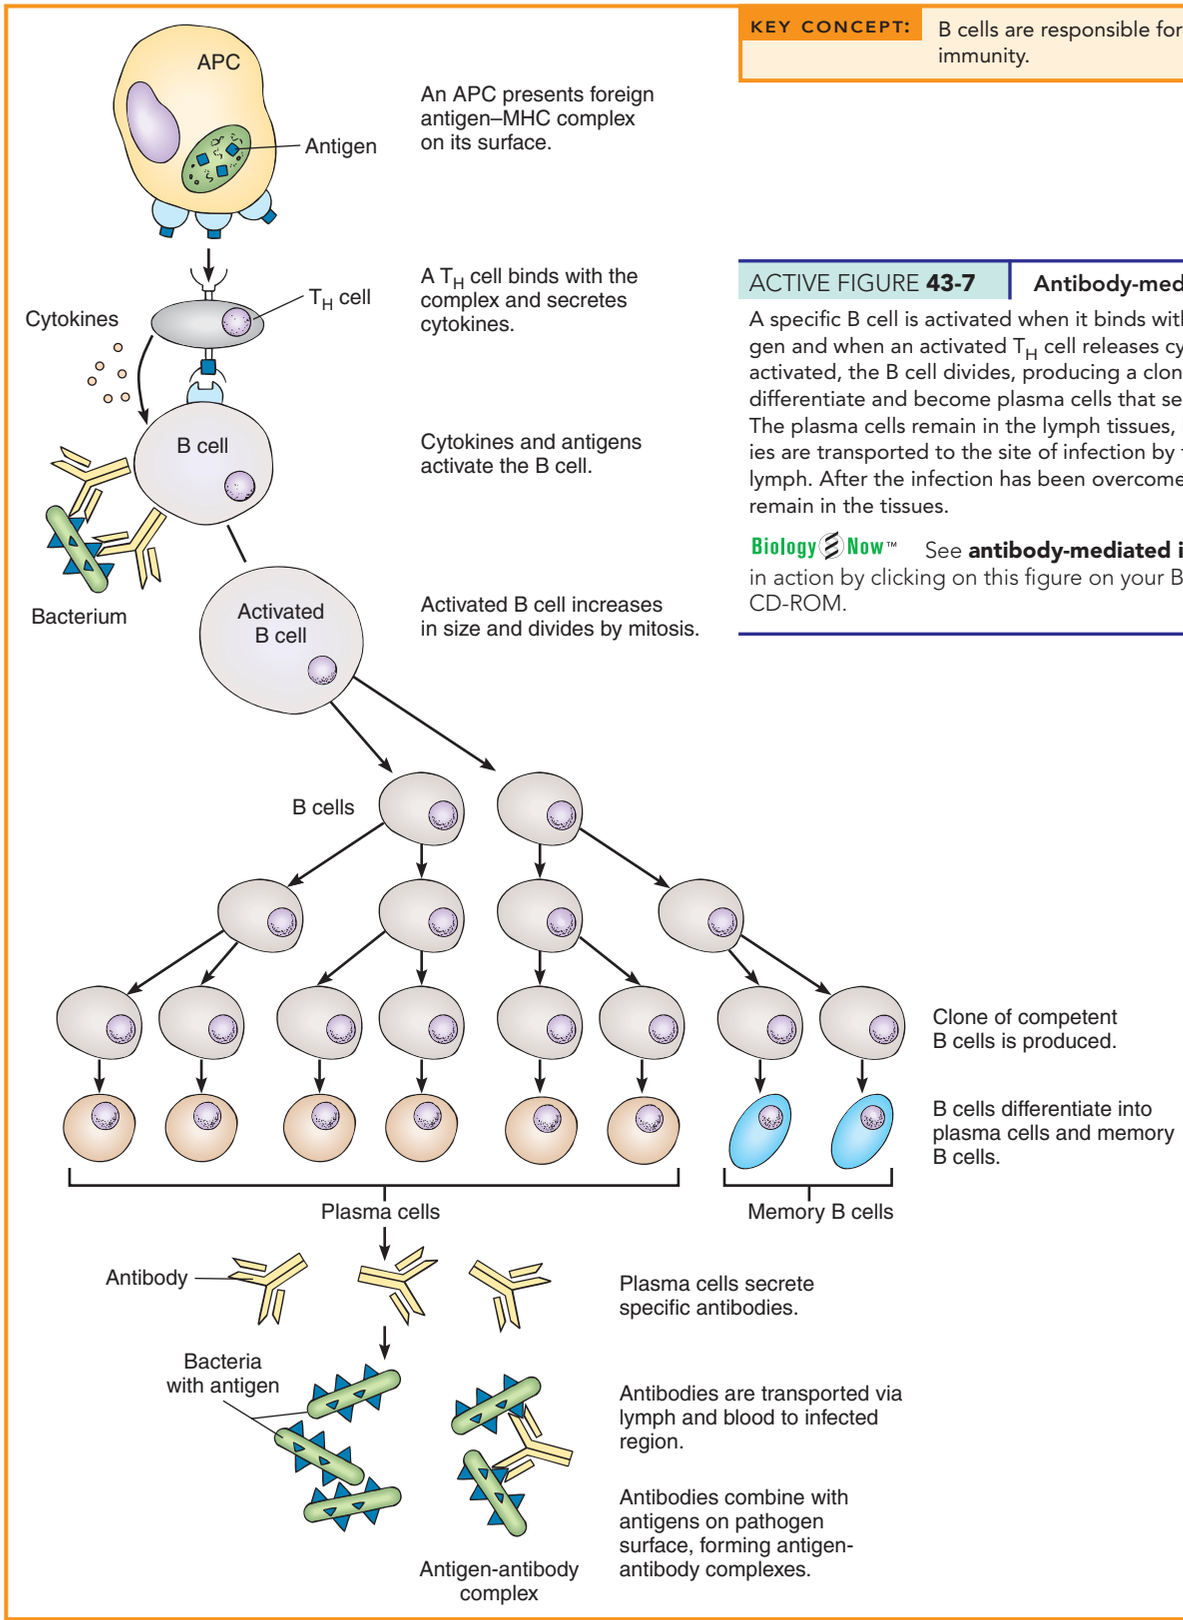
FIGURE **43-6** **B-cell activation.**

(a) An antigen-presenting cell (APC) takes in a bacterium, breaks it down, and presents foreign antigens on its surface in combination with MHC class II antigens. B cells can combine with foreign antigens on infected cells, but they are typically not active until stimulated by T helper (T_H) cells. **(b)** T_H cells are activated when their receptors combine with foreign antigen–MHC antigen complexes on an APC. Complex signaling takes place via cytokines secreted by both cells. **(c)** The activated T_H cell secretes cytokines that activate a B cell that has interacted with foreign antigen. The B cell then divides, forming a clone of identical B cells.

Pathogen invades body ⟶ APC phagocytizes pathogen ⟶ foreign antigen–MHC complex displayed on APC surface ⟶ T_H cell binds with foreign antigen–MHC complex ⟶ activated T_H cell interacts with a B cell that displays the same antigen

⟶ B cell activated ⟶ clone of B cells ⟶ B cells differentiate, becoming plasma cells ⟶ plasma cells secrete antibodies ⟶ antibodies form complexes with pathogen ⟶ destroy pathogen

KEY CONCEPT: B cells are responsible for antibody-mediated immunity.



ACTIVE FIGURE **43-7** **Antibody-mediated immunity.**

A specific B cell is activated when it binds with a specific antigen and when an activated T_H cell releases cytokines. Once activated, the B cell divides, producing a clone. These cells differentiate and become plasma cells that secrete antibodies. The plasma cells remain in the lymph tissues, but the antibodies are transported to the site of infection by the blood or lymph. After the infection has been overcome, memory B cells remain in the tissues.

Biology Now™ See **antibody-mediated immunity** in action by clicking on this figure on your BiologyNow CD-ROM.

Some activated B cells do not differentiate into plasma cells but instead become memory B cells (discussed in a later section).

A typical antibody consists of four polypeptide chains

An antibody molecule, also called **immunoglobulin (Ig),** has two main functions: It combines with antigen, and it activates processes that destroy the antigen that binds to it. For example, an antibody may stimulate phagocytosis. Note that an antibody does not destroy an antigen directly; rather, it *labels* the antigen for destruction.

PROCESS OF SCIENCE

The basic structure of the immunoglobulin molecule was clarified by Rodney Porter, of the University of Oxford in England, and Gerald Edelman, of Rockefeller University in New York, during the 1960s. Porter used the plant enzyme papain, a protease, to split Ig molecules into fragments. Based on his findings, Porter developed a working model of the structure of the Ig molecule and was the first to suggest that it is Y-shaped. These researchers then constructed an accurate model of the antibody molecule. Porter and Edelman won the 1972 Nobel Prize in Medicine for their contributions.

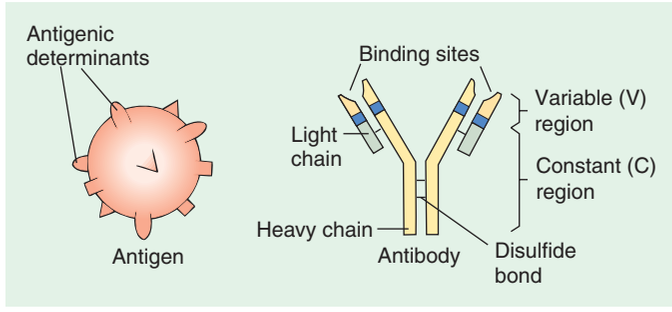
Two fragments of the antibody molecule bind antigen and are referred to as *Fab fragments* (*Fab* stands for *antigen-binding fragment*). The fragment that interacts with cells of the immune system is the *Fc fragment* (*c* indicates that this fragment crystallizes during cold storage). Many cells of the immune system have Fc receptors.

A typical antibody is a Y-shaped molecule in which the two arms of the Y (the Fab portions) bind with antigen (Fig. 43-8). This shape enables the antibody to combine with two antigen molecules and allows the formation of **antigen-antibody complexes.** While the arms of the Y bind to antigen, the tail of the Y, the Fc portion, interacts with cells of the immune system, such as phagocytes, or binds with molecules of the complement system.

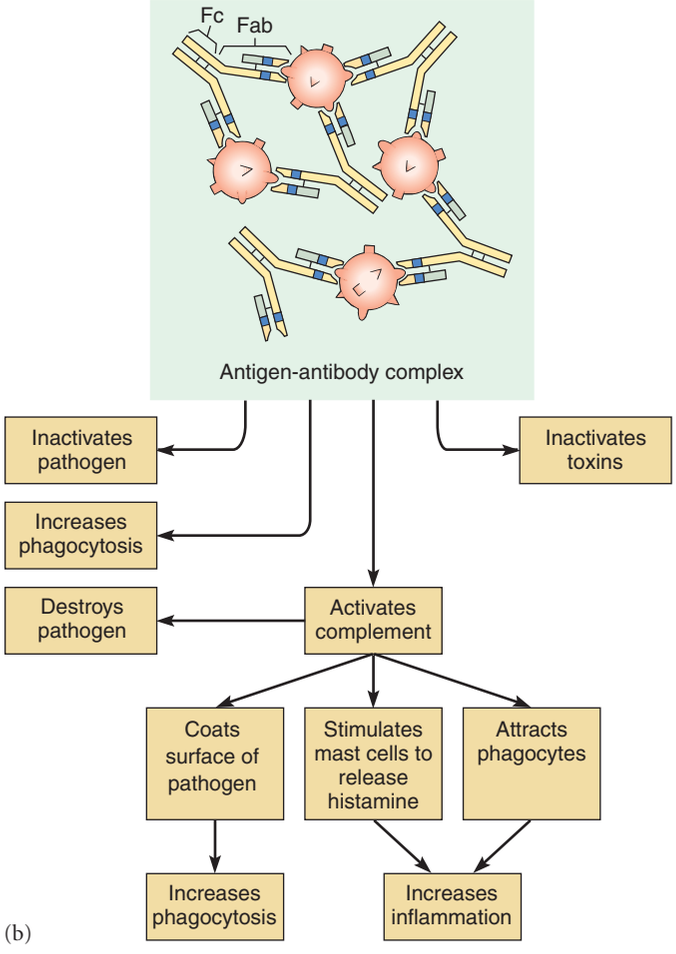
The antibody molecule consists of four polypeptide chains: two identical long chains called *heavy chains,* and two identical short chains called *light chains.* Each chain has a constant region and a variable region. In the **constant (C) region,** of the heavy chains, the amino acid sequence is constant within a particular immunoglobulin class. You can think of the C region as the handle portion of a door key. Like the pattern of bumps and notches at the part of a key that slides into a lock, the **variable (V) region,** has a unique amino acid sequence. The variable region of the immunoglobulin extends outward from the B cell, whereas the constant region anchors the molecule to the B cell.

At its variable regions, the antibody folds three-dimensionally, assuming a shape that enables it to combine with a specific antigen. When they meet, antigen and antibody fit together somewhat like a lock and key. They must fit in just the right way for the antibody to be effective (Fig. 43-9). A given antibody can bind with different strengths, or *affinities,* to different antigens. In the course of an immune response, higher-affinity antibodies are generated.

In an antigen, specific sequences of amino acids make up an **antigenic determinant,** or *epitope.* These sequences give part of the antigen molecule a specific shape that is recognized by an antibody or T cell receptor. Usually, an antigen has many different antigenic determinants on its surface; some have hundreds.



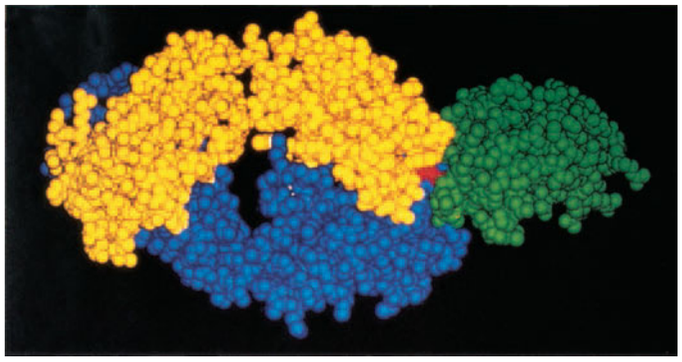
(a)



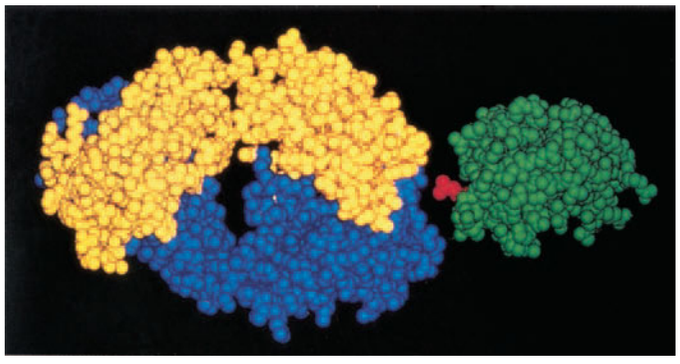
(b)

FIGURE **43-8** **Antibody structure and function.**

Antibodies combine with antigens, forming antigen-antibody complexes. **(a)** The antibody molecule is composed of two light chains and two heavy chains, joined by disulfide bonds. The constant (C) and variable (V) regions of the chains are labeled. **(b)** The Fab portion of the antibody binds to antigen. The Fc portion of the molecule binds to a cell of the immune system. Antigen-antibody complexes directly inactivate pathogens and increase phagocytosis. They also activate the complement system.



(a)



(b)

FIGURE **43-9** **An antigen-antibody complex.**

The components of an antigen-antibody complex fit together as shown in this computer simulation of their molecular structure. The antigen lysozyme is shown in green, the heavy chain of the antibody is shown in blue, and the light chain is shown in yellow. **(a)** A portion of the antigenic determinant, shown in red, fits into a groove in the antibody molecule. **(b)** The antigen-antibody complex has been pulled apart to show its structure.

Antigenic determinants often differ from one another, so several different kinds of antibodies can combine with a single antigen.

Antibodies are grouped in five classes

Antibodies are grouped in five classes, defined by unique amino acid sequences in the C regions of the heavy chains. Using the abbreviation *Ig* for *immunoglobulin,* the classes are designated IgG, IgM, IgA, IgD, and IgE. In humans, about 75% of the circulating antibodies belong to the **IgG** class; these are part of the gamma globulin fraction of the plasma. IgG and **IgM** interact with macrophages and activate the complement system. They defend against many pathogens carried in the blood, including bacteria, viruses, and some fungi. **IgA,** present in mucus, tears, saliva, and breast milk, prevents viruses and bacteria from attaching to epithelial surfaces. This immunoglobulin, which defends against inhaled or ingested pathogens, is strategically secreted into the respiratory, digestive, urinary, and reproductive tracts.

IgD has a low concentration (less than 1%) in plasma. Along with IgM, it is an important immunoglobulin on the B-cell surface. IgD helps activate B cells following antigen binding. **IgE,** which has an even lower plasma concentration, binds to mast cells, which contain potent signaling molecules such as histamine. When an antigen binds to IgE on a mast cell, these molecules are released. Histamine triggers many allergy symptoms, including inflammation. IgE is also responsible for an immune response to invading parasitic worms.

Antigen–antibody binding activates other defenses

Antibodies mark a pathogen as foreign by combining with an antigen on its surface. Generally, several antibodies bind with several antigens, creating a mass of clumped antigen-antibody complexes. The combination of antigen and antibody activates several defensive responses:

(1) The antigen-antibody complex may inactivate the pathogen or its toxin. For example, when an antibody attaches to its surface, a virus may lose the ability to attach to a host cell. Snake venom antitoxin contains antibodies that neutralize the toxins that enter the body with poisonous snake bites.

(2) The antigen-antibody complex stimulates phagocytic cells to ingest the pathogen.

(3) Antibodies of the IgG and IgM groups work mainly through the complement system. When antibodies combine with a specific antigen on a pathogen, complement proteins destroy the pathogen. IgG molecules have an Fc fragment that binds Fc receptors, expressed on most immune cells. When an antibody molecule is bound to a pathogen and the Fc portion of the antibody binds with an Fc receptor on a phagocyte, the pathogen is more easily destroyed.

The immune system responds to millions of different antigens

PROCESS OF SCIENCE

How can the immune system recognize every possible antigen, even those produced by newly mutated viruses never before encountered during the evolution of our species?

In the 1950s, the Danish researcher Niels Jerne of the Basel Institute for Immunology in Basel, Switzerland, David Talmage of the University of Chicago, and Frank Macfarlane Burnet of the Walter and Eliza Hall Institute for Medical Research in Melbourne, Australia, developed the **clonal selection** hypothesis, which proposes that before a lymphocyte ever encounters an antigen, the lymphocyte has specific receptors for that antigen on its surface. (Jerne and Burnet later won Nobel prizes in Medicine for their work in immunology). When an antigen binds to a matching receptor on a lymphocyte, it activates the lymphocyte, which then gives rise to a clone of cells with identical receptors. A major problem with this hypothesis was its suggestion that our cells must contain millions of separate antibody genes, each coding for an antibody with a different specificity. Although each human cell has a large amount of DNA, it is not enough to provide a different gene to code for each of the millions of possible specific antibody molecules.

In 1965 W. J. Dreyer of the Institute of Biochemistry at the University of Zurich, Switzerland, and Joe Claude Bennett of the University of Alabama at Birmingham, suggested that the C region and the V region of an immunoglobulin are encoded by two separate genes. Their hypothesis was at first rejected by many biologists because it contradicted the prevailing hypothesis that one gene codes for one polypeptide. The technology needed to test Dreyer and Bennett's hypothesis was not immediately available, and it was not until 1976 that Susumu Tonegawa, of the Massachusetts Institute of Technology, and his colleagues demonstrated that separate genes encode the V and C regions of immunoglobulins. Tonegawa further showed that three separate families of genes code for immunoglobulins and that each gene family contains a large number of DNA segments that code for V regions. Recombination of these DNA segments during the differentiation of B cells is responsible for antibody diversity. Tonegawa was awarded the 1987 Nobel Prize in Physiology or Medicine for his work, which transformed the emerging science of immunology.

We now understand that in undifferentiated B cells, gene segments are present for a number of different V regions, for one or more junction (J) regions, and for one or more different C regions (Fig. 43-10). Rearrangement of these DNA segments produces an enormous number of potential combinations! Millions of different types of B (and T) cells are produced. By chance, one of those cells may produce just the right antibody to destroy a pathogen that invades the body. To appreciate the capacity for antibody diversity, consider the diverse combinations of things you create in your everyday life. A familiar example is making an ice cream sundae. Imagine the varied combinations that are possible using 10 flavors of ice cream, six types of sauce, and 15 kinds of toppings.

Researchers have identified additional sources of antibody diversity. For example, the DNA of the mature B cells that codes for the regions of immunoglobulins mutates very readily. These somatic mutations produce genes that code for slightly different antibodies.

We have used antibody diversity here as an example, but similar genetic mechanisms account for the diversity of T cell receptors. Although we may actually use only a relatively few types of antibodies or T cells in a lifetime, the remarkable diversity of the immune system prepares it to attack most potentially harmful antigens that may invade the body.

Monoclonal antibodies are highly specific

PROCESS OF SCIENCE

Before 1975, the only method for obtaining antibodies for medicine or research was immunizing animals and collecting their

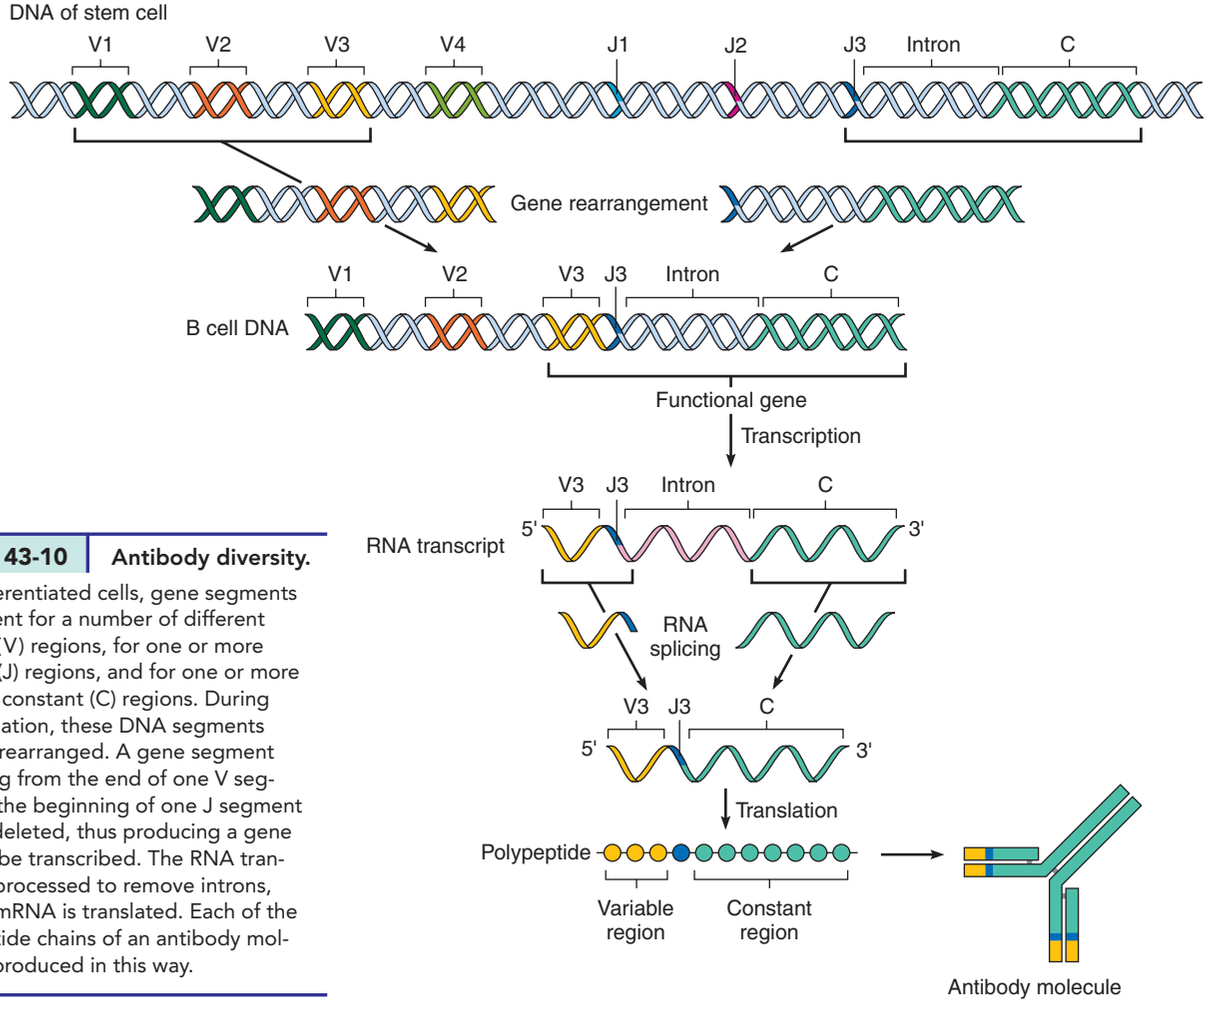


FIGURE **43-10** **Antibody diversity.**

In undifferentiated cells, gene segments are present for a number of different variable (V) regions, for one or more junction (J) regions, and for one or more different constant (C) regions. During differentiation, these DNA segments become rearranged. A gene segment extending from the end of one V segment to the beginning of one J segment may be deleted, thus producing a gene that can be transcribed. The RNA transcript is processed to remove introns, and the mRNA is translated. Each of the polypeptide chains of an antibody molecule is produced in this way.

blood. Then Cesar Milstein and Georges Kohler at the Laboratory of Molecular Biology in Cambridge, England, developed **monoclonal antibodies,** identical antibodies produced by cells cloned from a single cell.

One way to produce monoclonal antibodies in the laboratory is to inject mice with the antigen of interest, for example, an antigen from a particular bacterium. After the mice have produced antibodies to the antigen, their B cells are collected. However, these normal cells survive in culture for only a few generations, limiting the amount of antibody that can be produced. In contrast, cancer cells live and divide in tissue culture indefinitely. The B cells are suspended in a culture medium together with lymphoma cells from other mice. (Lymphoma is cancer of lymphocytes.) Then the B cells and lymphoma cells are induced to fuse. They form hybrid cells, known as **hybridomas,** which have properties of the two "parent" cells. Hybridomas can be cultured indefinitely (a cancer cell property) and continue to secrete antibodies (a B cell property).

Researchers select hybrid cells that are manufacturing the specific antibody needed and then clone them in a separate cell culture. Cells of this clone secrete large amounts of the particular antibody—thus the name *monoclonal antibodies.* Each type of monoclonal antibody is specific for a single antigenic determinant.

Immunologists also use recombinant DNA technology to produce monoclonal antibodies. Because of their purity and specificity, monoclonal antibodies have proved to be invaluable tools in modern biology. For example, a researcher may want to detect a specific molecule present in very small amounts in a mixture. The reaction of that molecule (the antigen) with a specific monoclonal antibody makes its presence known. Monoclonal antibodies are used in similar ways in various diagnostic tests. For example, home pregnancy tests make use of a monoclonal antibody that is specific for human chorionic gonadotropin (hCG), a hormone produced by a developing human embryo (see Chapters 48 and 49). Several monoclonal antibodies are being used clinically to treat cancer. For example, the drug herceptin is a monoclonal antibody used in treating a form of breast cancer.

IMMUNOLOGICAL MEMORY

Learning Objectives

9 Describe the basis of immunological memory; contrast secondary and primary immune responses.

10 Compare active and passive immunity, giving examples of each.

Memory B and memory T cells are responsible for long-term immunity. Following an immune response, memory T cells group strategically in many nonlymphatic tissues, including the lung, liver, kidney, and intestine. Many infections occur at such sites, and T cells stationed in those locations can respond quickly. In response to antigen, memory T cells rapidly become T_C cells that produce substances that kill invading cells.

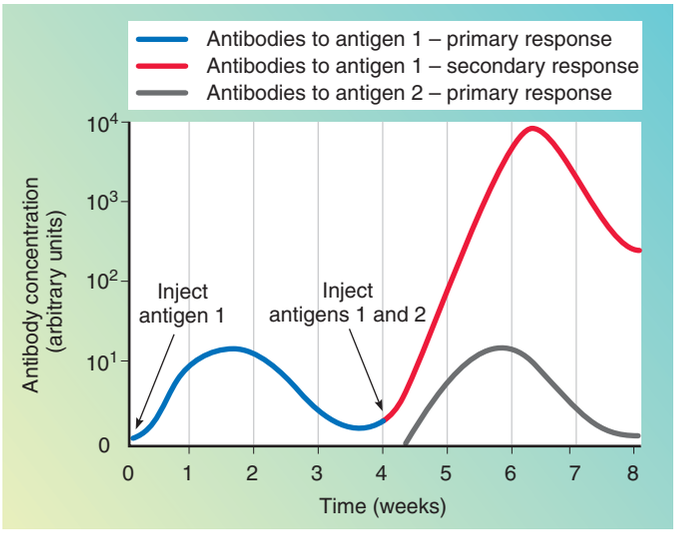
Memory B cells have a "survival gene" that prevents apoptosis, the programmed cell death that is the eventual fate of plasma cells. Memory B cells continue to live and produce small amounts of antibody long after the body has overcome an infection. This circulating antibody is part of the body's arsenal of chemical weapons. If the same pathogen enters the body again, the antibody immediately targets it for destruction. At the same time, specific memory cells are stimulated to divide, producing new clones of plasma cells that produce the same antibody. The presence of circulating antibodies is used clinically to detect previous exposure to specific pathogens. For example, some HIV screening tests measure antibody to the virus that causes AIDS.

A secondary immune response is more effective than a primary response

The first exposure to an antigen stimulates a **primary immune response.** An infection, or an antigen injected into an animal causes specific antibodies to appear in the blood plasma in 3 to 14 days. After antigen injection, there is a brief *latent period* during which the antigen is recognized and appropriate lymphocytes begin to form clones. A *logarithmic phase* follows, during which the antibody concentration rises rapidly for several days

FIGURE **43-11** **Immunological memory.**

Antigen 1 was injected at day 0, and the immune response was assessed by measuring antibody levels to the antigen. At week 4, the primary immune response had subsided. Antigen 1 was injected again, together with a new protein, antigen 2. The secondary immune response was greater and more rapid than the primary response. It was also specific to antigen 1. A primary immune response was made to the newly encountered antigen 2.



until it reaches a peak (Fig. 43-11). IgM is the principal antibody synthesized during the primary immune response. Finally, there is a *decline phase,* during which the antibody concentration decreases to a very low level.

A second exposure to (for example, by injection) of the same antigen, even years later, results in a **secondary immune response.** Because memory B cells bearing antibodies to that antigen (and also memory T cells) persist for many years, the secondary immune response is much more rapid than the primary immune response, with a shorter latent period. Much less antigen is necessary to stimulate a secondary immune response than a primary response, and more antibodies are produced. In addition, the affinity of antibodies is generally much higher. The predominant antibody in a secondary immune response is IgG.

The body's ability to launch a rapid, effective response during a second encounter with an antigen explains why we do not usually suffer from the same infectious disease several times. For example, most people contract measles or chickenpox only once. When exposed a second time, the immune system responds quickly, destroying the pathogens before they have time to multiply and cause symptoms of the disease. Booster shots of vaccine are given to elicit a secondary immune response, thus reinforcing immunological memory.

You may wonder, then, how a person can get influenza (the flu) or a cold more than once. The reason is that there are many varieties of these viral diseases, each caused by a virus with slightly different antigens. For example, more than 100 different viruses cause the common cold, and new varieties of cold and flu viruses evolve continuously by mutation (a survival mechanism for them), which may result in changes in their surface antigens. Even a slight change may prevent recognition by memory cells. Because the immune system is so specific, each different antigen is treated by the body as a new immunological challenge.

Immunization induces active immunity

We have been considering **active immunity,** immunity that develops following exposure to antigens. Active immunity can be naturally or artificially induced (Table 43-1). If someone with chickenpox sneezes near you and you contract the disease, you develop active immunity naturally. Active immunity can also be artificially induced by **immunization,** that is, by exposure to a *vaccine.* When an effective vaccine is introduced into the body, the immune system actively develops clones of cells, produces antibodies, and develops memory cells.

PROCESS OF SCIENCE

The first vaccine was prepared in 1796 by British physician Edward Jenner against vaccinia, the cowpox virus. The term *vaccination* was thus derived. Jenner's vaccine provided humans with immunity against the deadly disease smallpox. Jenner had no knowledge of microorganisms or of immunology, and it remained for French chemist Louis Pasteur to begin to develop scientific methods for preparing vaccines 100 years later. Pasteur showed that inoculations with preparations of attenuated (weakened) pathogens could be used to develop immunity against the virulent (infectious) form of the pathogen. However, not until 20th century advances in immunology—for example, Burnet's clonal selection theory in 1957 and the discovery of T and B cells in 1965—did scientists gain a modern understanding of vaccines. Effective vaccination stimulates the body to launch an immune response against the antigens contained in the vaccine. Memory cells develop, and future encounters with the same pathogen are dealt with rapidly.

Microbiologists prepare effective vaccines in a number of ways. They can attenuate a pathogen so it loses its ability to cause disease. When pathogens are cultured for long periods in nonhuman cells, mutations adapt the pathogen to the nonhuman host so that they no longer cause disease in humans. This is how the Sabin polio vaccine and the measles vaccine are produced.

Whooping cough and typhoid fever vaccines are made from killed pathogens that still have the necessary antigens to stimulate an immune response. Tetanus and botulism vaccines are made from toxins secreted by the respective pathogens. The toxin is altered so that it can no longer destroy tissues, but its antigenic determinants are still intact.

Most vaccines consist of the entire pathogen, attenuated or killed, or of a protein from the pathogen. Researchers are investigating several approaches that would reduce potential side effects. For example, they are developing **DNA vaccines** (or RNA vaccines), made from a part of the pathogen's genetic material. The DNA of the pathogen is altered so that it transfers genes that specify antigens. When injected into a patient, the altered DNA is taken up by cells and makes its way to the nucleus. The encoded antigens are manufactured and stimulate both cell-mediated and antibody-mediated immunity. Several DNA vaccines, including vaccines to prevent and treat HIV infection, are in clinical trials.

TABLE **43-1** Active and Passive Immunity

Type of Immunity	When Developed	Development of Memory Cells	Duration of Immunity
Active			
Naturally induced	After pathogens enter the body through natural encounters (e.g., a person with measles sneezes on you)	Yes	Many years
Artificially induced	After immunization with a vaccine	Yes	Many years
Passive			
Naturally induced	After transfer of antibodies from mother to developing baby	No	Few months
Artificially induced	After injection with gamma globulin	No	Few months

Passive immunity is borrowed immunity

To provide **passive immunity,** physicians inject people with antibodies actively produced by another organism. The serum or gamma globulin that contains these antibodies is obtained from humans or other animals. Nonhuman serums are less desirable, because nonhuman proteins can act as antigens, stimulating an immune response that may result in serum sickness.

Passive immunity is borrowed immunity. Its effects are temporary whether it is artificially or naturally induced (see Table 43-1). Physicians use artificially induced passive immunity to boost the body's defenses temporarily against a particular disease. For example, when exposed to hepatitis A, a form of viral hepatitis spread through contaminated food or water, people at risk of infection are injected with gamma globulin containing antibodies to the hepatitis pathogen. However, gamma globulin injections offer protection for only a few weeks. Because the body has not actively launched an immune response, it has no memory cells and cannot produce antibodies to the pathogen. Once the injected antibodies are broken down, the immunity disappears.

Pregnant women confer naturally induced passive immunity on their developing babies by manufacturing antibodies for them. These maternal antibodies, of the IgG class, pass through the placenta (the organ of exchange between mother and developing fetus) and provide the fetus and newborn infant with a defense system until its own immune system matures. Babies who are breast-fed continue to receive immunoglobulins, particularly IgA, in their milk.

Review

- A playmate in kindergarten exposes John and Jack to measles. John has been immunized against measles, but Jack has not received the measles vaccine. How are their immune responses different? Five years later, John and Jack are playing together when Judy, who has just been diagnosed with measles, sneezes on both of them. Compare their immune responses.
- Why is passive immunity temporary?

THE IMMUNE SYSTEM AND DISEASE

Learning Objective

11 Describe the body's response to cancer cells and HIV.

The immune system is generally very effective in defending the body against invading pathogens. However, many factors can impair immune function, including genetic mutations, malnutrition, sleep deprivation, pre-existing disease, stress, and virulent pathogens.

Cancer cells evade the immune system

Cancer is now the second leading cause of death in Western countries. An estimated one person in three in the United States will develop cancer, and one in five will die of cancer. We have discussed cancer in several previous chapters, including Chapters 16 and 37. Here we focus on the interaction between cancer cells and cells of the immune system, and on new treatment strategies based on immune mechanisms.

Cancer cells are body cells that have been transformed in a way that alters their normal growth-regulating mechanisms. Every day, a few normal cells may be transformed into precancer cells in each of us in response to the sun's UV rays, x-rays, certain viruses, chemical carcinogens in the environment, and yet unknown factors. How does the immune system respond? And why is immune response sometimes ineffective?

Human T cells recognize two main groups of cancer cell antigens: tumor-specific antigens and tumor-associated antigens. *Tumor-specific antigens* are unique to cancer cells. They are induced by certain viruses, and by chemical and physical carcinogens, such as ultraviolet light. Most cancer antigens are *tumor-associated antigens,* which are not unique to cancer cells; normal cells express them during fetal development. Some tumor-associated antigens are not expressed after birth, whereas others are expressed at very low levels. High levels stimulate the immune system. Researchers have shown that oncogenes encode tumor-associated antigens (see Chapter 16).

Antigens on cancer cells induce both cell-mediated and antibody-mediated immune responses. NK cells and macrophages destroy cancer cells. Macrophages produce cytokines, including TNFs (tumor necrosis factors) that inhibit tumor growth.

Dendritic cells present antigens to T cells, stimulating them to produce interferons, which have an antitumor effect. T_C cells attack cancer cells directly, and also produce interleukins, which attract and activate macrophages and NK cells (Fig. 43-12).

Sometimes cancer cells evade the immune system and multiply unchecked. Some types of cancer cells can block T_C cells. Others dramatically decrease their expression of class I MHC molecules. Recall that T_C cells only recognize antigen associated with class I MHC, so a low level of these molecules prevents tumor destruction. Some cancer cells do not produce costimulatory molecules needed to activate T_C cells.

Conventional cancer treatments such as chemotherapy and radiation destroy normal cells as well as cancer cells. To treat cancer effectively, treatment strategies must be more specific, or even customized to the particular cancer. For example, cancer researchers are genetically engineering cancer cells to secrete cytokines that would stimulate the patient's immune response.

A few new cancer drugs, such as Herceptin, are monoclonal antibodies. Herceptin binds with a growth-factor receptor that is present in excessive numbers on the cells of about 30% of metastatic breast cancers. Herceptin blocks the growth factors that would stimulate proliferation of the cells.

More than 50 *angiogenesis inhibitors* are currently being tested. These drugs inhibit the development of blood vessels tumors need, and although these inhibitors do not cure cancer, they slow its growth.

Researchers are developing vaccines that stimulate a cell-mediated immune response tumor-associated antigens. These vaccines differ from traditional vaccines that are used to destroy pathogens *before* they cause disease. Several research groups are experimenting with cancer vaccines made from dendritic cells from a cancer patient mixed with peptides from the patient's

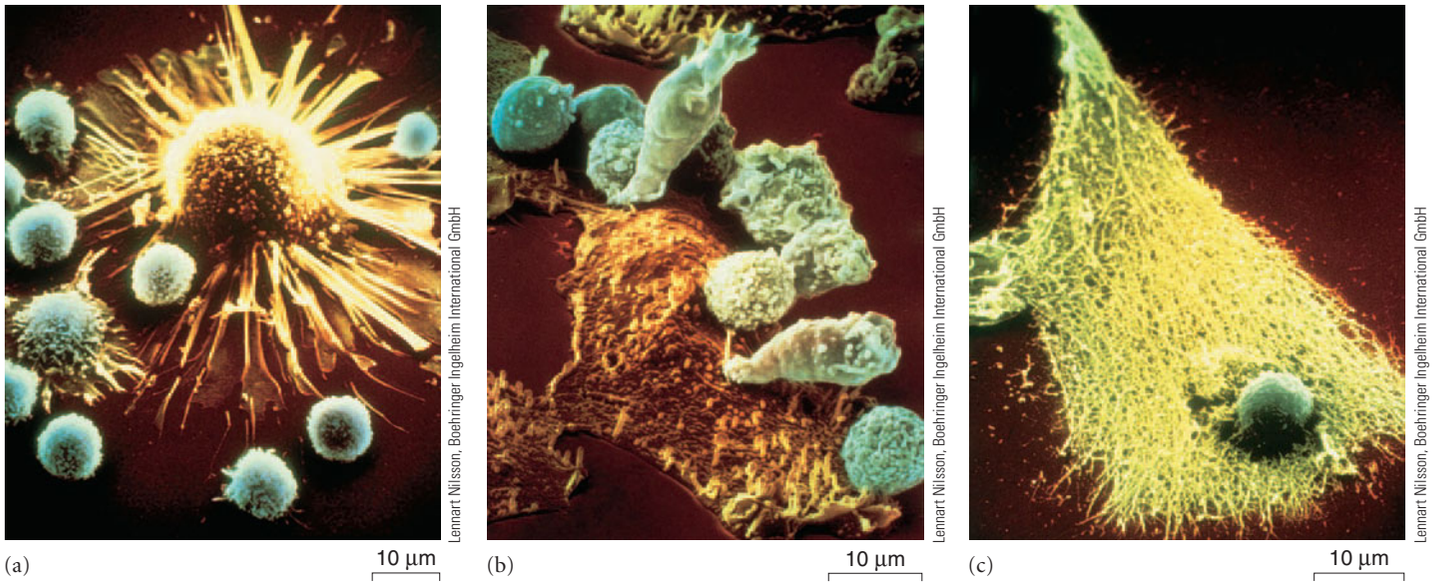

FIGURE **43-12** **Colorized SEMs showing cancer cell destruction.**

(a) An army of T_C cells surrounds a large cancer cell. The T_C cells recognize the cancer cell as nonself because it displays altered or unique antigens on its surface. **(b)** Some T_C cells elongate as they chemically attack the cancer cell, breaking down its plasma membrane. **(c)** The cancer cell has been destroyed. Only a collapsed fibrous cytoskeleton remains.

cancer cells. The hypothesis is that the dendritic cells will become sensitized to the cancer peptides and become more effective in recognizing the cancer cells in the patient.

DNA microarrays detect patterns of gene expression in cancer cells. The microarray is a slide or chip that the technician can dot with DNA from thousands of genes (see Fig. 15-3). These genes are used as probes to determine which genes are active in cancer cells. Researchers use microarrays to identify cancer subtypes, information that can help identify and develop the most effective treatments.

Immunodeficiency disease can be inherited or acquired

The absence or failure of some component of the immune system can result in **immunodeficiency disease,** a condition that increases susceptibility to infection. Inherited immunodeficiencies have an estimated incidence of 1 per 10,000 births. *Severe combined immunodeficiency syndromes (SCIDs)* are X-linked and autosomal recessive disorders that profoundly affect both cell-mediated immunity and antibody-mediated immunity, resulting in multiple infections. Babies born with SCID typically die by 2 years of age unless they are maintained in a protective bubble until they can be effectively treated, typically with bone marrow transplants.

In *DiGeorge syndrome,* the thymus is reduced or absent and the patient is deficient in T cells. Children born with this disorder are prone to serious viral infections. Treatment involves transplanting bone marrow or fetal thymus tissue.

Researchers use several animal models to study immunodeficiency. For example, the nude mouse (a hairless mutant mouse) does not develop a functional thymus. Because they are deficient in mature T cells, nude mice are used to study the effects of compromised cell-mediated immunity, as well as possible treatments. *Stem cell research* and advances in genetic engineering suggest new approaches to treating immunodeficiency (see Chapters 15 and 16).

Worldwide, the leading cause of acquired immunodeficiency in children is protein malnutrition. Lack of protein decreases T-cell numbers, and decreases the ability to manufacture antibodies, increasing the risk of contracting opportunistic infections. Another important cause of acquired immunodeficiency is chemotherapy administered to cancer patients.

HIV is the major cause of acquired immunodeficiency

The **human immunodeficiency virus (HIV)** was first isolated in 1983 and was shown to be the cause of **acquired immunodeficiency syndrome (AIDS)** in 1984. HIV, a retrovirus, has been studied more than any other virus. (Recall from Chapter 23 that a retrovirus is an RNA virus that uses its RNA as a template to make DNA with the help of reverse transcriptase.) Several different strains of the virus are known; HIV-1 is the most virulent form in humans.

The AIDS pandemic has claimed more than 26 million lives. It kills more than 3 million people every year, making it the fourth highest cause of death globally. Epidemiologists estimate that more than 38.6 million adults and 3.2 million children worldwide are now infected with HIV. The World Health Organization and the Joint United Nations Programme on HIV/AIDS predict that if the pandemic proceeds at its current alarming rate, there will be 45 million new infections by 2010 and nearly 70 million deaths by 2020. In 2001, the General Assembly of the

United Nations passed a declaration calling AIDS a "global emergency" and outlining measures for mobilizing world resources to combat this disease. The declaration, signed by 189 countries, views AIDS as more than a medical issue, stating that it is a political, economic, and human rights threat.

HIV is transmitted mainly during sexual intercourse with an infected person, or by direct exposure to infected blood or blood products. The virus is not spread by casual contact. People do not contract HIV by hugging, casual kissing, or using the same bathroom facilities. Friends and family members who have contact with AIDS patients are not more likely to get the virus.

Most individuals currently infected in the United States are men who engage in homosexual or bisexual behavior and people who use intravenous drugs. New infections are increasing most rapidly among women and teenagers who contract the virus through heterosexual contact. Heterosexual contact with infected individuals accounts for more than one third of HIV infections in women and for an increasing number of cases in both men and women. Use of a latex condom during sexual intercourse provides some protection against HIV transmission, and use of a spermicide containing nonoxynol-9 may provide additional protection.

An estimated 10% of AIDS patients are children born to infected mothers, but recent drug treatment protocols have reduced the rate of HIV transmission between mother and fetus. Mothers infected with HIV can also transmit the virus to their babies by breast-feeding. Effective blood-screening procedures have been developed to safeguard blood bank supplies, markedly reducing the risk of infection by blood transfusion in highly developed countries.

When HIV infects the body, an immune response is launched. Dendritic cells in the mucous membranes appear to be the first cells that HIV targets. When inflammation from a sexually transmitted disease or other infection is present in the mucosa of the cervix or rectum, large numbers of dendritic cells are present, increasing the risk of HIV infection. Dendritic cells transport HIV from their point of entry to the lymph nodes.

HIV has a protein (gp120) on its outer envelope that attaches to CD4 on the surface of T_H cells (CD4 T cells), its main target (Fig. 43-13; also see chapter opening figure). The virus also binds to a second receptor that normally binds chemokines. HIV enters the T_H cell and destroys it. Over time HIV causes a dramatic decrease in the T_H cell population, which severely impairs the body's ability to resist infection. T_C cells appear to be the main cells that attack HIV, limiting viral replication and delaying the progress of the disease. Too often, the virus eventually wins the battle.

Although most individuals have no symptoms, about 15% of infected individuals experience mild flulike symptoms (fever

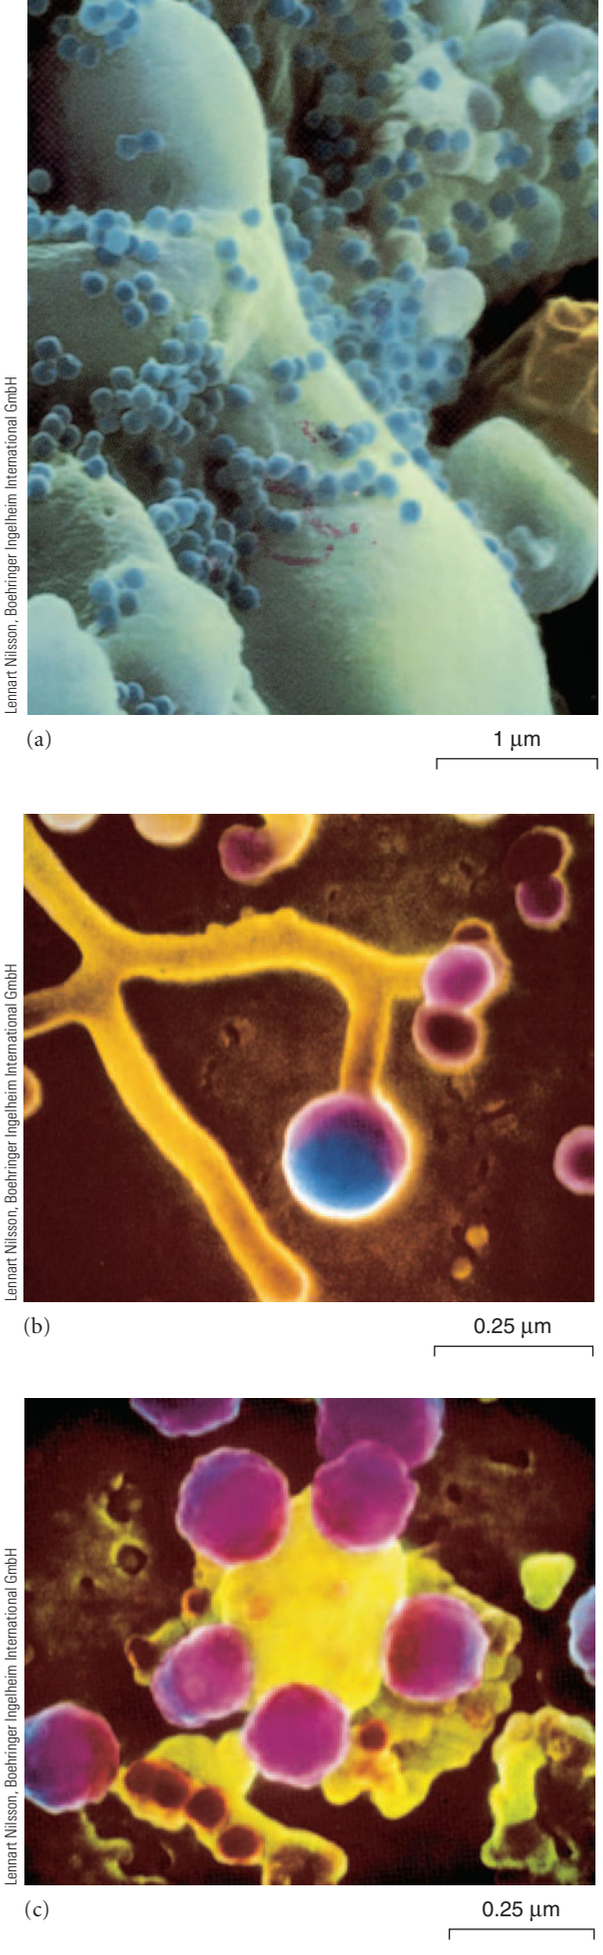

FIGURE **43-13** **Colorized SEMs of HIV infecting a T helper cell.**

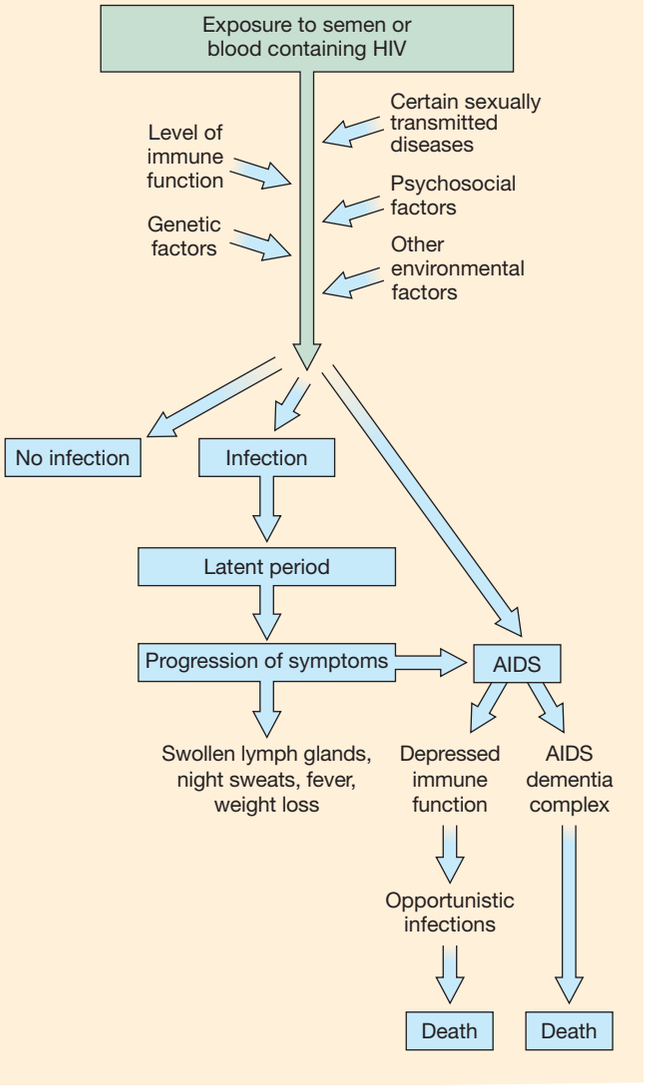
(a) HIV particles *(blue)* attack a T_H cell *(light green)*. **(b)** HIV particles budding from the ends of the branched microvilli of a T_H cell. **(c)** An even higher magnification of viral particles budding from a bleb (a cytoplasmic extension broader than a microvillus).

and aching muscles) for a week or so. Some cells infected by HIV are not destroyed, and the virus may continue to replicate slowly for many years. After a time, a progression of symptoms occurs, including swollen lymph glands, night sweats, fever, and weight loss (Fig. 43-14).

In about one third of AIDS patients, the virus infects the nervous system, causing *AIDS dementia complex*. These patients exhibit progressive cognitive, motor, and behavioral dysfunction that typically ends in coma and death. As a consequence of immunosuppression, many AIDS patients develop and die from serious opportunistic infections or rare forms of cancer, such as Kaposi's sarcoma, an endothelial cell tumor that causes purplish spots on the skin.

FIGURE **43-14** **The course of HIV infection.**

Exposure to semen or blood that contains HIV can lead to HIV infection and AIDS. Although some exposed individuals apparently do not become infected, the risk increases with multiple exposures. Many factors determine whether a person exposed to HIV will develop AIDS.



Researchers throughout the world are searching for drugs that will successfully combat the AIDS virus. Because HIV often infects the central nervous system, an effective drug must cross the blood–brain barrier. **AZT** (azidothymidine), the first drug developed to treat HIV infection, can prolong the period prior to the onset of AIDS symptoms. AZT blocks HIV replication by inhibiting the action of reverse transcriptase, the enzyme the retrovirus uses to synthesize DNA. Without producing DNA, the virus cannot incorporate itself into the host cell's DNA. Unfortunately, the reverse transcriptase HIV uses to synthesize DNA makes many mistakes: About 1 in every 2000 nucleotides it incorporates is incorrect. By mutating in this way, viral strains resistant to AZT have evolved.

Protease inhibitors block the viral enzyme protease, resulting in viral copies that cannot infect new cells. Protease inhibitors are used in combination with AZT and other reverse transcriptase inhibitors. Triple-combination treatment has been very effective for many AIDS patients, preventing opportunistic infections and prolonging life. In fact, combination treatment has led to a decline in AIDS incidence and mortality in the United States. Unfortunately, people in many parts of the world cannot afford these expensive drugs, and in poor areas, the AIDS epidemic continues to grow. In addition, the emergence of drug-resistant HIV viruses has been a serious problem.

Worldwide containment of the AIDS epidemic will require an effective vaccine that prevents the spread of HIV. Developing such a vaccine remains a daunting challenge for immunologists. More than three dozen vaccines have been developed and tested clinically, but none has proved effective. An effective vaccine would have to counteract HIV's destruction of key cells needed to mount an immune response. Also, because mutations arise at a very high rate, new viral strains with new antigens evolve quickly. A vaccine would not be effective against new antigens and would quickly become obsolete. Other obstacles to the development of a vaccine include the absence of an effective animal model for AIDS, and the ethical and practical difficulties associated with using human volunteers to test the vaccine.

While immunologists work to develop a successful vaccine and more effective drugs to treat infected patients, massive educational programs have been launched to slow the spread of HIV. Educating the public that having multiple sexual partners increases the risk of AIDS, and teaching sexually active individuals the importance of "safe sex" may help contain the pandemic. Some have suggested that public health facilities should provide free condoms to those who are sexually active and free sterile hypodermic needles to those addicted to intravenous drugs. The cost of these measures would be far less than the cost of medical care for increasing numbers of AIDS patients and the toll in human suffering.

HARMFUL IMMUNE RESPONSES

Learning Objective

12 Summarize the immunological basis of graft rejection, and describe the events that occur during hypersensitivity reactions, including Rh incompatibility, allergic reactions, and autoimmune diseases.

The immune system's ability to distinguish self from nonself sometimes interferes with clinical interventions. For example, efforts to save a patient's life with a blood transfusion or organ transplant can be disastrous if physicians ignore the effects of immune function. Sometimes the immune system malfunctions. **Hypersensitivity** is an exaggerated, damaging immune response to an antigen that is normally harmless, as occurs in an allergic reaction. Inappropriately directed or ineffective immune responses also result in disease states.

Graft rejection is an immune response against transplanted tissue

Skin can be successfully transplanted from one part of the same body to another or from one identical twin to another. However, when skin is taken from one person and grafted onto the body of a nontwin, it is rejected and sloughs off. Why? Recall that tissues from the same individual or from identical twins have identical MHC alleles and thus the same MHC antigens. Such tissues are compatible.

Because there are many alleles for each of the MHC genes, it is difficult to find identical matches. When a tissue or organ is taken from a donor and transplanted to the body of a nontwin host, several of the MHC antigens are likely to be different. The host's immune system regards the graft as foreign and launches an immune response called **graft rejection.** In the first stage of rejection, the sensitization stage, T_H cells and T_C cells recognize the antigens. In the second stage, the effector stage, T_C cells, the complement system, and cytokines secreted by T_H cells attack the transplanted tissue and can destroy it within a week.

Tissue from donor transplanted into body of recipient ⟶ T_C cells recognize MHC antigens on transplant cells as foreign ⟶ T_C cells launch immune response (graft rejection) ⟶ T_C cells destroy transplant cells

Before transplants are performed, tissues from the patient and from potential donors must be typed and matched as closely as possible. Cell typing is somewhat similar to blood typing but is more complex. If all the MHC antigens are matched, the graft has about a 95% chance of surviving the first year. Unfortunately, not many people are lucky enough to have an identical twin to supply spare parts, so perfect matches are difficult to find. Furthermore, some organs such as the heart cannot be spared. Most organs to be transplanted, therefore, are removed from unrelated donors, often from patients who have just died.

To prevent graft rejection in less compatible matches, physicians use anti-rejection drugs and/or radiation to suppress the immune system. Unfortunately, these treatments make the transplant patient more vulnerable to pneumonia or other infections, and increase the risk of certain types of cancer. If the patient survives the first few months, immunosuppressant drug dosages are reduced. Researchers are developing specific immunosuppression techniques, monoclonal antibodies that will target the specific lymphocytes that cause graft rejection.

Within the United States alone, thousands of patients are in need of organ transplants. Because the number of human donors does not meet this need, investigators are developing techniques for transplanting animal tissues and organs to humans. Challenges include risks of transmitting animal diseases to humans, and graft rejection. Researchers are developing methods for genetically engineering pigs and other animals so that they don't produce antigens that stimulate immune responses in human recipients. These animals could then be cloned and used as donors of hearts, kidneys, and other organs. Effective artificial organs are also being developed.

The body has a few immunologically privileged locations where foreign tissue is accepted. For example, corneal transplants are highly successful because the cornea has almost no associated blood or lymphatic vessels and is thus out of reach of most lymphocytes. Furthermore, antigens in the corneal graft probably would not find their way into the circulatory system and therefore could not stimulate an immune response.

Rh incompatibility can result in hypersensitivity

Named for the rhesus monkeys in whose blood it was first found, the Rh system consists of more than 40 kinds of Rh antigens, each referred to as an **Rh factor.** By far the most important of these factors is *antigen D.* About 85% of U.S. residents who are of western European descent are Rh-positive. This means they have antigen D on the surfaces of their red blood cells (in addition to the antigens of the ABO system and other blood group antigens). The 15% or so of this population who are Rh-negative have no antigen D. Unlike the situation discussed in Chapter 10 for the ABO blood group, Rh-negative individuals do not naturally produce antibodies against antigen D (anti-D). However, they produce anti-D antibodies if they are exposed to Rh-positive blood. The allele coding for antigen D is dominant to the allele for the absence of antigen D. Hence, Rh-negative people are homozygous recessive, and Rh-positive people are heterozygous or homozygous dominant.

Although several kinds of maternal-fetal blood type incompatibilities are known, **Rh incompatibility** is the most serious (Fig. 43-15). If a woman is Rh-negative and the father of the fetus she is carrying is Rh-positive, the fetus may also be Rh-positive, having inherited the D allele from the father. Ordinarily no mixing of maternal and fetal blood occurs; nutrients, oxygen, and other substances are exchanged between these two circulatory systems across the placenta. However, late in pregnancy or during the birth process, a small quantity of blood from the fetus may pass through a defect in the placenta.

The fetus's red blood cells, which bear antigen D, activate the mother's immune system, stimulating B cells to produce

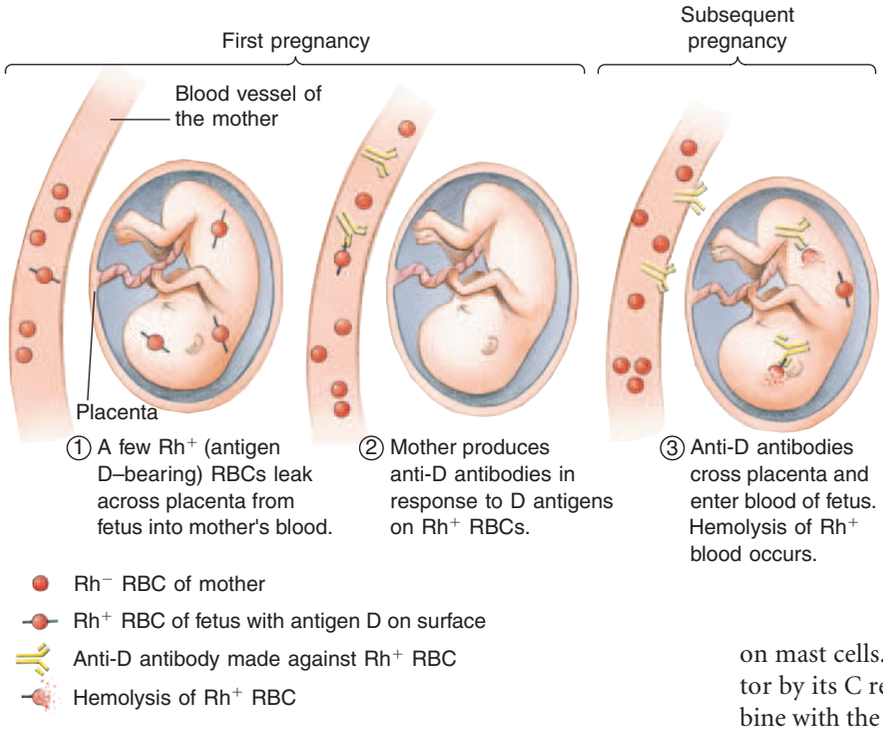

FIGURE **43-15** **Rh incompatibility.**

When an Rh-negative woman produces Rh-positive offspring, her immune system can be sensitized. In subsequent pregnancies she may produce anti-D antibodies that cross the placenta and destroy fetal red blood cells.

antibodies to antigen D. If the woman becomes pregnant again, she produces anti-D antibodies that cross the placenta and enter the fetal blood. They combine with antigen D molecules on the surface of the fetal red blood cells, causing hemolysis (cells rupture and release hemoglobin into the circulation). The ability to transport oxygen is reduced, and breakdown products of the released hemoglobin damage organs, including the brain. In extreme cases of this disease, known as **erythroblastosis fetalis,** so many fetal red blood cells are destroyed that the fetus may die.

When Rh-incompatibility problems are suspected, fetal blood can be exchanged by transfusion before birth, but this is a risky procedure. More commonly, Rh-negative women are treated just after childbirth (or at termination of pregnancy by miscarriage or abortion) with a preparation of anti-D antibodies known as RhoGAM. These antibodies clear the Rh-positive fetal red blood cells from the mother's blood very quickly, minimizing the chance for her own white blood cells to become sensitized, and develop memory cells. The antibodies are also soon eliminated from her body. As a result, if she becomes pregnant again, her blood does not contain the anti-D that could harm her baby.

Allergic reactions are directed against ordinary environmental antigens

About 20% of the U.S. population is plagued by an allergic disorder such as allergic asthma or hayfever. A predisposition toward these disorders appears to be inherited. In **allergic reactions,** hypersensitivity results in the manufacture of antibodies against mild antigens, called **allergens,** that normally do not stimulate an immune response. Common environmental agents such as house-dust mites, roach feces, pet dander, and pollen can trigger allergic reactions in some individuals. Allergic reactions are referred to as *Type I hypersensitivity.* In many kinds of allergic reactions, distinctive IgE immunoglobulins are produced.

Let's examine a common allergic reaction, a hayfever response to ragweed pollen (Fig. 43-16). Step ① Exposure to pollen causes *sensitization.* Macrophages degrade the allergen and present fragments of it to T cells. The activated T cells then stimulate B cells to become plasma cells and produce pollen-specific IgE. ② These antibodies attach to receptors on mast cells. Each IgE molecule attaches to a mast cell receptor by its C region end, leaving the V region end free to combine with the ragweed pollen allergen.

③ When a sensitized, allergic person inhales the microscopic pollen, ④ allergen molecules rapidly attach to the IgE on sensitized mast cells. This binding of allergen with IgE antibody ⑤ stimulates the mast cell to release granules filled with histamine and other molecules that cause inflammation. ⑥ Blood vessels dilate and capillaries become more permeable, leading to edema and redness. Such responses cause the nasal passages to become swollen and irritated. A runny nose, sneezing, watery eyes, and a general feeling of discomfort are common.

A prolonged allergic response occurs when neutrophils are attracted by chemical compounds released by the mast cells. Neutrophils migrate to the inflamed area, and release compounds that prolong the allergic reaction.

In **allergic asthma,** an allergen-IgE response occurs in the bronchioles of the lungs. Mast cells release substances that cause smooth muscle to contract, and the airways in the lungs sometimes constrict for several hours, making breathing difficult. An antibody to IgE is being clinically tested as a treatment for allergic asthma.

Certain foods or drugs act as allergens in some people, causing a reaction in the walls of the digestive tract that leads to discomfort and diarrhea. The allergen may be absorbed and cause mast cells to release granules elsewhere in the body. When the allergen-IgE reaction takes place in the skin, the histamine released by mast cells causes the swollen red welts we know as **hives.**

Systemic anaphylaxis is a dangerous allergic reaction that can occur when a person develops an allergy to a specific drug such as penicillin, to compounds in the venom injected by a stinging insect, or even to certain foods. Within minutes after the substance enters the body, a widespread allergic reaction takes place. Mast cells release large amounts of histamine and other compounds into the circulation, causing extreme vasodilation and capillary permeability. So much plasma may be lost from the

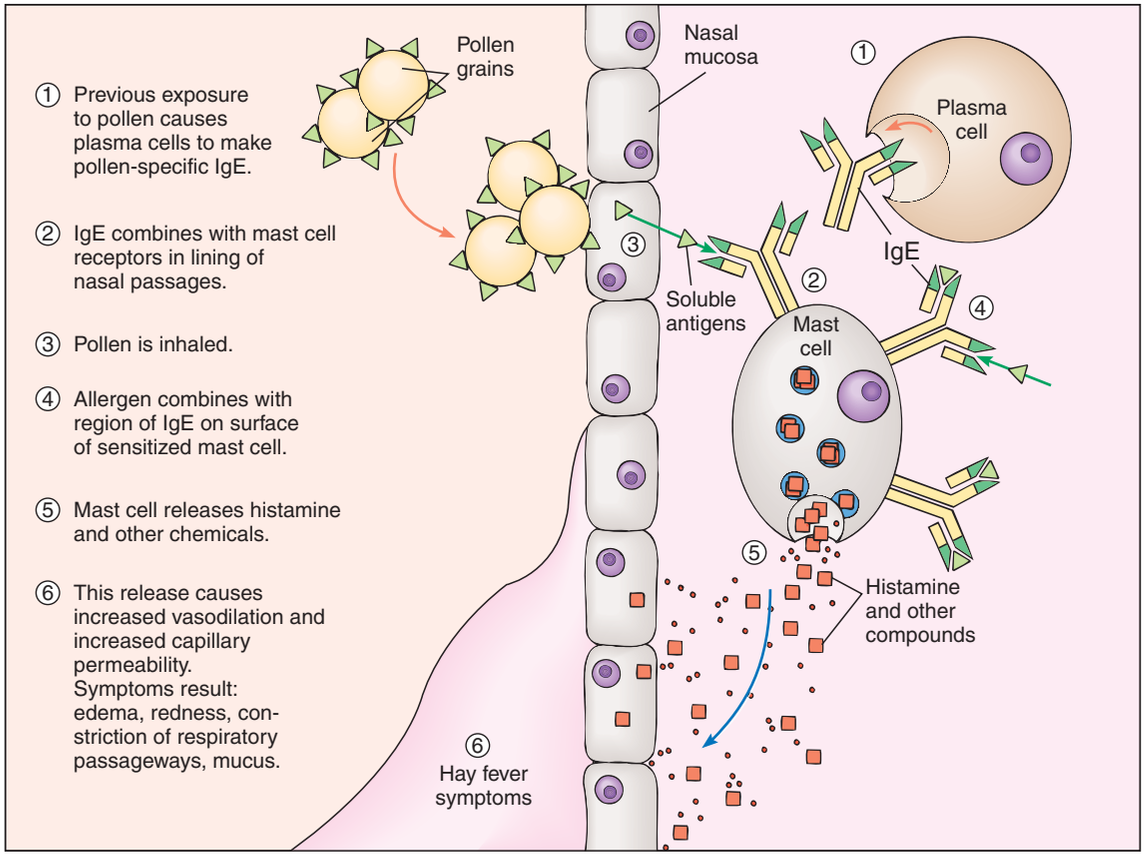

FIGURE **43-16**

An allergic reaction.

Pollen causes a common type of allergic reaction in many people.

blood that circulatory shock and death can occur within a few minutes.

The symptoms of allergic reactions are often treated with **antihistamines,** drugs that block the effects of histamine. These drugs compete for the same receptors on cells targeted by histamine. When the antihistamine combines with the receptor, it prevents the histamine from binding and thus prevents its harmful effects. Antihistamines are useful clinically in relieving the symptoms of hives and hayfever. They are not completely effective, because mast cells release molecules other than histamine that also cause allergic symptoms.

In an autoimmune disease, the body attacks its own tissues

During their development, complex mechanisms establish self-tolerance (self-recognition) so that lymphocytes do not attack tissues of their own body. However, some lymphocytes remain that have the potential to be *autoreactive,* that is, to launch an immune response against self tissues. Such autoreactivity can lead to a form of hypersensitivity known as *autoimmunity,* or **autoimmune disease,** in which T cells react immunologically against the body's own cells. Some of the diseases that result from such failure in self tolerance are rheumatoid arthritis, systemic lupus erythematosus (SLE), insulin-dependent diabetes, scleroderma, and multiple sclerosis.

In autoimmune diseases, antibodies and T cells attack the body's own tissues. In **rheumatoid arthritis,** T cells in the area of inflammation produce IL-15, an interleukin that promotes inflammation, and generates an immune complex. In **multiple sclerosis,** antibodies attack the glial cells that produce the myelin sheath surrounding neurons in the brain and spinal cord. MRI scans show the absence of myelin sheaths around axons that are normally myelinated.

Genetic risk factors are important in autoimmune diseases. Mutations that cause abnormal apoptosis or inadequate clearing of dead cells may result in danger signals that activate the immune system. Another important fact is that viral or bacterial infection often precedes the onset of an autoimmune disease. Some pathogens have evolved a tactic known as *molecular mimicry.* They trick the body by producing molecules that look like self molecules. For example, an adenovirus that causes respiratory and intestinal illness produces a peptide that mimics myelin protein. When the body launches responses to the adenovirus peptide, it may also begin to attack the similar self molecule, myelin.

To maintain homeostasis and health, the numerous types of cells, regulatory and signaling molecules, and the complex actions of the immune system must be carefully regulated. Specific T cells and B cells proliferate and respond to challenges by pathogens, but after an effective immune response the expanded populations of T and B cells must be decreased to normal numbers. Cells that are no longer needed die by apoptosis. Overactivation of critical components can result in inflammation and autoimmune disease. Underactivation would allow pathogens to cause serious disease. Either situation can lead to death.

Review

- What is the immunological basis for graft rejection?
- What immunological events take place in a common type of allergic reaction such as hayfever?
- What is an autoimmune disease? Give two examples.

BiologyNow™ Assess your understanding of **harmful immune responses** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Distinguish between nonspecific and specific immune responses.

- The body defends itself against **pathogens,** toxins, and other harmful agents. **Immunology** is the study of internal defensive responses. An **immune response** is the process of recognizing foreign or dangerous macromolecules and responding to eliminate them.
- **Nonspecific immune responses** provide general and immediate protection against pathogens, some toxins and drugs, and cancer cells.
- **Specific immune responses** are highly specific and include immunological memory. An **antigen** is a molecule specifically recognized as foreign or dangerous by cells of the immune system. **Antibodies** are highly specific proteins that recognize and bind to specific antigens.

2 Compare, in general terms, the immune responses of invertebrates and vertebrates.

- Invertebrates depend on nonspecific immune responses such as physical barriers (cuticle, skin, mucous membranes), **phagocytosis,** and **antimicrobial peptides,** soluble molecules that destroy pathogens.
- Vertebrates use both nonspecific and specific immune responses.

3 Describe nonspecific immune responses, including physical and chemical barriers; soluble molecules such as cytokines and the proteins that make up the complement system; phagocytes; natural killer cells; and the inflammatory response.

- Vertebrate nonspecific immune responses include physical barriers, such as the skin and the mucous linings of the respiratory and digestive tracts. When pathogens break through these first-line defenses, other nonspecific defenses are activated.
- Soluble molecules important in immune responses include antimicrobial peptides, regulatory peptides, and proteins that destroy pathogens.
- **Cytokines** are signaling proteins that regulate interactions between cells. Important groups are interferons, interleukins, chemokines, and tumor necrosis factors. **Interferons** inhibit viral replication and activate natural killer cells. **Interleukins** help regulate interactions between lymphocytes and other cells of the body; some have widespread effects. **Chemokines** attract, activate, and direct the movement of certain cells of the immune system. **Tumor necrosis factors (TNFs)** kill tumor cells and stimulate immune cells to initiate an inflammatory response.
- **Complement** proteins lyse the cell wall of pathogens, coat pathogens, enhancing phagocytosis, and attract white blood cells to the site of infection. These actions enhance the inflammatory response.
- **Phagocytes,** including **neutrophils** and **macrophages,** destroy bacteria. **Natural killer cells (NK cells)** destroy cells infected with viruses and foreign or altered cells such as tumor cells.
- When pathogens invade tissues, they trigger an **inflammatory response,** which includes three main processes: vasodilation (increased blood vessel diameter); increased capillary permeability, which allows fluid and antibodies to leave the circulation and enter the tissues; and increased phagocytosis. In response to tissue injury, several types of molecules in the plasma that mediate inflammation are activated. **Mast cells** release **histamine** and other compounds that cause vasodilation and increased capillary permeability.

4 Distinguish between cell-mediated and antibody-mediated immunity.

- In **cell-mediated immunity,** specific T cells are activated; these cells release proteins that destroy cells infected with viruses or other intracellular pathogens.
- In **antibody-mediated immunity,** specific B cells are activated; they multiply and differentiate into plasma cells, which produce antibodies.

5 Describe the principal cells of the immune system, and summarize the function of the major histocompatibility complex.

- Two main types of cells important in specific immune responses are lymphocytes and antigen-presenting cells.
- Lymphocytes develop from stem cells in the bone marrow. **T cells** are lymphocytes responsible for cell-mediated immunity. The **thymus gland** confers immunocompetence on T cells by making them capable of distinguishing between self and nonself. Three types of T cells are **T cytotoxic cells (T_C cells), T helper cells (T_H),** and **memory T cells.** T cells are distinguished by their **T-cell receptors (TCRs).**
- **B cells** are lymphocytes responsible for antibody-mediated immunity. B cells differentiate into **plasma cells,** which produce antibodies. Some activated B cells become **memory B cells,** which continue to produce antibodies after an infection has been overcome.
- **Antigen-presenting cells (APCs)** display foreign antigens as well as their own surface proteins. Dendritic cells, macrophages, and B cells are important APCs. **Dendritic cells** are located in the skin and other tissues of the body that interact with the environment. They are specialized to process, transport, and present antigens.
- Immune responses depend on the **major histocompatibility complex (MHC),** a group of genes that encode MHC proteins. Class I MHC genes encode self antigens, glycoproteins expressed on the surface of most nucleated cells. Class II MHC genes encode glycoproteins expressed on APCs of the immune system. Class III MHC genes encode components of the complement system and TNFs.

6 Describe the sequence of events in cell-mediated immunity.

- In cell-mediated immunity, specific T cells are activated by a foreign antigen–MHC complex on the surface of an infected cell. A co-stimulatory signal and interleukins are also required.
- Activated T_C cells multiply, giving rise to a clone. These cells migrate to the site of infection and destroy pathogen-infected cells.

SUMMARY WITH KEY TERMS *(continued)*

- Activated T_H cells give rise to a clone of T_H cells, which secrete cytokines that activate B cells and macrophages.

7 Summarize the sequence of events in antibody-mediated immunity, including the effects of antigen-antibody complexes on pathogens.

- In antibody-mediated immunity, B cells are activated when they combine with antigen. Activation requires an APC (such as a dendritic cell or macrophage) that has a foreign antigen–MHC complex displayed on its surface; a T_H cell that secretes interleukins is also needed.
- Activated B cells multiply, giving rise to clones of cells. The cloned cells differentiate, forming plasma cells.
- Plasma cells produce specific antibodies, also called **immunoglobulins (Ig),** in response to the specific antigens that activated them.
- An antibody combines with a specific antigen to form an **antigen-antibody complex,** which may inactivate the pathogen, stimulate phagocytosis, or activate the complement system.

8 Describe the basic structure and function of an antibody, and explain the basis of antibody diversity.

- A typical antibody is Y-shaped; the two arms combine with antigen. An antibody molecule consists of four polypeptide chains: two identical heavy chains and two shorter light chains. Each chain has a **constant (C) region** and a **variable (V) region.**
- Rearrangement of DNA segments during the differentiation of B cells is the main factor responsible for antibody diversity; millions of different types of B (and T) cells are produced.

9 Describe the basis of immunological memory; contrast secondary and primary immune responses.

- After an infection, memory B and memory T cells remain in the body. These cells are responsible for long-term immunity.
- The first exposure to an antigen stimulates a **primary immune response.** A second exposure to the same antigen evokes a **secondary immune response,** which is more rapid and more intense than the primary response.

10 Compare active and passive immunity, giving examples of each.

- **Active immunity** develops as a result of exposure to antigens; it may occur naturally after recovery from a disease or can be artificially induced by immunization with a vaccine.
- **Passive immunity** is a temporary condition that develops when an individual receives antibodies produced by another person or animal.

11 Describe the body's response to cancer cells and HIV.

- NK cells, macrophages, T cells, and other cells of the immune system recognize antigens on cancer cells and launch an immune response against them. Cancer cells evade the immune system by blocking T_C directly or by decreasing the class I MHC molecules on T_C cells.
- **Acquired immunodeficiency syndrome (AIDS)** is caused by the **human immunodeficiency virus (HIV),** a retrovirus. HIV destroys T helper cells, severely impairing immunity and placing the patient at risk for opportunistic infections.

12 Summarize the immunological basis of graft rejection, and describe the events that occur during hypersensitivity reactions, including Rh incompatibility, allergic reactions, and autoimmune diseases.

- Transplanted tissues have MHC antigens that stimulate **graft rejection,** an immune response in which T cells destroy the transplant.
- When an Rh-negative woman gives birth to an Rh-positive baby, she may develop anti-D antibodies. **Rh incompatibility** can then occur in future pregnancies.
- In an **allergic reaction,** an **allergen** stimulates the production of IgE, which combines with receptors on mast cells. The mast cells release histamine and other molecules that cause inflammation and other symptoms of allergy. **Systemic anaphylaxis** is a rapid, widespread allergic reaction that can lead to death.
- In **autoimmune diseases,** the body reacts immunologically against its own tissues.

POST-TEST

1. A molecule recognized as foreign by cells of the immune system is a (an) (a) antibody (b) antigen (c) immunoglobulin (d) interferon (e) cytokine
2. Nonspecific (innate) immune responses include (a) inflammation (b) antigen-antibody complexes (c) immunoglobulin action (d) complement and memory T cells (e) interferon and memory B cells
3. Invertebrate defense responses include (a) phagocytosis (b) antimicrobial peptides (c) ability to distinguish between self and nonself (d) answers a, b, and c are correct (e) answers a and c only
4. Cytokines (a) are regulatory nucleic acids (b) prevent the inflammatory response (c) include interferons and interleukins (d) are immunoglobulins (e) include interleukins and complement proteins
5. Which of the following is *not* an action of complement? (a) enhances phagocytosis (b) enhances inflammatory response (c) coats pathogens (d) lyses viruses release (e) stimulates allergen release
6. Which of the following cells are antigen-presenting cells? (a) NK cells and monocytes (b) macrophages and plasma cells (c) dendritic cells and macrophages (d) mast cells and B cells (e) memory T cells and memory B cells
7. Which of the following cells are especially adept at destroying tumor cells? (a) NK cells (b) plasma cells (c) neutrophils (d) B cytotoxic cells (e) mast cells
8. Which of the following cells become immunologically competent after processing in the thymus gland? (a) NK cells (b) T cells (c) macrophages (d) B cells (e) plasma cells
9. Cells that have a surface marker called CD4 are (a) NK cells (b) T cytotoxic cells (c) T helper cells (d) B cells (e) plasma cells
10. The major histocompatibility complex (MHC) (a) encodes a group of cell surface proteins (b) encodes certain antibodies (c) is important mainly in allergic reactions (d) inhibits complement release from macrophages (e) consists of Y-shaped molecules

POST-TEST *(continued)*

11. Which sequence most accurately describes antibody-mediated immunity? (1) B cell divides and gives rise to clone (2) antibodies produced (3) cells differentiate, forming plasma cells (4) activated helper T cell interacts with B cell displaying same antigen complex (5) B cell activated (a) 1 ⟶ 2 ⟶ 3 ⟶ 4 ⟶ 5 (b) 3 ⟶ 2 ⟶ 1 ⟶ 4 ⟶ 5 (c) 4 ⟶ 5 ⟶ 3 ⟶ 4 ⟶ 1 (d) 4 ⟶ 5 ⟶ 1 ⟶ 3 ⟶ 2 (e) 4 ⟶ 3 ⟶ 1 ⟶ 2 ⟶ 5
12. A typical antibody (a) is activated by APCs (b) has four identical heavy chains and four identical light chains (c) has IgG and IgD components (d) suppresses phagocyte actions (e) has a Y shape
13. Immunoglobulin A (a) combines with mast cells in allergic reactions (b) combines with NK cells (c) prevents pathogens from attaching to epithelial surfaces (d) is found mainly on B-cell surfaces (e) is found mainly on T cells
14. When a person is exposed to the same antigen a second time, the response is (a) called a *secondary immune response* (b) more rapid (c) mediated by dendritic cells (d) answers a, b, and c are correct (e) answers a and b only
15. Graft rejection (a) is an example of passive immunity (b) occurs in mild form after immunization (c) generates monoclonal antibodies (d) does not occur when tissue is transplanted from one identical twin to the other (e) is initiated by the thymus gland
16. In an allergic reaction (a) the body is immunodeficient (b) an allergen binds with IgE (c) T helper cells release histamine (d) allergen stimulates graft rejection (e) mast cells are deactivated
17. HIV (a) is a retrovirus (b) destroys T cytotoxic cells (c) is attacked mainly by B cells (d) answers a, b, and c are correct (e) none of the preceding answers is correct

CRITICAL THINKING

1. Specificity, diversity, and memory are key features of the immune system. Giving specific examples, explain how each of these features is important.
2. Macrophages can be selectively destroyed in the body by the administration of a certain chemical. What would be the effects of such a loss of macrophages? Which do you think would have a greater effect on the immune system, loss of macrophages or loss of B cells?
3. What are the advantages of having MHC antigens? Disadvantages? What do you think would be the consequences of not having them?
4. Imagine that you are a researcher developing new HIV treatments. What approaches might you take? What public policy decisions would you recommend that might help slow the spread of AIDS while new treatments or vaccines are being developed?

Gas Exchange

Skip Moody/Dembinsky Photo Associates

The white-tailed deer (*Odocoileus virginanus*) and other terrestrial vertebrates ventilate their lungs by breathing air.

CHAPTER OUTLINE

- Adaptations for Gas Exchange in Air or Water
- Types of Respiratory Surfaces
- The Mammalian Respiratory System
- Breathing Polluted Air

Most animal cells require a continuous supply of oxygen for cellular respiration. Some cells, such as mammalian brain cells, may be damaged beyond repair if their oxygen supply is cut off for only a few minutes. Animal cells must also rid themselves of carbon dioxide. The exchange of gases between an organism and its environment is known as **respiration.** Two phases of respiration are organismic and cellular respiration. During **organismic respiration,** oxygen from the environment is taken up by the animal and delivered to its individual cells. At the same time, carbon dioxide generated during cellular respiration is excreted into the environment. In **aerobic cellular respiration,** which takes place in mitochondria, oxygen is necessary for the citric acid cycle to proceed. Oxygen serves as the final electron acceptor in the mitochondrial electron transport chain (see Chapter 7). Carbon dioxide is a metabolic waste product of cellular respiration.

In small, aquatic organisms such as sponges, hydras, and flatworms, gas exchange occurs entirely by simple **diffusion,** the passive movement of particles (atoms, ions, or molecules) from a region of higher concentration to a region of lower concentration, that is, down a concentration gradient. Most cells are in direct contact with the environment. Dissolved oxygen from the surrounding water diffuses into the cells, whereas carbon dioxide diffuses out of the cells and into the water. No specialized respiratory structures are needed.

Oxygen diffuses through tissues slowly, however. In an animal more than about 1 mm thick, oxygen cannot diffuse quickly enough through layers of cells to support life. Specialized respiratory structures such as gills or lungs are required to deliver oxygen to the cells or to a transport system and to facilitate excretion of carbon dioxide. Such respiratory systems, working with circulatory systems, provide the efficient intake and transport of oxygen necessary to support high metabolic rates.

If the air or water supplying oxygen to the cells can be continuously renewed, more oxygen will be available. For this reason animals carry on **ventilation;** that is, they actively move air or water over their respiratory surfaces. Sponges do this with flagella, setting up a current of water through the channels of their bodies. Most fishes gulp water, which then passes over their gills. Terrestrial vertebrates have lungs and breathe air (see photograph); the diaphragm and other muscles move air in and out of the lungs. ■

ADAPTATIONS FOR GAS EXCHANGE IN AIR OR WATER

Learning Objective

1 Compare the advantages and disadvantages of gas exchange in air with those of gas exchange in water.

Gills are adapted for gas exchange in water, and the tracheal tubes of insects and lungs of vertebrates are respiratory structures adapted for gas exchange in air. Respiratory surfaces must be kept moist to prevent drying out, and oxygen and carbon dioxide are dissolved in the fluid that bathes the cells of these surfaces. Whether an animal makes its home on land or water, gas exchange takes place across a moist surface.

Animals that carry out gas exchange in water require no special mechanisms for maintaining moisture. In contrast, animals that respire in air struggle continuously with water loss. Adaptations have evolved that keep respiratory surfaces moist and minimize desiccation. For example, the lungs of air-breathing vertebrates are located deep within the body, not exposed like gills. Air is humidified and brought to body temperature as it passes through the upper respiratory passageways, and expired air must again pass through these airways (providing opportunity for retaining water) before leaving the body. These adaptations protect the lungs from the drying and cooling effects of air.

Gas exchange in air has certain advantages over gas exchange in water. Compared with water, air contains a much higher concentration of molecular oxygen. In addition, oxygen diffuses much faster through air than through water. Another advantage is that less energy is needed to move air than to move water over a gas exchange surface. This is because air is less dense and less viscous.

BiologyNow™ Assess your understanding of **adaptations for gas exchange in air or water** by taking the pretest on your BiologyNow CD-ROM.

TYPES OF RESPIRATORY SURFACES

Learning Objective

2 Describe the following adaptations for gas exchange: body surface, tracheal tubes, gills, and lungs.

Not only must respiratory structures be moist, but they must also have thin walls through which diffusion can easily occur. Respiratory structures are generally richly supplied with blood vessels to facilitate transport and exchange of respiratory gases. Four main types of respiratory surfaces have evolved in animals: the animal's own body surface, tracheal tubes, gills, and lungs (Fig. 44-1). Some animals use a combination of these adaptations.

The body surface may be adapted for gas exchange

Gas exchange occurs through the entire body surface in many animals, including nudibranch mollusks, most annelids, and some amphibians. All these animals are small, with a high surface-to-volume ratio. They also have a low metabolic rate that requires smaller quantities of oxygen per cell. In aquatic animals, the body surface is kept moist by the surrounding water. In terrestrial animals, the body secretes fluids that keep its surface moist. Many animals that exchange gases across the body surface also have gills or lungs.

Tracheal tube systems of arthropods deliver air directly to the cells

The relatively inefficient open circulatory system of arthropods cannot supply these active animals with enough oxygen. They need a specialized respiratory system. In insects and some other arthropods (such as chilopods, diplopods, some mites, and some spiders), the respiratory system is a network of **tracheal tubes,** also called **tracheae** (Fig. 44-2). Air enters the tracheal tubes through a series of up to 20 tiny openings called **spiracles** along the body surface. In some insects, especially large, active ones, muscles help ventilate the tracheae by pumping air in and out of the spiracles. For example, the grasshopper draws air in through the first four pairs of spiracles when the abdomen expands. Then the abdomen contracts, forcing air out through the last six pairs of spiracles.

Once inside the body, the air passes through a system of branching tracheal tubes, which extend to all parts of the animal. The tracheal tubes terminate in microscopic, fluid-filled tracheoles. Gases are exchanged between this fluid and the body cells. The tracheal system supplies enough oxygen to support the high metabolic rates characteristic of many insects.

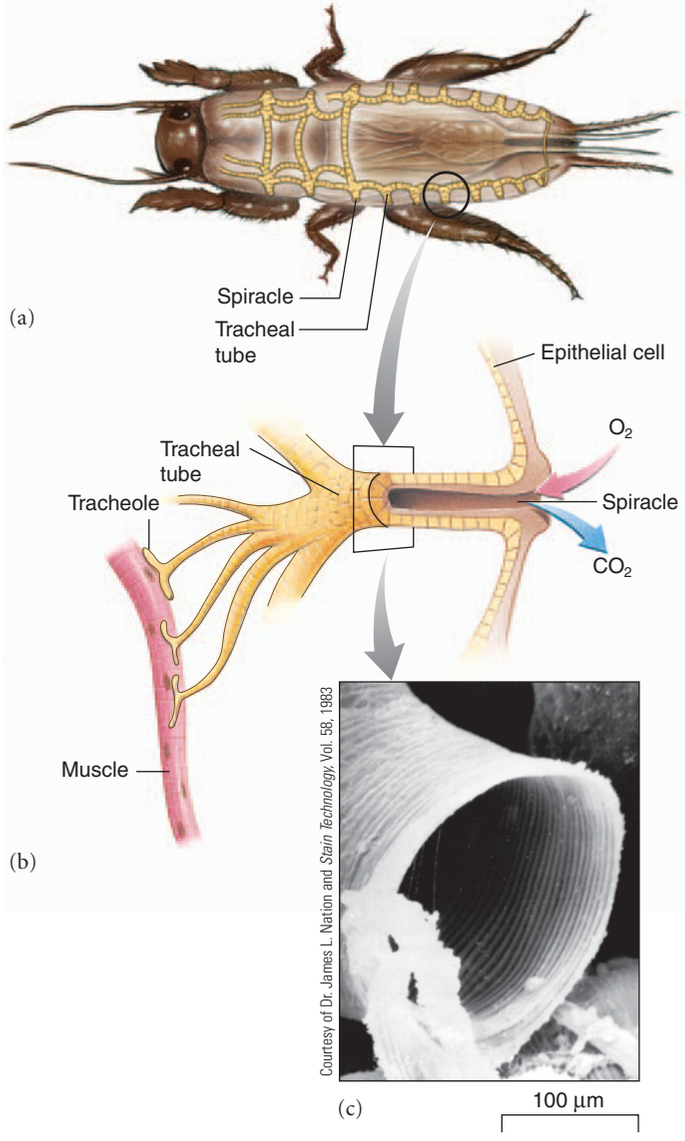

FIGURE **44-2** **Tracheal tubes.**

(a) Air enters the system of tracheal tubes through openings called spiracles. **(b)** Air passes through a system of branching tracheal tubes that conduct oxygen to all cells of the insect. **(c)** SEM of a mole cricket trachea. The wrinkles are a part of a long spiral that wraps around the tube, strengthening the tracheal wall somewhat as a spring strengthens the plastic hoses of many vacuum cleaners. The tracheal wall is composed of chitin.

Gills of aquatic animals are respiratory surfaces

Found mainly in aquatic animals, **gills** are moist, thin structures that extend from the body surface. They are supported by the buoyancy of water but tend to collapse in air. In many ani-

mals, the outer surface of the gills is exposed to water, whereas the inner side is in close contact with networks of blood vessels.

Sea stars and sea urchins have **dermal gills** that project from the body wall. Their ciliated epidermal cells ventilate the gills by beating a stream of water over them. Gases are exchanged between the water and the coelomic fluid inside the body by diffusion through the gills.

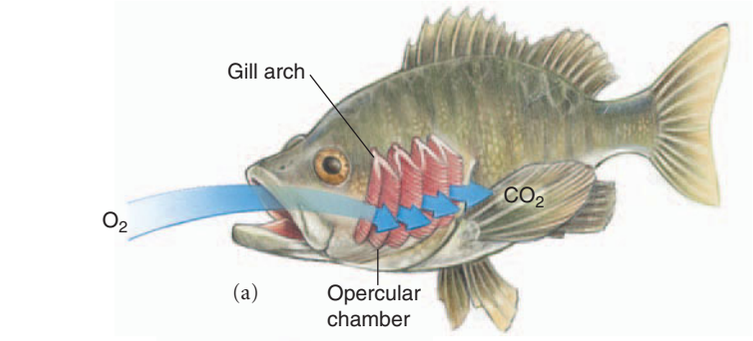
Various types of gills are found in some annelids, aquatic mollusks, crustaceans, fishes, and amphibians. Mollusk gills are folded, providing a large surface for respiration. In clams and other bivalve mollusks and in simple chordates, gills may also be adapted for trapping and sorting food. The rhythmic beating of cilia draws water over the gill area, and food is filtered out of the water while gases are exchanged. In mollusks, gas exchange also takes place through the mantle.

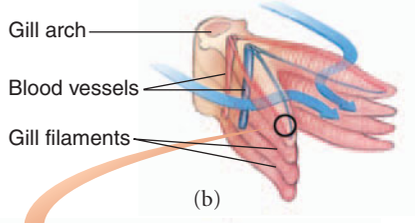
In chordates, gills are usually internal. A series of slits perforates the pharynx, and the gills lie along the edges of these gill slits (see Fig. 30-4). In bony fishes, the fragile gills are protected by an external bony plate, the **operculum.** In some fish, movements of the jaw and operculum help pump water rich in oxygen through the mouth and across the gills. The water leaves through the gill slits.

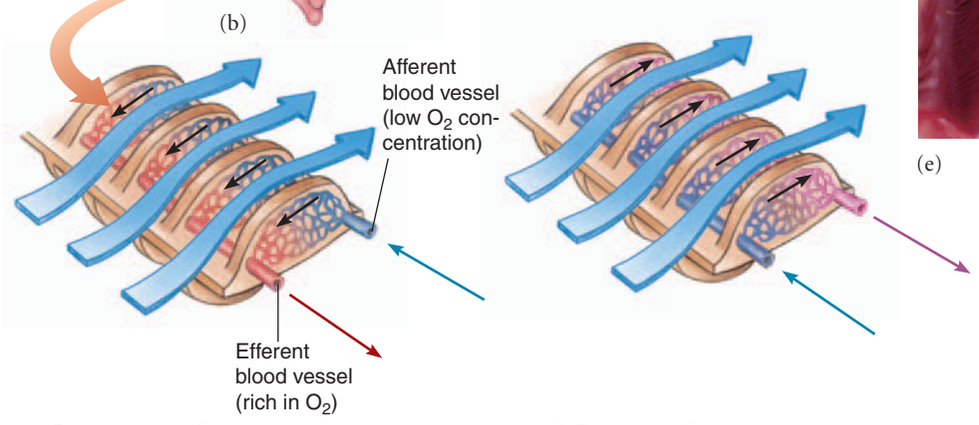
Each gill in the bony fish consists of many **filaments,** which provide an extensive surface for gas exchange (Fig. 44-3). The filaments extend out into the water, which continuously flows over them. A capillary network delivers blood to the gill filaments, facilitating diffusion of oxygen and carbon dioxide between blood and water. The impressive efficiency of this system is possible because blood flows in a direction opposite to the movement of the water. This arrangement, called a **countercurrent**

FIGURE **44-3** **Gills in bony fish.**

(a) The gills lie under a bony plate, the operculum, which has been removed in this side view. The gills form the lateral wall of the pharyngeal cavity. **(b)** Each gill consists of a cartilaginous gill arch to which two rows of leaflike gill filaments attach. As water flows past the gill filaments, blood circulates within them. **(c)** Each gill filament has many smaller extensions rich in capillaries. Blood entering the capillaries is deficient in oxygen. The blood flows through the capillaries in a direction opposite to that taken by the water. This countercurrent exchange system efficiently charges the blood with oxygen. **(d)** If the system were concurrent, that is, if blood flowed through the capillaries in the same direction as the flow of the water, much less of the oxygen dissolved in the water could diffuse into the blood. **(e)** Gills of the salmon.







(c) Countercurrent flow

(d) Concurrent flow (does not occur)

Bernard Photo Production/Animals Animals

exchange system, maximizes the difference in oxygen concentration between blood and water throughout the area where the two remain in contact (Fig. 44-3c).

If blood and water flowed in the *same* direction, that is, *concurrent exchange,* the difference between the oxygen concentrations in blood (low) and water (high) would be very large initially and very small at the end. The oxygen concentration in the water would decrease as that in the blood increased. When the concentrations in the two fluids became equal, an equilibrium would be reached, and the net diffusion of oxygen would stop. Only about 50% of the oxygen dissolved in the water could diffuse into the blood.

In the countercurrent exchange system, however, blood low in oxygen comes in contact with water that is partly depleted of oxygen. Then, as the blood flowing through the capillaries becomes more and more rich in oxygen, it comes in contact with water with a progressively higher concentration of oxygen. Thus, all along the capillaries, the diffusion gradient favors passage of oxygen from the water into the gill. A high rate of diffusion is maintained, ensuring that a very high percentage (more than 80%) of the available oxygen in the water diffuses into the blood.

Oxygen and carbon dioxide do not interfere with one another's diffusion, and they simultaneously diffuse in opposite directions. This is because oxygen is more concentrated outside the gills than within, but carbon dioxide is more concentrated inside the gills than outside. Thus, the same countercurrent exchange mechanism that ensures efficient inflow of oxygen also results in equally efficient outflow of carbon dioxide.

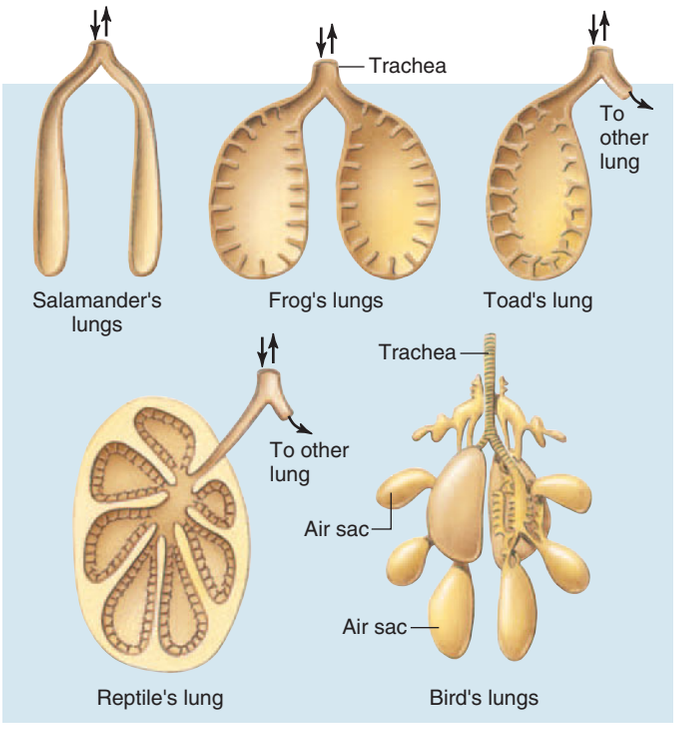

FIGURE **44-4** **Comparison of vertebrate lungs.**

The surface area of the lung has increased during vertebrate evolution. Salamander lungs are simple sacs. Other amphibians and reptiles have lungs with small ridges or folds that help increase surface area. Birds have an elaborate system of lungs and air sacs. Mammalian lungs have millions of alveoli that increase the surface available for gas exchange (see Fig. 44-7).

Terrestrial vertebrates exchange gases through lungs

Lungs are respiratory structures that develop as ingrowths of the body surface or from the wall of a body cavity such as the pharynx (throat region). For example, the **book lungs** of spiders are enclosed in an inpocketing of the abdominal wall. These lungs consist of a series of thin, parallel plates of tissue (like the pages of a book) filled with hemolymph (see Fig. 44-1d). The plates of tissue are separated by air spaces that receive oxygen from the outside environment through a spiracle. A different type of lung evolved in land snails and slugs. (These terrestrial mollusks lack gills.) Gas exchange takes place through a lung, that is a vascularized region of the mantle.

Fossil evidence suggests that early lobe-finned fishes had lungs somewhat similar to those of modern lungfish. The Australian lungfish can use either its gills or its lungs, depending on the conditions in its environment. The gills of African and South American lungfishes degenerate with age, so adults must rise to the surface and exchange gases entirely through their lungs.

Remains of early lobe-finned fishes occur extensively in the fossil record. Those found in Devonian strata are thought to be similar to the ancestors of amphibians, and many amphibian fossils have been found in adjacent ancient strata. Some paleontologists hypothesize that lungs evolved as an adaptation to the periodic droughts in Devonian times and that all early bony fishes may have had lungs or lunglike structures. Most modern bony fishes have no lungs, but nearly all have homologous **swim bladders** (see Chapter 30). By adjusting the amount of gas in its swim bladder, the fish can control its buoyancy.

Some amphibians do not have lungs. Among plethodontid (lungless) salamanders, for example, all gas exchange takes place in the pharynx or across the thin, wet skin. However, even though they depend mainly on their body surface for gas exchange, most amphibians have lungs (Fig. 44-4). The lungs of salamanders are two long, simple sacs richly supplied by capillaries. Frogs and toads have ridges containing connective tissue on the inside of the lungs, somewhat increasing the respiratory surface.

The lungs of most reptiles are rather simple sacs, with only some folding of the wall to increase the surface for gas exchange. The gas exchange is not very efficient and does not supply enough oxygen to sustain long periods of activity. In some lizards, turtles, and crocodiles, the lungs are somewhat more complex, with subdivisions that give them a spongy texture.

Birds have the most efficient respiratory system of any living vertebrate. Very active, endothermic animals with high metabolic rates, birds require large amounts of oxygen to sustain flight and other activities. Their small, bright red lungs have extensions (usually nine) called **air sacs,** which reach into all parts of the body and even connect with air spaces in some of the bones (Fig. 44-5). The air sacs act as bellows, drawing air into the sys-

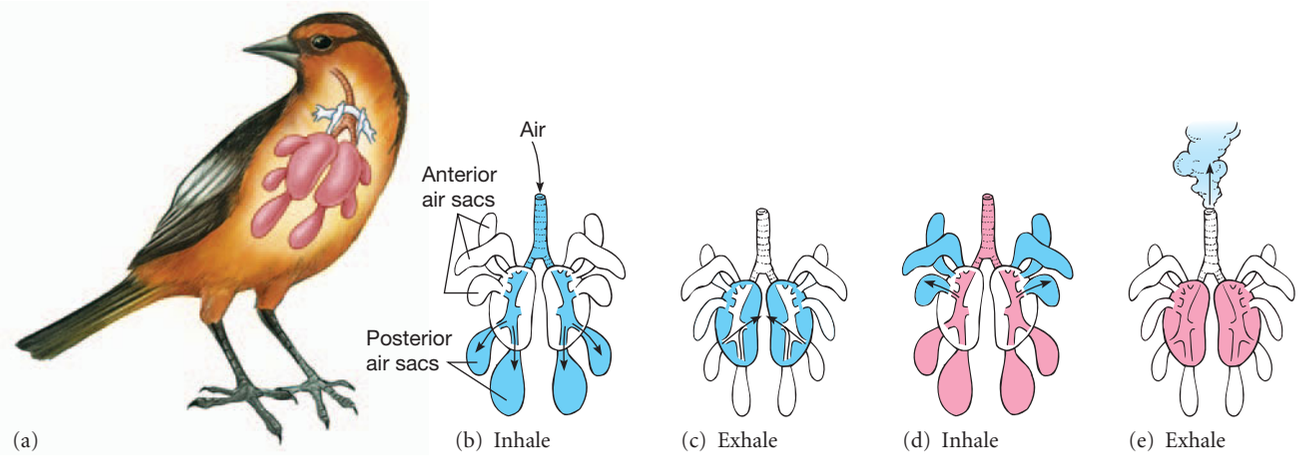

FIGURE **44-5** **How bird lungs function.**

The bird's breathing process requires two cycles of inhalation and exhalation to support a one-way flow of air through the lungs. **(a)** The bird respiratory system includes lungs and extensions called air sacs. **(b)** As the bird inhales, new air flows into the posterior air sacs *(blue)* and partly into the lungs (not shown). **(c)** As the bird exhales, this air is forced into the lungs. **(d)** At the second inhalation, most of the air from the first breath moves into the anterior air sacs and partly into the lungs (not shown). Air from the second inhalation flows into the posterior air sacs *(pink)*. **(e)** At the second exhalation, most of the air from the first inhalation leaves the body, and air from the second inhalation flows into the lungs.

tem. Collapse of the air sacs during exhalation forces air out. Gas exchange does not take place across the walls of the air sacs.

The high-performance bird respiratory system is arranged so that air flows in one direction through the lungs and is renewed during a two-cycle process. Air entering the body passes into the posterior air sacs and the part of the lungs closest to these air sacs. When the bird exhales, that air flows into the lungs. At the second breath, the air flows from the lungs to the anterior air sacs. Finally, at the second exhalation, the air leaves the body as another breath of air enters the lungs. Thus, a bird gets fresh air across its lungs through both inhalation and exhalation.

Bird lungs have tiny, thin-walled tubes, the **parabronchi,** which are open at both ends. Gas exchange takes place across the walls of these tubes. Chickens and other weak-flying birds have about 400 parabronchi per lung compared with pigeons and other strong-flying birds, which have about 1800 parabronchi per lung. The direction of blood flow in the lungs is opposite that of air flow through the parabronchi. This arrangement, similar in principle to the countercurrent exchange in the gills of fishes, increases the amount of oxygen that enters the blood. However, in birds the capillaries are oriented at right angles to the parabronchi rather than along their length. For this reason, this arrangement is referred to as *crosscurrent,* rather than as countercurrent.

Review

- Why are specialized respiratory structures necessary in a tadpole but not in a flatworm?
- How does gas exchange differ among the following animals: (a) earthworm (b) grasshopper (c) fish (d) bird?
- How does the countercurrent exchange system increase the efficiency of gas exchange between a fish's gills and blood?

BiologyNow™ Assess your understanding of **types of respiratory surfaces** by taking the pretest on your BiologyNow CD-ROM.

THE MAMMALIAN RESPIRATORY SYSTEM

Learning Objectives

3 Trace the passage of oxygen through the human respiratory system from nostrils to alveoli.

4 Summarize the mechanics and the regulation of breathing in humans, and describe gas exchange in the lungs and tissues.

5 Explain the role of hemoglobin in oxygen transport, and identify factors that determine and influence the oxygen–hemoglobin dissociation curve.

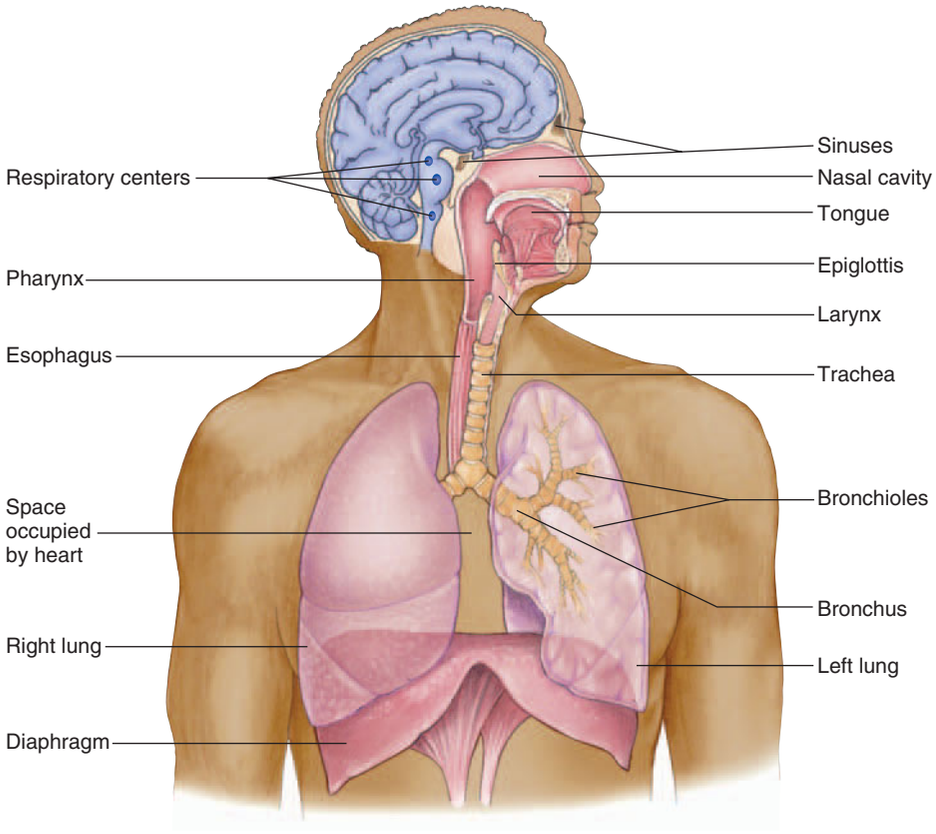
6 Summarize the mechanisms by which carbon dioxide is transported in the blood.

7 Describe the physiological effects of hyperventilation, and of sudden decompression when a diver surfaces too quickly from deep water.

The respiratory system of mammals consists of the lungs and a series of tubes through which air passes on its journey from the nostrils to the lungs and back (Fig. 44-6). The complex lungs have an enormous surface area. In the following sections we focus on the human respiratory system.

The airway conducts air into the lungs

A breath of air enters the body through the **nostrils** and flows through the **nasal cavities.** As air passes through the nose, it is filtered, moistened, and brought to body temperature. The nasal cavities are lined with a moist, ciliated epithelium rich in blood vessels. Inhaled dirt, bacteria, and other foreign particles are trapped in the stream of mucus produced by cells within the epithelium and pushed along toward the throat by the cilia. In this way, foreign particles are delivered to the digestive system,



ACTIVE FIGURE **44-6** **The human respiratory system.**

The muscular diaphragm forms the floor of the thoracic cavity. The internal view of one lung illustrates a portion of its extensive system of air passageways. The respiratory centers in the brain regulate the rate of respiration.

BiologyNow™ Learn more about **the human respiratory system** by clicking on this figure on your BiologyNow CD-ROM.

which can more effectively dispose of such materials than can the delicate lungs. A person normally swallows more than a pint of nasal mucus each day, and even more during an infection or allergic reaction.

The back of the nasal cavities is continuous with the throat region, or **pharynx.** Air finds its way into the pharynx whether one breathes through the nose or mouth. An opening in the floor of the pharynx leads into the **larynx,** sometimes called the "Adam's apple." Because the larynx contains the vocal cords, it is also referred to as the voice box. Cartilage embedded in its wall prevents the larynx from collapsing and makes it hard to the touch when felt through the neck.

During swallowing, a flap of tissue called the **epiglottis** automatically closes off the larynx so that food and liquid enter the esophagus rather than the lower airway. If this mechanism fails and foreign matter enters the sensitive larynx, a cough reflex expells the material. Despite these mechanisms, choking sometimes occurs.

From the larynx, air passes into the **trachea,** or windpipe, which is kept from collapsing by rings of cartilage in its wall. The trachea divides into two branches, the **bronchi** (sing., *bronchus*), each of which connects to a lung. Both trachea and bronchi are lined by a mucous membrane containing ciliated cells that traps medium-sized particles that escape the cleansing mechanisms of nose and larynx. Mucus containing these particles is constantly beaten upward by the cilia to the pharynx, where it is periodically swallowed. This mechanism, functioning as a cilia-propelled elevator of mucus, helps keep foreign material out of the lungs.

Gas exchange occurs in the alveoli of the lungs

The lungs are large, paired, spongy organs occupying the *thoracic* (chest) *cavity.* The right lung is divided into three lobes, the left lung into two lobes. Each lung is covered with a **pleural membrane,** which forms a continuous sac that encloses the lung and becomes the lining of the thoracic cavity. The *pleural cavity* is the space between the pleural membranes. A film of fluid in the pleural cavity provides lubrication between the lungs and the chest wall.

Because the lung consists largely of air tubes and elastic tissue, it is a spongy, elastic organ with a very large internal surface area for gas exchange. Inside the lungs the bronchi branch, becoming smaller and more numerous. These branches give rise to more than 1 million tiny **bronchioles** in each lung. Each bronchiole ends in a cluster of tiny air sacs, the **alveoli** (sing., *alveolus*) (Fig. 44-7). Each human lung contains more than 300 million alveoli, and thus has an internal surface area the approximate size of a tennis court. Each alveolus is lined by an extremely thin, single layer of epithelial cells. Gases diffuse freely through the wall of the alveolus and into the capillaries that surround it. Only two thin cell layers, the epithelia of the alveolar wall and the capillary wall, separate the air in the alveolus from the blood.

In summary, the sequence of structures through which air passes after it enters the body is as follows:

Nostrils ⟶ nasal cavities ⟶ pharynx ⟶ larynx ⟶ trachea ⟶ bronchi ⟶ bronchioles ⟶ alveoli

Ventilation is accomplished by breathing

Breathing is the mechanical process of moving air from the environment into the lungs and of expelling air from the lungs. Inhaling air is called **inhalation** or *inspiration;* exhaling air is **exhalation** or *expiration.* The thoracic cavity is closed so no air can enter except through the trachea. (When the chest wall is punctured, for example, by a fractured rib or gunshot wound, air enters the pleural space and the lung collapses.)

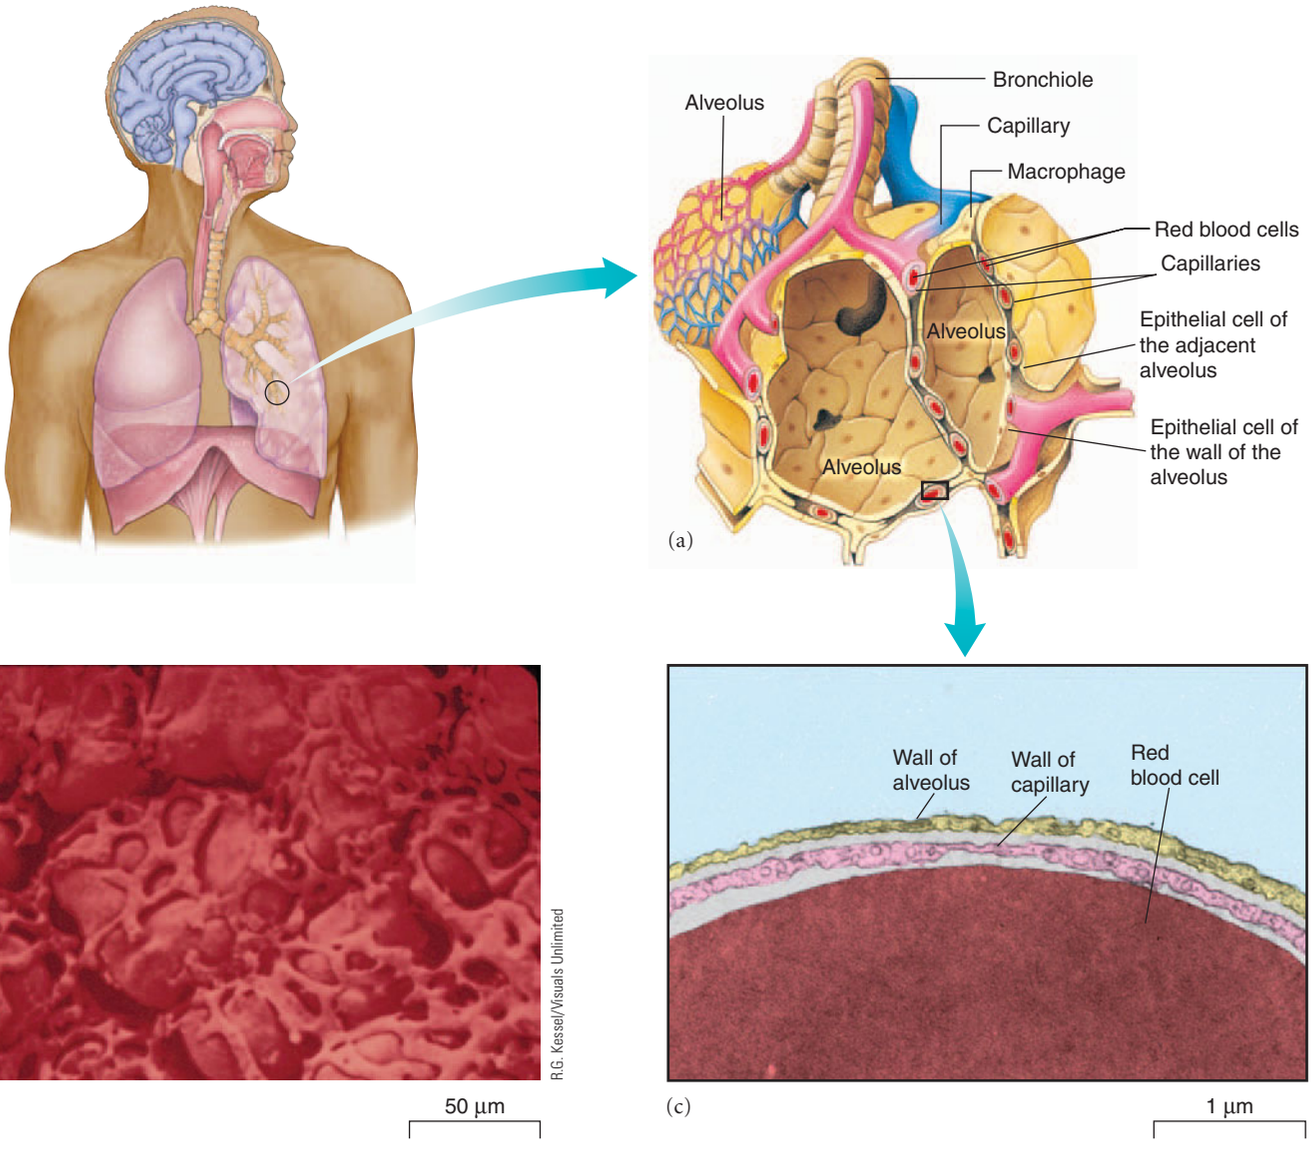


FIGURE **44-7** **Structure of alveoli.**

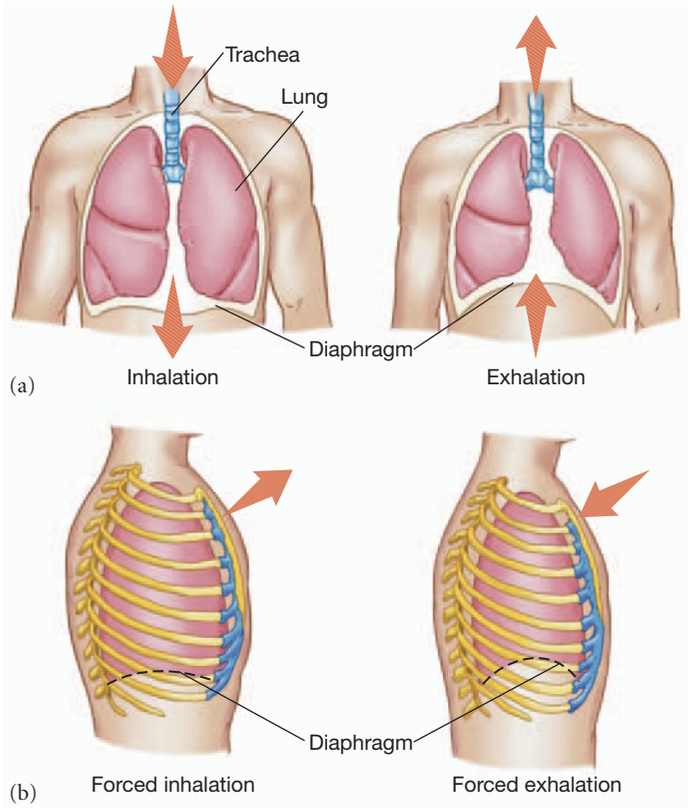
(a) Gas exchange takes place across the thin wall of the alveolus. Extensive capillary networks lie between the walls of the alveoli. **(b)** Color-enhanced SEM showing the capillary network surrounding a portion of several alveoli. **(c)** Color-enhanced TEM of a portion of a capillary and the wall of an alveolus. The dark structure extending through the capillary is part of a red blood cell. The wall of the alveolus is visible just above the wall of the capillary. Notice the very short distance oxygen must diffuse to get from the air within the alveolus to the red blood cells that transport it to the body tissues.

During inhalation, the volume of the thoracic cavity is increased by the contraction of the **diaphragm,** the dome-shaped muscle that forms its floor. When the diaphragm contracts, it moves downward, increasing the volume of the thoracic cavity (Fig. 44-8). During forced inhalation, when a large volume of air is inhaled, the *external intercostal muscles* contract as well. This action moves the ribs upward, also increasing the volume of the thoracic cavity.

Because the lungs adhere to the walls of the thoracic cavity, when the volume of the thoracic cavity increases the space within each lung also increases. The air in the lungs now has more space in which to move about, and the air pressure in the lungs falls by 2 or 3 millimeters of mercury (mm Hg) below the air pressure outside the body. As a result of this pressure difference, air from the outside rushes in through the respiratory passageways and fills the lungs until the two pressures are equal once again.

Exhalation occurs when the diaphragm relaxes. The volume of the thoracic cavity decreases, raising the pressure in the lungs to 2 to 3 mm Hg above atmospheric pressure. The millions of distended air sacs partially deflate, expelling the inhaled air. The pressure returns to normal, and the lung is ready for another inhalation. Thus in inhalation the millions of alveoli fill with air like so many tiny balloons. Then, during exhalation, the air rushes out of the alveoli, partially deflating them. During deep or forced breathing, the *external intercostal muscles* also contract, pulling the ribcage upward and outward. This action further



ACTIVE FIGURE **44-8** **Mechanics of breathing.**

(a) Changes in position of the diaphragm in exhalation and inhalation change the volume of the thoracic cavity. During inhalation, the diaphragm contracts, increasing the volume of the thoracic cavity. When the volume of the thoracic cavity increases, air moves into the lungs. During exhalation, the diaphragm relaxes, decreasing the volume of the thoracic cavity. **(b)** During forced inhalation, the external intercostal muscles contract, pulling the rib cage upward and outward. This increases the front-to-back dimension of the chest and correspondingly increases the volume of the thoracic cavity. During forced exhalation, the intercostal muscles contract, pulling the rib cage downward and inward, which decreases the volume of the thoracic cavity.

BiologyNow™ See **the breathing mechanisms in action** by clicking on this figure on your BiologyNow CD-ROM.

increases the volume of the thoracic cavity. During forced exhalation, muscles of the abdominal wall and the *internal intercostal muscles* contract, pushing the diaphragm up and the ribs down. This action decreases the volume of the thoracic cavity.

Some of the work in stretching the thorax and the lungs is necessary to stretch elastic connective tissue. Work is also required to overcome the cohesive force of water molecules associated with the respiratory membrane. The forces between the water molecules produce a surface tension that resists stretching. The work of breathing is reduced by **pulmonary surfactant,** a detergent-like phospholipid mixture secreted by specialized epithelial cells in the lining of the alveoli. Pulmonary surfactant intersperses between the water molecules, reducing their cohesive force. This action markedly reduces the surface tension of the water, prevents the alveoli from collapsing, and reduces the energy required to stretch the lungs. Premature infants often cannot produce enough surfactant and thus suffer from respiratory distress syndrome. In these infants, high surface tension makes it difficult to inflate the lungs, and the alveoli collapse during expiration. Breathing is labored. These infants may be placed on respirators that help them breathe.

The quantity of respired air can be measured

The amount of air moved into and out of the lungs with each normal resting breath is called the **tidal volume.** The normal tidal volume is about 500 mL. The **vital capacity** is the maximum amount of air a person can exhale after filling the lungs to the maximum extent. Vital capacity is greater than tidal volume because the lungs are not completely emptied of stale air and filled with fresh air with each normal resting breath. The volume of air that remains in the lungs at the end of a normal expiration is the **residual capacity.**

Gas exchange takes place in the alveoli

The respiratory system delivers oxygen to the alveoli, but if oxygen remained in the lungs all the other body cells would soon die. The vital link between alveolus and body cell is the circulatory system. Each alveolus serves as a tiny depot from which oxygen diffuses into blood brought close to the alveolar air by capillaries (Fig. 44-9).

Oxygen molecules efficiently pass by simple diffusion from the alveoli, where they are more concentrated, into the blood in the pulmonary capillaries, where they are less concentrated. At the same time, carbon dioxide moves from the blood, where it is more concentrated, to the alveoli, where it is less concentrated. Each gas diffuses through the single layer of cells lining the alveoli and the single layer of cells lining the capillaries.

Cellular respiration results in the continuous use of oxygen and production of carbon dioxide. Inhaled (atmospheric) air contains about 20.9% oxygen, but exhaled (alveolar) air contains only 14% oxygen. Because carbon dioxide is produced during cellular respiration, exhaled air contains 100 times more (5.6%) carbon dioxide than inhaled air (.04% carbon dioxide).

The concentration of oxygen in the cells is lower than in the capillaries entering the tissues, and the concentration of carbon dioxide is higher in the cells than in the capillaries. As blood circulates through capillaries of a tissue such as brain or muscle, oxygen moves by simple diffusion from the blood to the cells, and carbon dioxide moves from the cells into the blood.

The factor that determines the direction and rate of diffusion is the pressure or tension of the particular gas. According to **Dalton's law of partial pressures,** in a mixture of gases the total pressure of the mixture is the sum of the pressures of the individual gases. Each gas exerts, independently of the others, a **partial pressure**—the same pressure it would exert if it were present alone. At sea level, the barometric pressure (the pressure of Earth's atmosphere) typically supports a column of mer-

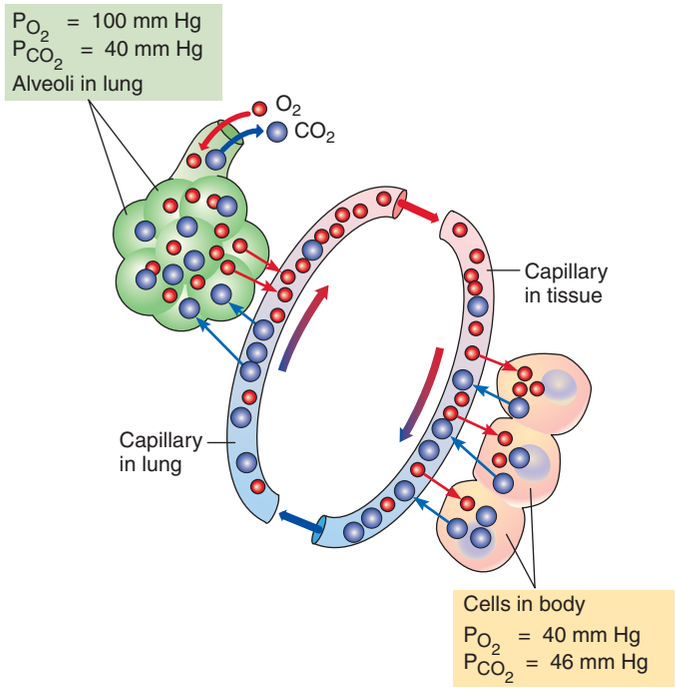


FIGURE **44-9** **Gas exchange in the lungs and tissues.**

The concentration of oxygen is greater in the alveoli than in the pulmonary capillaries, so oxygen diffuses from the alveoli into the blood. Carbon dioxide is more concentrated in the blood than in the alveoli, so it diffuses out of the capillaries and into the alveoli. In the tissues, oxygen is more concentrated in the blood than in the body cells; it diffuses out of the capillaries into the cells. Carbon dioxide is more concentrated in the cells, so it diffuses out of the cells and moves into the blood. Note the differences in partial pressures of oxygen and carbon dioxide before and after gases are exchanged in the tissues.

cury 760 mm high. Because oxygen makes up about 21% of the atmosphere, oxygen's share of that pressure is 0.21 × 760 = 160 mm Hg. Thus 160 mm Hg is the partial pressure of atmospheric O_2, abbreviated Po_2. In contrast, the partial pressure of atmospheric CO_2 is 0.3 mm Hg, abbreviated P_{CO_2}.

Fick's law of diffusion explains that the amount of oxygen or carbon dioxide that diffuses across the membrane of an alveolus depends on the differences in partial pressure on the two sides of the membrane and also on the surface area of the membrane. The gas diffuses faster if the difference in pressure or the surface area increases.

Gas exchange takes place in the tissues

The partial pressure of oxygen in arterial blood is about 100 mm Hg. The P_{O_2} in the tissues is still lower, ranging from 0 to 40 mm Hg. Consequently, oxygen diffuses out of the capillaries and into the tissues. Not all the oxygen leaves the blood, however. The blood passes through the tissue capillaries too rapidly for equilibrium to be reached. As a result, the partial pressure of oxygen in venous blood returning to the lungs is about 40 mm Hg. Thus, exhaled air has had only part of its oxygen removed—a good thing for those in need of mouth-to-mouth resuscitation!

Respiratory pigments increase capacity for oxygen transport

Complex animals have **respiratory pigments** that combine reversibly with oxygen and greatly increase the capacity of blood to transport it. **Hemocyanins** are copper-containing proteins dispersed in the hemolymph of many species of mollusks and arthropods. Without oxygen, these pigments are colorless. When oxygen combines with the copper, hemocyanins are blue.

Hemoglobin and **myoglobin** are the most common respiratory pigments in animals. Myoglobin is a form of hemoglobin found in muscle fibers. Hemoglobin is the only type of pigment found in the blood of vertebrates. It is also present in many invertebrate species, including annelids, nematodes, mollusks, and arthropods. In some of these animals, the hemoglobin is dispersed in the plasma rather than confined to blood cells.

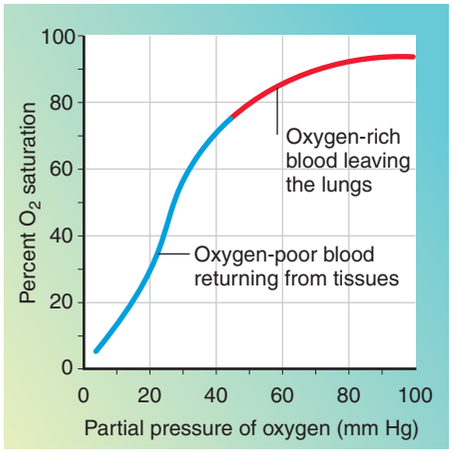
In humans and other mammals, inhaled oxygen diffuses out of the alveoli and enters the pulmonary capillaries. Plasma in equilibrium with alveolar air can take up only 0.25 mL of oxygen per 100 mL. However, oxygen diffuses into red blood cells (RBCs) and combines with hemoglobin. The properties of hemoglobin permit whole blood to carry some 20 mL of oxygen per 100 mL. Hemoglobin transports almost 99% of the oxygen. The rest is dissolved in the plasma.

The term hemoglobin is actually a general name for a group of related compounds, all of which consist of an iron-porphyrin, or heme, group bound to a protein known as a *globin*. The protein portion of the molecule varies in size, amino acid composition, and physical properties among various species. When combined with oxygen, hemoglobin is bright red; without oxygen, it appears dark red, imparting a purplish color to venous blood.

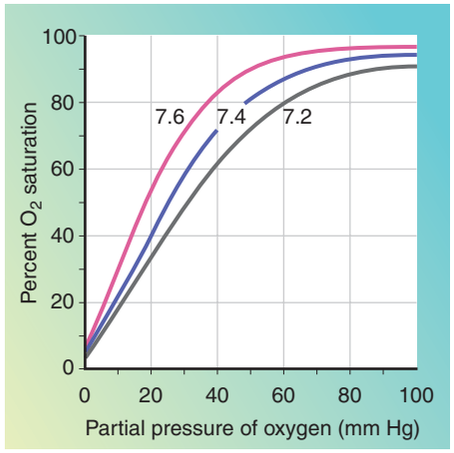
The protein portion of hemoglobin is composed of four peptide chains, typically two α and two β chains, each attached to a heme (iron-porphyrin) ring (see Fig. 3-22a). An iron atom is bound in the center of each heme ring. Hemoglobin has the remarkable property of forming a weak chemical bond with oxygen. An oxygen molecule can attach to the iron atom in each heme. In the lung (or gill), oxygen diffuses into the red blood cells and combines with hemoglobin (Hb) to form **oxyhemoglobin (HbO_2).** Because the chemical bond formed between the oxygen and the hemoglobin is weak, the reaction is readily reversible. As blood circulates through tissues where the oxygen concentration is low, the reaction proceeds to the left. Hemoglobin releases oxygen, which diffuses out of the blood and into the tissue cells.

$$Hb + O_2 \rightleftharpoons HbO_2$$

The maximum amount of oxygen that hemoglobin can transport is called the **oxygen-carrying capacity.** The actual amount of oxygen bound to hemoglobin is the **oxygen content.** The ratio of O_2 content to O_2 capacity is the **percent O_2 saturation** of the hemoglobin. The percent saturation is highest in the pulmonary capillaries, where the concentration of oxygen is greatest. In the capillaries of the tissues, where there is less oxygen, the oxyhemoglobin dissociates, releasing oxygen. There, the percent saturation of hemoglobin is correspondingly lower. The **oxygen–hemoglobin dissociation curve** shown in Figure 44-10a illustrates this relationship. As oxygen concentration increases,



(a) Normal oxygen–hemoglobin dissociation curve



(b) Effect of pH

FIGURE **44-10** **Oxygen–hemoglobin dissociation curves.**

(a) Normal curve showing the relationship between the partial pressure of oxygen and the percent oxygen saturation of hemoglobin. Oxygen binds to hemoglobin in the lungs and unloads from hemoglobin in the tissues. **(b)** Effect of pH on the oxygen–hemoglobin curve (Bohr effect). The normal pH of human blood is 7.4. Find the location on the horizontal axis where the partial pressure of oxygen is 40, and follow the line up through the curves. Notice how the saturation of hemoglobin with oxygen differs among the three curves, even though the partial pressure of oxygen is the same. Oxygen loading increases at higher pH (7.6). At lower pH (7.2), hemoglobin unloads more oxygen. For example, during muscular activity the pH decreases, and more oxygen is unloaded and available for the muscle cells.

there is a progressive increase in the percentage of hemoglobin that is combined with oxygen. The ability of oxygen to combine with hemoglobin and be released from oxyhemoglobin is influenced by several factors in addition to percent O_2 saturation; these include pH, carbon dioxide concentration, and temperature.

Carbon dioxide formed in respiring tissue reacts with water in the plasma to form carbonic acid, H_2CO_3. In this way any increase in the carbon dioxide concentration also increases the acidity (lowers the pH) of the blood. Oxyhemoglobin unloads oxygen more readily in an acidic environment than in an environment with normal pH. Displacement of the oxygen–hemoglobin dissociation curve by a change in pH is known as the **Bohr effect** (Fig. 44-10b). Lactic acid released from active muscles also lowers blood pH and has a similar effect on the oxygen–hemoglobin dissociation curve—more oxygen is unloaded and available for the muscle cells.

Some carbon dioxide is transported by the hemoglobin molecule. Although it attaches to the hemoglobin molecule in a different way and at a different site from oxygen, the attachment of a carbon dioxide molecule releases an oxygen molecule from the hemoglobin. The effect of carbon dioxide concentration on the oxygen–hemoglobin dissociation curve is important. In the capillaries of the lungs (or gills in fishes), carbon dioxide concentration is relatively low and oxygen concentration is high, so oxygen combines with a very high percentage of hemoglobin. In the capillaries of the tissues, carbon dioxide concentration is high and oxygen concentration is low, so hemoglobin readily unloads oxygen. The oxygen and carbon dioxide bound to hemoglobin in red blood cells does not contribute to the partial pressures that govern diffusion. The loading and unloading of gases onto hemoglobin depend on partial pressures of the plasma and interstitial fluid (which is determined by the gases dissolved in these fluids).

Carbon dioxide is transported mainly as bicarbonate ions

Blood transports carbon dioxide in three forms. About 10% of carbon dioxide dissolves in plasma. Another 30% enters the RBCs and combines with hemoglobin. Because the bond between the hemoglobin and carbon dioxide is very weak, the reaction is readily reversible. Most carbon dioxide (about 60%) moves through plasma as **bicarbonate ions** (HCO_3^-).

In plasma, carbon dioxide slowly combines with water to form carbonic acid. This reaction proceeds much more rapidly inside RBCs owing to the action of the enzyme **carbonic anhydrase** (Fig. 44-11). Carbonic acid dissociates, forming hydrogen ions and bicarbonate ions.

$$\underset{\text{Carbon dioxide}}{CO_2} + \underset{\text{Water}}{H_2O} \xrightarrow{\text{Carbonic anhydrase}} \underset{\text{Carbonic acid}}{H_2CO_3} \longrightarrow \underset{\text{Hydrogen ion}}{H^+} + \underset{\text{Bicarbonate ion}}{HCO_3^-}$$

Most hydrogen ions released from carbonic acid combine with hemoglobin, which is a very effective buffer. Many of the bicarbonate ions diffuse into the plasma. The action of carbonic anhydrase in the RBCs maintains a diffusion gradient for carbon dioxide to move into and then out of RBCs. As the negatively charged bicarbonate ions move out of RBCs, chloride ions (Cl^-) in the plasma diffuse into the RBCs to replace them, a process known as the **chloride shift.** In the alveolar capillaries, CO_2 diffuses out of the plasma and into the alveoli. As the CO_2 concentration decreases, the reaction sequence just described reverses.

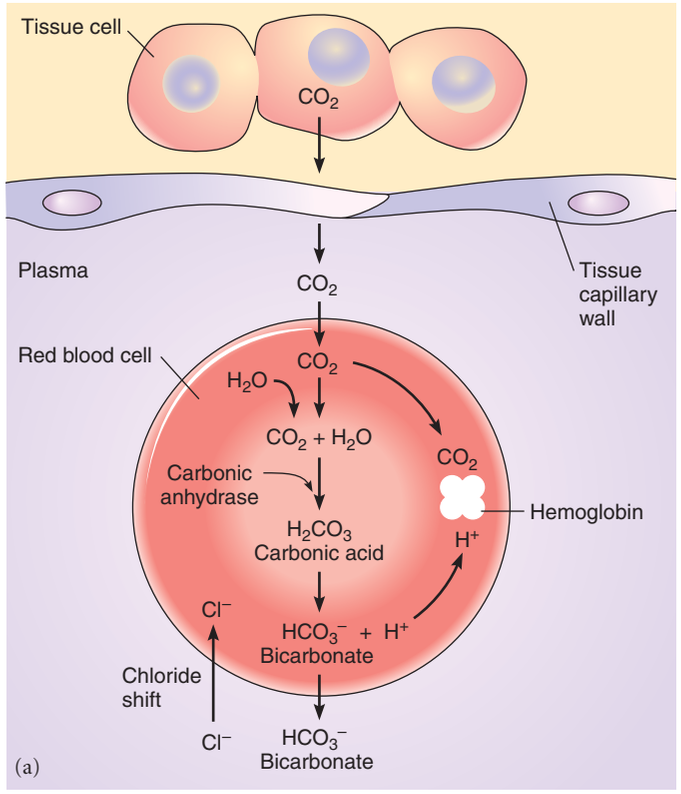
Any condition (such as emphysema) that interferes with the removal of carbon dioxide by the lungs can lead to *respiratory acidosis.* Carbon dioxide is produced more rapidly than it is excreted by the lungs. As a result, the concentration of carbonic acid in the blood increases. When blood pH falls below 7.0, the central nervous system becomes depressed. Such depression disorients the individual, and untreated respiratory acidosis can cause coma and death.

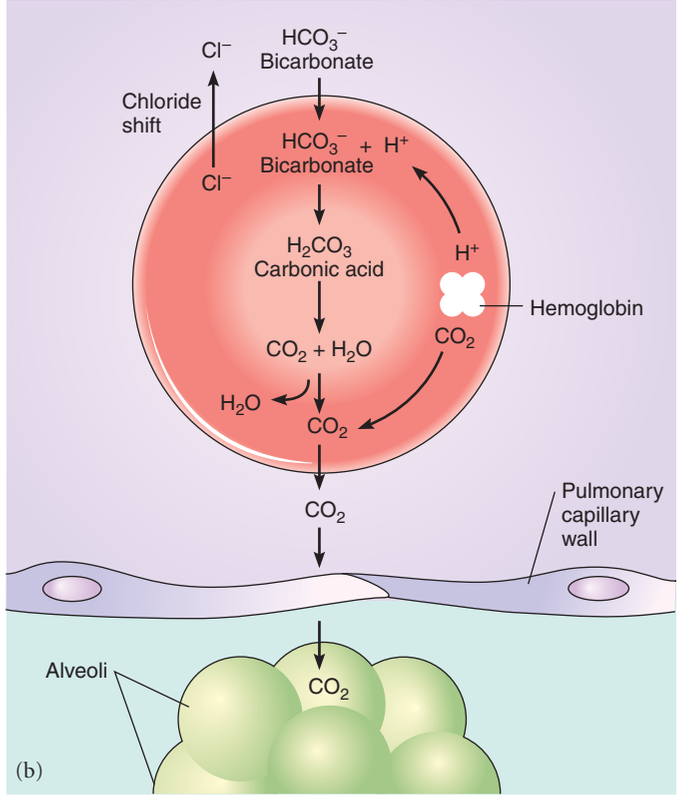
Breathing is regulated by respiratory centers in the brain

Breathing is a rhythmic, involuntary process regulated by **respiratory centers** in the brain stem (see Fig. 44-6). Groups of neurons in the medulla regulate the basic rhythm of breathing.

FIGURE **44-11** **Carbon dioxide transport.**

(a) In the tissues, carbon dioxide diffuses from cells into the plasma. Most of the carbon dioxide enters red blood cells, where the enzyme carbonic anhydrase rapidly converts it to carbonic acid. Carbonic acid dissociates, forming bicarbonate and hydrogen ions. As bicarbonate ions move out into the plasma, chloride ions replace them. Hemoglobin combines with hydrogen ions, preventing a decrease in pH. **(b)** In the lungs, carbon dioxide diffuses out of the plasma and into the alveoli, and these processes are reversed. Bicarbonate ions diffuse from the plasma into the red blood cells. H^+ released from hemoglobin combines with bicarbonate ions, forming carbonic acid. Carbon dioxide produced from the carbonic acid diffuses out of the blood and into the alveoli.





These neurons send a burst of impulses to the diaphragm and external intercostal muscles, causing them to contract. After several seconds, these neurons become inactive, the muscles relax, and exhalation occurs. Respiratory centers in the pons help control the transition from inspiration to exhalation. These centers can stimulate or inhibit the respiratory centers in the medulla. The cycle of activity and inactivity repeats itself so that at rest you breathe about 14 times per minute. Overdose of certain medications such as barbiturates depresses the respiratory centers and may lead to respiratory failure.

The basic rhythm of respiration changes in response to needs of the body. When you are playing a fast game of tennis, you need more oxygen than when you're studying biology. During exercise the rate of aerobic cellular respiration increases, producing more carbon dioxide. Your body must dispose of this carbon dioxide through increased ventilation.

Carbon dioxide concentration is the most important chemical stimulus for regulating the rate of respiration. Specialized **chemoreceptors** in the medulla and in the walls of the aorta and carotid arteries are sensitive to changes in arterial carbon dioxide concentration. When stimulated, they send impulses to the respiratory centers, which increase breathing rate.

The chemoreceptors in the walls of the aorta, called *aortic bodies,* and those in the walls of the carotid arteries, the *carotid bodies,* are sensitive to changes in hydrogen ion concentration and oxygen concentration, as well as to carbon dioxide levels. Recall that an increase in carbon dioxide concentration increases hydrogen ions from carbonic acid, lowering blood pH. Even a slight decrease in pH stimulates these chemoreceptors, leading to faster breathing. As the lungs remove carbon dioxide, the hydrogen ion concentration in the blood and other body fluids decreases, and homeostasis is re-established.

Interestingly, oxygen concentration generally does not play an important role in regulating respiration. Only if the partial pressure of oxygen falls markedly do the chemoreceptors in the aorta and carotid arteries become stimulated to send messages to the respiratory centers.

Although breathing is involuntary, the action of the respiratory centers can be consciously influenced for a short time by stimulating or inhibiting them. For example, you can inhibit respiration by holding your breath. You can't hold your breath indefinitely, however, because eventually you feel a strong urge to breathe. Even if you could ignore this urge, you would eventually pass out, and would resume breathing.

People who have stopped breathing because of drowning, smoke inhalation, electric shock, or cardiac arrest can sometimes be sustained by mouth-to-mouth resuscitation until their own breathing reflexes return. **Cardiopulmonary resuscitation (CPR)** is a method for aiding victims who have suffered respiratory and

cardiac arrest. CPR must be started immediately, because irreversible brain damage occurs within about 4 minutes of oxygen deprivation. A number of organizations offer training in CPR.

Hyperventilation reduces carbon dioxide concentration

Underwater swimmers and some Asian pearl divers voluntarily **hyperventilate** before going under water. By making a series of deep inhalations and exhalations, they "blow off" CO_2, markedly reducing the carbon dioxide content of the alveolar air and of the blood. As a result, they can last longer before the urge to breathe becomes irresistible.

When hyperventilation continues for a long period, dizziness and sometimes unconsciousness may occur. This is because a certain concentration of carbon dioxide is needed in the blood to maintain normal blood pressure. (This mechanism operates by way of the vasoconstrictor center in the brain, which maintains the muscle tone of blood vessel walls.) Furthermore, if divers hold their breath too long, the low concentration of oxygen may result in unconsciousness and drowning.

High flying or deep diving can disrupt homeostasis

The barometric pressure decreases at progressively higher altitudes. Because the concentration of oxygen in the air remains at 21%, the partial pressure of oxygen decreases along with the barometric pressure. At an altitude of 6,000 m (19,500 ft), the barometric pressure is about 350 mm Hg, the partial pressure of oxygen is about 75 mm Hg, and the hemoglobin in arterial blood is about 70% saturated with oxygen. At 10,000 m (33,000 ft) the barometric pressure is about 225 mm Hg, the partial pressure of oxygen is 50 mm Hg, and arterial oxygen saturation is only 20%. Thus getting sufficient oxygen from the air becomes an ever-increasing problem at higher altitudes.

When a person moves to a high altitude, the body adjusts over time by producing a greater number of RBCs. In a person breathing pure oxygen at 10,000 m, the oxygen would have a partial pressure of 225 mm Hg and the hemoglobin would be almost fully saturated with oxygen. Above 13,000 m, however, barometric pressure is so low that even breathing pure oxygen does not permit complete oxygen saturation of arterial hemoglobin.

A person becomes unconscious when the arterial oxygen saturation falls to between 40% and 50%. This level is reached at about 7000 m (23,000 ft) when the person is breathing air, or 14,500 m (47,100 ft) when pure oxygen is used. All high-flying jets have airtight cabins pressurized to the equivalent of the barometric pressure at an altitude of about 2000 m.

Shallow breathing, which occurs in many respiratory diseases, causes **hypoxia,** a deficiency of oxygen. Even *rapid,* shallow breathing results in hypoxia, because the tidal volume includes the air in the respiratory passages. When we breathe shallowly, we don't clear out the stale air in the airway and ventilate the lung. Hypoxia causes drowsiness, mental fatigue, headache, and sometimes euphoria. The ability to think and make judgments is impaired, as is the ability to perform tasks requiring coordination. If a jet flying at 11,700 m (over 38,000 ft) suddenly decompressed, the pilot would lose consciousness in about 30 seconds and become comatose in about 1 minute.

In addition to the problems of hypoxia, a rapid decrease in barometric pressure causes **decompression sickness** (commonly known as the "bends" because those suffering from it bend over in pain). Whenever the barometric pressure drops below the total pressure of all gases dissolved in the blood and other body fluids, the dissolved gases tend to come out of solution and form gas bubbles. A familiar example occurs each time you uncap a bottle of soda, reducing pressure in the bottle. Carbon dioxide is released from solution and bubbles out into the air. In the body, nitrogen has a low solubility in blood and tissues. When it comes out of solution, the bubbles formed may damage tissues and block capillaries, interfering with blood flow. The clinical effects of decompression sickness are pain, dizziness, paralysis, unconsciousness, and even death.

Decompression sickness is more common in scuba diving than in high-altitude flying. As a diver descends, the surrounding pressure increases tremendously—1 atmosphere (the atmospheric pressure at sea level, which equals 760 mm Hg) for each 10 m. To prevent lung collapse, a diver must be supplied with air under pressure, exposing the lungs to very high alveolar gas pressures.

At sea level an adult human has about 1 L of nitrogen dissolved in the body, with about half in the fat and half in the body fluids. After a diver's body has been saturated with nitrogen at a depth of 100 m (325 ft), the body fluids contain about 10 L of nitrogen. To prevent this nitrogen from rapidly bubbling out of solution and causing decompression sickness, the diver must rise to the surface gradually, with stops at certain levels on the way up. This allows nitrogen to be expelled slowly through the lungs.

Some mammals are adapted for diving

Some air-breathing mammals can spend rather long periods in the ocean depths without coming up for air. Dolphins, whales, seals, and beavers have structural and physiological adaptations that allow them to dive for food or to elude their enemies (Fig. 44-12). With their streamlined bodies and forelimbs modified as fins or flippers, diving mammals perform impressive aquatic feats. The Weddell seal can swim under the ice at a depth of 596 m (1955 ft) for more than an hour without coming up for air. The enormous northern elephant seal, which measures about 5 m (16 to 18 ft) in length and weighs 2 to 4 tons, can plunge even deeper. A female elephant seal can dive to more than 1500 m (almost 5000 ft) and stay beneath the surface for more than an hour.

Turtles and birds that dive depend on oxygen stored in their lungs. Diving mammals do not take in and store extra air before a dive. In fact, seals exhale before they dive. With less air in their lungs, they are less buoyant. Their lungs collapse at about 50 to 70 m into their dive and then reinflate as they ascend. This means their lungs do not function for most of the dive. These adaptations are thought to reduce the chance of decompression sickness, because with less air in the lungs there is less nitrogen in the blood to dissolve during the dive.

Flip Nicklin/Minden Pictures

FIGURE **44-12** **Deep diver.**

Elephant seals (*Mirounga angustirostris*) may be the deepest divers on Earth. Researchers have recorded their dives at depths of more than 5,000 feet.

Physiologic adaptations, including ways to distribute and store oxygen, permit some mammals to dive deeply and remain under water for long periods. Seals have about twice the volume of blood, relative to their body weight, as nondiving mammals. Diving mammals also have high concentrations of myoglobin, which stores oxygen in muscles. These animals have up to 10 times more myoglobin than do terrestrial mammals. The very large spleen typical of many diving mammals stores oxygen-rich red blood cells. Under pressure (during a dive), the spleen is squeezed and releases these red blood cells into the circulation.

Diving mammals markedly reduce the energy expended in deep (more than 200 m) diving by gliding. Filmed video sequences of diving seals and whales show that they glide most of the way down. Gliding is possible because the animal's buoyancy decreases as the lungs gradually collapse, reducing the amount of air in the lungs.

When a mammal dives to its limit, physiological mechanisms known collectively as the **diving reflex** are activated. Metabolic rate decreases by about 20%, which conserves oxygen. Breathing stops, and bradycardia (slowing of the heart rate) occurs. The heart rate may decrease to one tenth of the normal rate, reducing the body's consumption of oxygen and energy. Blood is redistributed; skin, muscles, digestive organs, and other internal organs can survive with less oxygen and receive less blood while an animal is submerged.

The diving reflex is present to some extent in humans, where it may act as a protective mechanism during birth, when an infant may be deprived of oxygen for several minutes. Cases of near-drownings, especially of young children, have been documented in which the victim was submerged for as long as 45 minutes in very cold water before being rescued and resuscitated. Many of these survivors showed no brain damage. The shock of icy water slows heart rate, increases blood pressure, and shunts blood to internal organs of the body that most need oxygen (blood flow in arms and legs decreases). Metabolic rate decreases, so less oxygen is required.

Review

- What is the sequence of inhaled air flow through the respiratory structures in a mammal?
- What is the function of respiratory pigments? How do they work?
- Why does alveolar air differ in composition from atmospheric air? Explain.
- What physiological mechanisms bring about an increase in rate and depth of breathing during exercise? Why is such an increase necessary?

BREATHING POLLUTED AIR

Learning Objective

8 Describe the defense mechanisms that protect the lungs, and describe the effects of polluted air on the respiratory system.

Several defense mechanisms protect the delicate lungs from the harmful substances we breathe (Fig. 44-13). The hair in the

FIGURE **44-13** **Urban air pollution.**

Industry spews tons of pollutants into the atmosphere. Harmful gases, such as sulfur dioxide and nitrogen oxides, contribute to acid rain.

David Nunuk/Photo Researchers, Inc.

Smoking is the single most preventable cause of death in the United States. More than 440,000 adults die each year of tobacco-related causes. Tobacco smoke is by far the most important risk factor for lung cancer, the most common lethal cancer in the United States and in the world. Tobacco smoke is also an important risk factor for cardiovascular disease and a number of other diseases. Still, an estimated 26% of men and 21% of women ages 18 and over continue to smoke. Nonsmokers are also affected by tobacco smoke, which is a "portable" air pollutant. This secondhand smoke has been linked to death from lung cancer of about 3000 nonsmokers each year in the United States. The direct medical costs of tobacco use amount to more than $75 billion dollars annually

Nicotine is highly addictive. Like morphine, amphetamines, and cocaine, nicotine increases dopamine concentration and activates cells in the *nucleus accumbens,* an area at the base of the forebrain. This area helps integrate emotion, and dopamine may facilitate learning an association between the pleasurable effects of the drug and other stimuli such as the smell of smoke. In 2001, Eric Nestler of the University of Texas Southwestern Medical Center reported in *Science* that nicotine, like cocaine and other abused drugs, causes long-lasting changes in the brain. This researcher pointed out that cell signaling and other mechanisms underlying drug addiction are very similar to those of learning and memory. Investigators are searching for drugs that block the dopamine release caused by nicotine and other addictive drugs.

Here are some facts about smoking:

- The life of a 30-year-old who smokes 15 cigarettes a day is shortened by an average of more than five years.
- If you smoke more than one pack per day, you are about 20 times more likely to develop lung cancer than is a nonsmoker. According to the American Cancer Society, cigarette smoking causes more than 75% of all lung cancer deaths.
- If you smoke, you double your chances of dying from cardiovascular disease.
- If you smoke, you are 20 times more likely to develop chronic bronchitis and emphysema than is a nonsmoker.
- If you smoke, you have about 5% less oxygen circulating in your blood (because carbon monoxide binds to hemoglobin) than does a nonsmoker.
- If you smoke when you are pregnant, your baby will weigh about 6 ounces less at birth, and there is double the risk of miscarriage, stillbirth, and infant death.
- Infants whose parents smoke have double the risk of contracting pneumonia or bronchitis in their first year of life.
- Secondhand smoke causes up to 300,000 lung infections (such as pneumonia and bronchitis) in infants and young children each year.
- When smokers quit smoking, their risk of dying from chronic obstructive pulmonary disease, cardiovascular disease, or cancer gradually decreases. (Precise changes in risk depend on the number of years the person smoked, the number of cigarettes smoked per day, the age of starting to smoke, and the number of years since quitting.)
- Nicotine replacement with gum, patches, or nasal spray has been shown to be effective as an aid to smoking cessation, especially used with behavioral therapy. More recently certain antidepressants have been used to reduce the craving for nicotine.
- Almost every American who takes up smoking is a teenager—5000 every day, almost 2 million every year. Of children who begin smoking, 10% start by the fourth grade, and nearly two thirds start by the tenth grade.

nostrils, the ciliated mucous lining in the nose and pharynx, and the cilia-mucus elevator of the trachea and bronchi trap foreign particles in inspired air. One of the body's most rapid defense responses to breathing dirty air is **bronchial constriction.** In this process, the bronchial tubes narrow, increasing the chance that inhaled particles will land on the sticky mucous lining. Unfortunately, bronchial constriction narrows the airway so less air can reach the lungs, decreasing the amount of oxygen available to body cells. Fifteen puffs on a cigarette during a 5-minute period increases airway resistance as much as threefold, and this added resistance to breathing lasts more than 30 minutes. Chain-smokers and those who breathe heavily polluted air are in a state of chronic bronchial constriction.

Neither the smallest bronchioles nor the alveoli are equipped with mucus or ciliated cells. Foreign particles that get through other respiratory defenses and find their way into the alveoli may be engulfed by macrophages. The macrophages may then accumulate in the lymph tissue of the lungs. Lung tissues of chronic smokers and those who work in dirty industries burning fossil fuel, contain large blackened areas where carbon particles have been deposited (Fig. 44-14).

Continued insult to the respiratory system results in disease. Chronic bronchitis, pulmonary emphysema, and lung cancer have been linked to cigarette smoking and breathing polluted air. More than 75% of patients with **chronic bronchitis** have a history of heavy cigarette smoking (see *Focus On: The Effects of Smoking*). Victims of chronic bronchitis often develop **pulmonary emphysema,** a disease also most common in cigarette smokers. In this disorder, alveoli lose their elasticity, and walls between adjacent alveoli are destroyed. The surface area of the lung is so reduced that gas exchange is seriously impaired. Air is not expelled effectively, and stale air accumulates in the lungs. The emphysema victim struggles for every breath, and still the body does not get enough oxygen. To compensate, the right ven-

(a) Lungs and major bronchi of a nonsmoker. **(b)** Lungs and heart of a cigarette smoker. The dark spots in the lung tissue are particles of carbon, tar, and other substances that passed through the respiratory defenses and lodged in the lungs.

tricle of the heart pumps harder and becomes enlarged. Emphysema patients frequently die of heart failure.

Most patients with **chronic obstructive pulmonary disease (COPD),** a condition characterized by obstructed airflow, have both chronic bronchitis and emphysema. Asthma also contributes to COPD. People with asthma respond to inhaled stimuli with exaggerated bronchial constriction, and the airway is typically inflamed.

Cigarette smoking is also the main cause of **lung cancer.** More than 69 of the 4800 chemical compounds in tobacco smoke cause cancer in humans and animals. These carcinogenic substances irritate the cells lining the respiratory passages and alter their metabolic balance. Normal cells are transformed into cancer cells, which may multiply rapidly and invade surrounding tissues.

Review

- What mechanisms does the human respiratory system have for getting rid of inhaled dirt?
- What happens when so much dirty air is inhaled that these mechanisms cannot function effectively?

Biology Now™ Assess your understanding of **breathing polluted air** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Compare the advantages and disadvantages of gas exchange in air with those of gas exchange in water.

- Air contains a higher concentration of molecular oxygen than does water, and oxygen diffuses more rapidly through air than through water. Air is less dense and less viscous than water, so less energy is needed to move air over a gas exchange surface.
- Terrestrial animals have adaptations that protect their respiratory surfaces from drying.

2 Describe the following adaptations for gas exchange: body surface, tracheal tubes, gills, and lungs.

- Small aquatic animals exchange gases by diffusion, requiring no specialized respiratory structures.
- Some invertebrates, including most annelids, and a few vertebrates (many amphibians) exchange gases across the body surface.
- In insects and some other arthropods, air enters a network of **tracheal tubes,** or **tracheae,** through openings, called **spiracles,** along the body surface. Tracheal tubes branch and extend to all regions of the body.
- **Gills** are moist, thin projections of the body surface found mainly in aquatic animals. In chordates, gills are usually internal, located along the edges of the gill slits. In bony fishes an **operculum** protects the gills; A **countercurrent exchange system** maximizes diffusion of oxygen into the blood and diffusion of carbon dioxide out of blood.
- Animals carry on **ventilation,** the process of actively moving air or water over respiratory surfaces. Terrestrial vertebrates have **lungs** and some means of ventilating them. Most fishes do not have lungs but have a homologous swim bladder that permits the fish to control its buoyancy. Amphibians and reptiles have lungs with only some ridges or folds that increase surface area.
- In birds, the lungs have extensions, called **air sacs,** that act as bellows, drawing air into the system. Two cycles of inhalation and exhalation support a one-way flow of air through the lungs. Air flows from the outside into the posterior air sacs, to the lung, through the anterior air sacs, and then out of the body. Gas exchange takes place through the walls of the **parabronchi** in the lungs. A crosscurrent arrangement, in which blood flow is at right angles to the parabronchi, increases the amount of oxygen that enters the blood.

3 Trace the passage of oxygen through the human respiratory system from nostrils to alveoli.

- The mammalian respiratory system includes the lungs and a system of airways. A breath of air passes in sequence through the **nostrils, nasal cavities, pharynx, larynx, trachea, bronchi, bronchioles,** and **alveoli.** Each lung occupies a pleural cavity and is covered with a **pleural membrane.**

4 Summarize the mechanics and the regulation of breathing in humans, and describe gas exchange in the lungs and tissues.

- During breathing, the **diaphragm** contracts, expanding the chest cavity. The membranous walls of the lungs move outward along with the chest walls, lowering pressure within the lungs. Air from outside the body rushes in through the air passageways and fills the lungs until the pressure equals atmospheric pressure.
- **Tidal volume** is the amount of air moved into and out of the lungs with each normal breath. **Vital capacity** is the maximum volume that can be exhaled after the lungs fill to the maximum extent. The volume of air that remains in the lungs at the end of a normal expiration is the **residual capacity.**
- **Respiratory centers** in the medulla and pons regulate respiration. These centers are stimulated by **chemoreceptors** sensitive to an increase in carbon dioxide concentration. They also respond to an increase in hydrogen ions and to very low oxygen concentration.

SUMMARY WITH KEY TERMS *(continued)*

- Oxygen and carbon dioxide are exchanged between alveoli and blood by diffusion. The pressure of a particular gas determines its direction and rate of diffusion.
- **Dalton's law of partial pressures** explains that in a mixture of gases, the total pressure of the mixture is the sum of the pressures of the individual gases. Thus each gas in a mixture of gases exerts a **partial pressure,** the same pressure it would exert if it were present alone. The partial pressure of atmospheric oxygen, P_{O_2}, is 160 mm Hg at sea level.
- According to **Fick's law of diffusion,** the greater the difference in pressure on the two sides of a membrane and the larger the surface area, the faster the gas diffuses across the membrane.

5 Explain the role of hemoglobin in oxygen transport, and identify factors that determine and influence the oxygen–hemoglobin dissociation curve.

- **Hemoglobin** is the respiratory pigment in the blood of vertebrates. Almost 99% of the oxygen in human blood is transported as **oxyhemoglobin (HbO_2).**
- The maximum amount of oxygen that can be transported by hemoglobin is the **oxygen-carrying capacity.** The actual amount of oxygen bound to hemoglobin is the **oxygen content.** The **percent O_2 saturation,** the ratio of oxygen content to oxygen-carrying capacity, is highest in pulmonary capillaries, where oxygen concentration is greatest.
- The **oxygen–hemoglobin dissociation curve** shows that as oxygen concentration increases, there is a progressive increase in the amount of hemoglobin that combines with oxygen. The curve is affected by pH, temperature, and CO_2 concentration.
- Owing to lowered pH caused by carbonic acid, oxyhemoglobin dissociates more readily as carbon dioxide concentration increases. This is the **Bohr effect.**

6 Summarize the mechanisms by which carbon dioxide is transported in the blood.

- About 60% of the carbon dioxide in the blood is transported as bicarbonate ions. About 30% combines with hemoglobin, and another 10% is dissolved in plasma.
- Carbon dioxide combines with water to form carbonic acid; the reaction is catalyzed by **carbonic anhydrase.** Carbonic acid dissociates, forming bicarbonate ions (HCO_3^-) and hydrogen ions (H^+).
- Hemoglobin combines with H^+, buffering the blood. Many bicarbonate ions diffuse into the plasma and are replaced by Cl^- ions; this exchange is known as the **chloride shift.**

7 Describe the physiological effects of hyperventilation and of sudden decompression when a diver surfaces too quickly from deep water.

- **Hyperventilation** reduces the concentration of carbon dioxide in the alveolar air and in the blood. A certain carbon dioxide concentration in the blood is needed to maintain normal blood pressure.
- As altitude increases, barometric pressure (the pressure of Earth's atmosphere) falls, and less oxygen enters the blood. This situation can lead to **hypoxia,** or oxygen deficiency, which can lead to loss of consciousness and death. In addition to hypoxia, rapid decrease in barometric pressure can cause **decompression sickness,** especially common among divers who ascend too rapidly from a dive.
- Diving mammals have high concentrations of **myoglobin,** a pigment that stores oxygen, in their muscles. The **diving reflex,** a group of physiological mechanisms (including a decrease in metabolic rate) is activated when a mammal dives to its limit.

8 Describe the defense mechanisms that protect the lungs, and describe the effects of polluted air on the respiratory system.

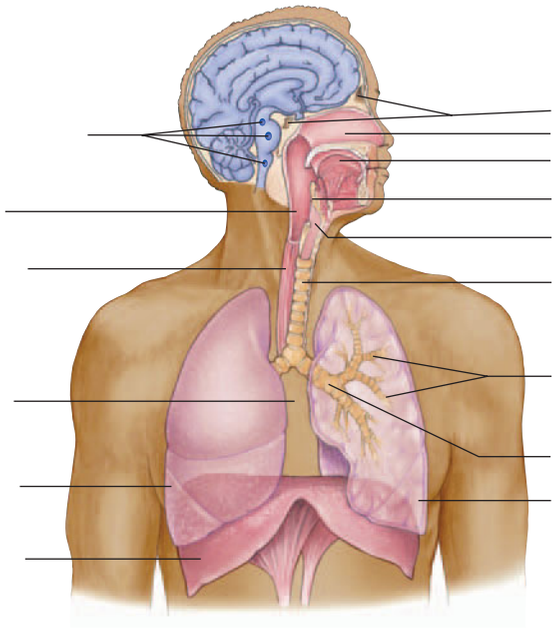
- The ciliated mucous lining of the nose, pharynx, trachea, and bronchi trap inhaled particles.
- Inhaling polluted air results in **bronchial constriction,** increased mucous secretion, damage to ciliated cells, and coughing. Breathing polluted air or inhaling cigarette smoke can cause **chronic bronchitis, pulmonary emphysema,** and **lung cancer.**

POST-TEST

1. Breathing is an example of (a) countercurrent exchange (b) cellular respiration (c) ventilation (d) diffusion (e) gas exchange through the body surface
2. Which of the following is a benefit of gas exchange in air compared with water? (a) higher concentration of molecular oxygen (b) oxygen diffuses more slowly in air (c) no energy required for ventilation (d) moist respiratory surface not needed (e) air is denser than water
3. Which of the following adaptations for gas exchange is most characteristic of insects? (a) lungs (b) tracheal tubes (tracheae) (c) parabronchi (d) air sacs (e) dermal gills
4. Which of the following are accurately matched? (a) bony fish—operculum (b) insect—alveoli (c) bird—spiracles (d) mammal—gill filaments (e) shark—dermal gills
5. Tracheal tubes (tracheae) (a) are typically found in mollusks (b) are highly vascular (c) branch and extend to all the cells (d) are characteristic of many mammals (e) end in book lungs
6. The most efficient vertebrate respiratory system is that of (a) amphibians (b) birds (c) reptiles (d) mammals (e) humans
7. In a bird, the correct sequence for a breath of air is (a) anterior air sacs ⟶ posterior air sacs ⟶ lung (b) posterior air sacs ⟶ lung ⟶ anterior air sacs (c) parabronchi ⟶ posterior air sacs ⟶ anterior air sacs (d) posterior air sacs ⟶ alveoli ⟶ anterior air sacs (e) posterior air sacs ⟶ capillaries ⟶ cells
8. Respiratory pigments (a) combine reversibly with oxygen (b) are found only in vertebrates (c) all have a heme (porphyrin) group that combines with oxygen (d) diffuse into the air sacs (e) attach to the alveolar wall
9. Which sequence most accurately describes the sequence of air flow in the human respiratory system? (a) pharynx ⟶ bronchus ⟶ trachea ⟶ alveolus (b) pharynx ⟶ parabronchi ⟶ alveoli ⟶ bronchioles (c) bronchus ⟶ trachea ⟶ larynx ⟶ lung (d) larynx ⟶ trachea ⟶ bronchus ⟶ bronchiole (e) trachea ⟶ larynx ⟶ bronchus ⟶ alveolus

POST-TEST *(continued)*

10. The amount of air moved in and out of the lungs with each normal resting breath is the (a) vital capacity (b) residual capacity (c) vital volume (d) partial pressure (e) tidal volume
11. The greater the difference in pressure and the larger the surface area, the faster a gas will diffuse. This is explained by (a) Dalton's law of partial pressure (b) Fick's law of diffusion (c) the percent saturation (d) the Bohr effect (e) the oxygen–hemoglobin dissociation curve
12. Oxygen in the blood is transported mainly (a) in combination with hemoglobin (b) as bicarbonate ions (c) as carbonic acid (d) dissolved in plasma (e) combined with carbon dioxide
13. The concentration of which of the following substances is most important in regulating the rate of respiration? (a) chloride ions (b) oxygen (c) bicarbonate ions (d) nitrogen (e) carbon dioxide
14. When a diver ascends too rapidly (a) bronchial constriction occurs (b) a diving reflex is activated (c) nitrogen rapidly bubbles out of solution in the body fluids (d) nitrogen hypoxia occurs (e) carbon dioxide bubbles damage the alveoli
15. Which of the following is *not* true of the diving reflex? (a) breathing stops (b) the heart slows (c) less blood is distributed to the muscles (d) metabolic rate increases by about 20% (e) energy consumption decreases
16. Pulmonary emphysema (a) results from chronic obstructive pulmonary disease (b) is uncommon in cigarette smokers (c) results from bronchial constriction (d) is sometimes referred to as the Bohr effect (e) is characterized by loss of elasticity of the alveolar walls
17. Label the figure. Use Fig. 44-6 to check your answers.



CRITICAL THINKING

1. What problems would be faced by a terrestrial animal having gills instead of lungs?
2. Under what conditions might it be advantageous for a fish to have lungs as well as gills? What function do the "lungs" of modern fishes serve?
3. Aquatic mammals such as whales and dolphins use lungs rather than gills for gas exchange. Propose a hypothesis to explain this.
4. What are the advantages of having millions of alveoli rather than a pair of simple, balloon-like lungs?

Processing Food and Nutrition

CHAPTER OUTLINE

- Nutritional Styles and Adaptations
- The Vertebrate Digestive System
- Required Nutrients
- Energy Metabolism

Sponges and baleen whales feed on food particles suspended in the water. Giraffes eat leaves, and antelope graze on grasses. Frogs, lions, and some insects capture other animals. Although their choices of food and feeding mechanisms are diverse, all animals are **heterotrophs,** organisms that must obtain their energy and nourishment from the organic molecules manufactured by other organisms. What they eat, how they obtain food, and how they process and use food are the focus of this chapter.

Nutrients are substances in food that are used as energy sources to run the systems of the body, as ingredients to make compounds for metabolic processes, and as building blocks in the growth and repair of tissues. Obtaining nutrients is of such vital importance that both individual organisms and ecosystems are structured around the central theme of **nutrition,** the process of taking in and using food. An organism's body plan and its lifestyle are adapted to its particular mode of obtaining food. For example, spotted hyenas, which are formidable predators as well as scavengers, have massive jaws that let them consume an entire elephant carcass, including bones and hide (see photograph). Few nutrients are wasted.

Nutrition has also been an important force in human evolution. Through natural selection, the human diet became more varied than the diets of other primates. Humans also became very efficient at obtaining food. Their higher-quality diet supported the evolution of a larger, more complex brain.

With only slight variations, all animals require the same basic nutrients: minerals, vitamins, carbohydrates, lipids, and proteins. Carbohydrates, lipids, and proteins are used as energy sources. Eating too much of any of these nutrients can result in weight gain, whereas eating too few nutrients or an unbalanced diet can result in malnutrition and death. **Malnutrition,** or poor nutritional status, results from dietary intake that is either below or above required needs. In human populations, both undernutrition (particularly protein deficiency) and obesity (which results from overnutrition) are serious health problems.

Food processing and nutrition are active areas of research. For example, researchers investigating the regulation of digestion are discovering a number of peptide messengers in the digestive tract. Nutritionists are studying a variety of plant compounds that may be important in maintaining health. And the food industry continues to search for new fat and sugar substitutes. ■

NUTRITIONAL STYLES AND ADAPTATIONS

Learning Objective

1 Describe food processing, including ingestion, digestion, absorption, and egestion or elimination, and compare the digestive system of a cnidarian (such as *Hydra*) with that of an earthworm or vertebrate.

Feeding is the selection, acquisition, and ingestion of food. **Ingestion** is the process of taking food into the digestive cavity. In many animals, including vertebrates, ingestion includes taking food into the mouth and swallowing it. Most animals have a specialized digestive system that processes the food they eat. The process of breaking down food is called **digestion.** Because animals eat the macromolecules tailor-made by and for other organisms, they must break down these molecules and refashion them for their own needs. For example, a hyena cannot incorporate the proteins and other complex organic compounds from an elephant carcass directly into its own cells. It must *mechanically digest* its food, and then *chemically digest* it by enzymatic hydrolysis (see Chapter 3). During digestion, complex organic compounds are degraded into smaller molecular components. For example, proteins are broken down into their component amino acids.

Amino acids and other nutrients pass through the lining of the digestive tract and into the blood by **absorption.** Then the circulatory system transports them to the body cells. In the cells they are used to synthesize proteins and other complex organic compounds that the animal needs. Food that is not digested and absorbed is discharged from the body. Biologists call this process **egestion** in simple animals and **elimination** in more complex animals.

Animals are adapted to their mode of nutrition

We classify animals as herbivores, carnivores, or omnivores on the basis of the type of food they typically eat (Fig. 45-1). Animals that feed directly on producers are **herbivores,** or primary consumers. Animals cannot digest the cellulose of plant cell walls, and many adaptations have evolved for extracting nutrients from the plant material they eat. Many herbivores, including termites, cows, and horses, have a symbiotic relationship with bacteria that inhabit their digestive tracts. For example, cud-chewing ruminants (cattle, sheep, deer, giraffes), have a stomach divided into four chambers. Bacteria living in the first two chambers digest cellulose, splitting some of it into sugars, which are then used by the host and the bacteria themselves. The bacteria produce fatty acids during their metabolism, some of which are absorbed by the animal and serve as an important energy source. Food that is not sufficiently chewed, called cud, is regurgitated into the animal's mouth and chewed again.

Most of what a herbivore eats is not efficiently digested and is eliminated from the body, almost unchanged, as waste. For this reason herbivores must eat large quantities of food to obtain the nourishment they need. Many herbivores—grasshoppers, locusts, elephants, and cattle, for example—spend a major part of their lives eating.

Herbivores are sometimes eaten by flesh-eating **carnivores,** which may also eat one another. Many carnivores (secondary and higher-level consumers in ecosystems) are predators, adapted for capturing and killing prey. Some carnivores seize their victims and swallow them alive and whole (Fig. 45-1d). Others paralyze, crush, or shred their prey before ingesting it. Carnivorous mammals have well-developed canine teeth for stabbing their prey during combat. The digestive juice of the stomach breaks down proteins, and because meat is more easily digested than plant food, their digestive tracts are shorter than those of herbivores.

Omnivores, such as bears and humans, consume both plants and animals. Earthworms ingest large amounts of soil containing both animal and plant material. The blue whale, the largest animal, is a filter feeder that strains out tiny algae and animals as it swims. Omnivores often have adaptations that help them distinguish among a wide range of smells and tastes and thereby select a variety of foods.

Animals can also be classified according to the mechanisms they use to feed. Many omnivores are **suspension feeders** that remove suspended food particles from the water. Some animals expose a sticky, mucus-coated surface to flowing water; suspended particles adhere to the surface. For example, some echinoderms have tentacles coated with mucus. Others, like bivalve mollusks, filter water. Baleen whales use rows of hard plates (baleen) suspended from the roof of the mouth to filter small crustaceans.

Some animals feed on fluids by piercing and sucking. Mosquitos have highly adapted structures for piercing skin and sucking blood. Birds that feed on pollen and nectar have long bills and tongues. The shape, size, and curve of the beak may be specialized for feeding on a particular type of flower (see Fig. 19-15). Bats that feed on nectar have a long tongue and reduced dentition (number of teeth).

Many animals, including carnivores, ingest large pieces of food. Adaptations for this type of feeding include claws, fangs, poison glands, tentacles, and teeth. The beaks of birds and the teeth of many vertebrates are specialized for cutting, tearing, or chewing food.

Some invertebrates have a digestive cavity with a single opening

The simplest invertebrates, sponges, obtain food by filtering microscopic organisms from the surrounding water. Individual

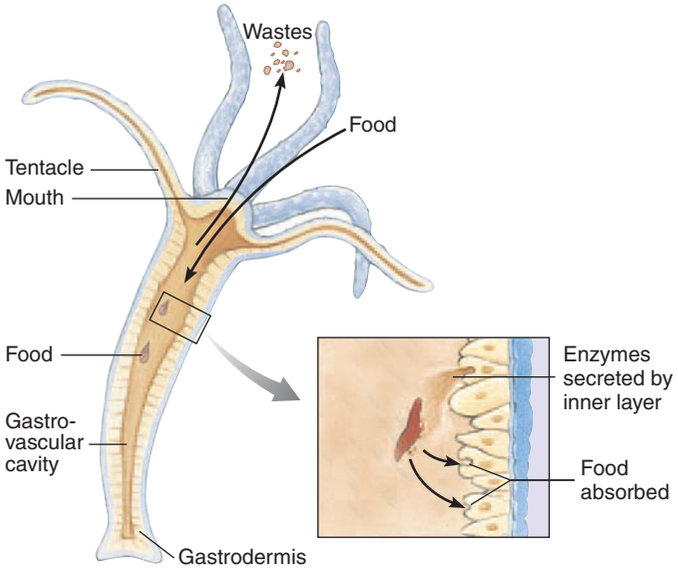
FIGURE **45-1** **Adaptations for obtaining and processing food.**

(a) The impressively long "snout" of the herbivorous acorn weevil (*Curculio*) is adapted both for feeding and for making a hole in the acorn through which it deposits an egg. When it has hatched, the larva feeds on the contents of the acorn seed. **(b)** The herbivorous giant panda's (*Ailuropoda melanoleuca*) large, flat teeth and well-developed jaws and jaw muscles are adaptations for grinding high-fiber plant food. **(c)** The mouth *(on left)* of the carnivorous long-nose butterfly fish (*Forcipiger longirostris*) is adapted for extracting small worms and crustaceans from tight spots in coral reefs. **(d)** This carnivorous snake (*Dromicus*) is strangling a lava lizard (*Tropidurus*).

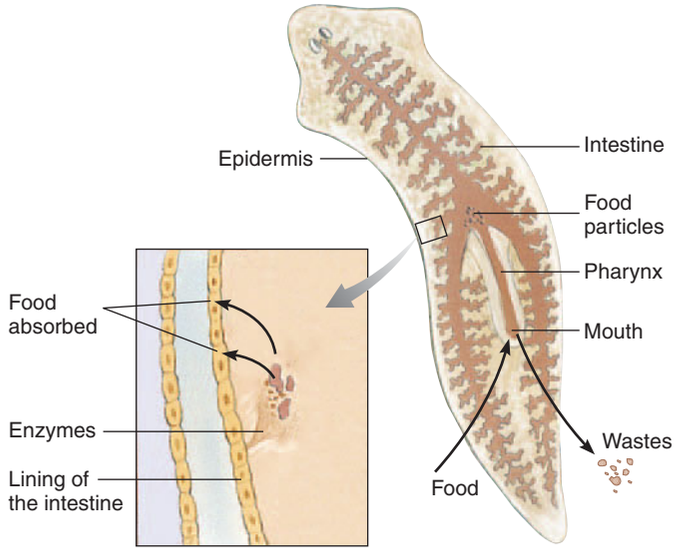
cells phagocytize the food particles, and digestion is *intracellular* within food vacuoles. Wastes are egested into the water that continuously circulates through the sponge body.

Most animals have a digestive cavity. Digestion within a cavity is more efficient than intracellular digestion because digestive enzymes can be released into one confined space, and less surface area is required. Cnidarians (such as hydras and jellyfish) and flatworms have a **gastrovascular cavity,** a central digestive cavity with a single opening. Cnidarians capture small aquatic animals with the help of their stinging cells and tentacles (Fig. 45-2a). The mouth opens into the gastrovascular cavity. Cells lining this digestive cavity secrete enzymes that break down proteins. Digestion continues *intracellularly* within food vacuoles, and digested nutrients diffuse into other cells. Body contractions promote egestion of undigested food particles through the mouth.

Free-living flatworms begin to digest their prey even before ingesting it. They extend their pharynx out through their mouth and secrete digestive enzymes onto the prey (Fig. 45-2b). When ingested, the food enters the branched gastrovascular cavity, where enzymes continue to digest it. Partly digested food frag-



(a) Hydra



(b) Flatworm

FIGURE **45-2** **Simple invertebrate digestive systems.**

(a) Hydras and **(b)** flatworms (planarians) have digestive tracts with a single opening that serves as both mouth and anus.

ments are then phagocytized by cells lining the gastrovascular cavity, and digestion is completed within food vacuoles. As in cnidarians, the flatworm digestive cavity has only one opening, so undigested wastes are egested through the mouth.

Most animal digestive systems have two openings

Most invertebrates, and all vertebrates, have a tube-within-a-tube body plan. The body wall forms the outer tube. The inner tube is a digestive tract with two openings, sometimes referred to as a complete digestive system (Fig. 45-3). Food enters through

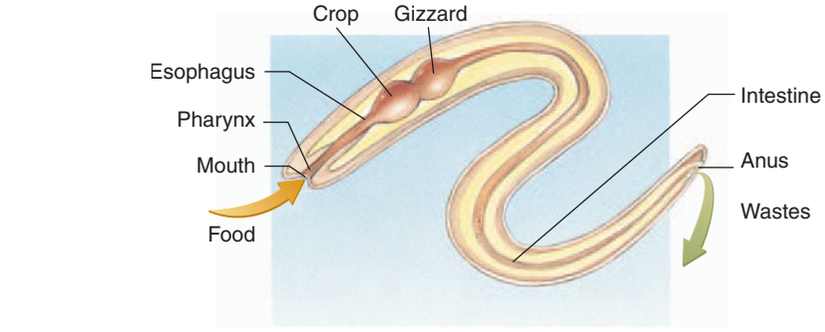


FIGURE **45-3** **Digestive tract with two openings.**

The earthworm, like most complex animals, has a complete digestive tract extending from mouth to anus. Various regions of the digestive tract are specialized to perform different food processing functions.

the mouth, and undigested food is eliminated through the anus. **Motility** is the mixing and propulsive movements of the digestive tract. The propulsive activity characteristic of most regions of the digestive tract is **peristalsis,** waves of muscular contraction that push the food in one direction. More food can be taken in while previously eaten food is being digested and absorbed farther down the digestive tract. In a digestive tract with two openings, various regions of the tube are adapted to perform specific functions.

Review

- How have carnivores adapted to their mode of nutrition?
- How does food processing differ in earthworms and flatworms?

BiologyNow™ Assess your understanding of **nutritional styles and adaptations,** by taking the pretest on your BiologyNow CD-ROM.

THE VERTEBRATE DIGESTIVE SYSTEM

Learning Objectives

2 Trace the pathway traveled by an ingested meal in the human digestive system, describing the structure and function of each organ involved.

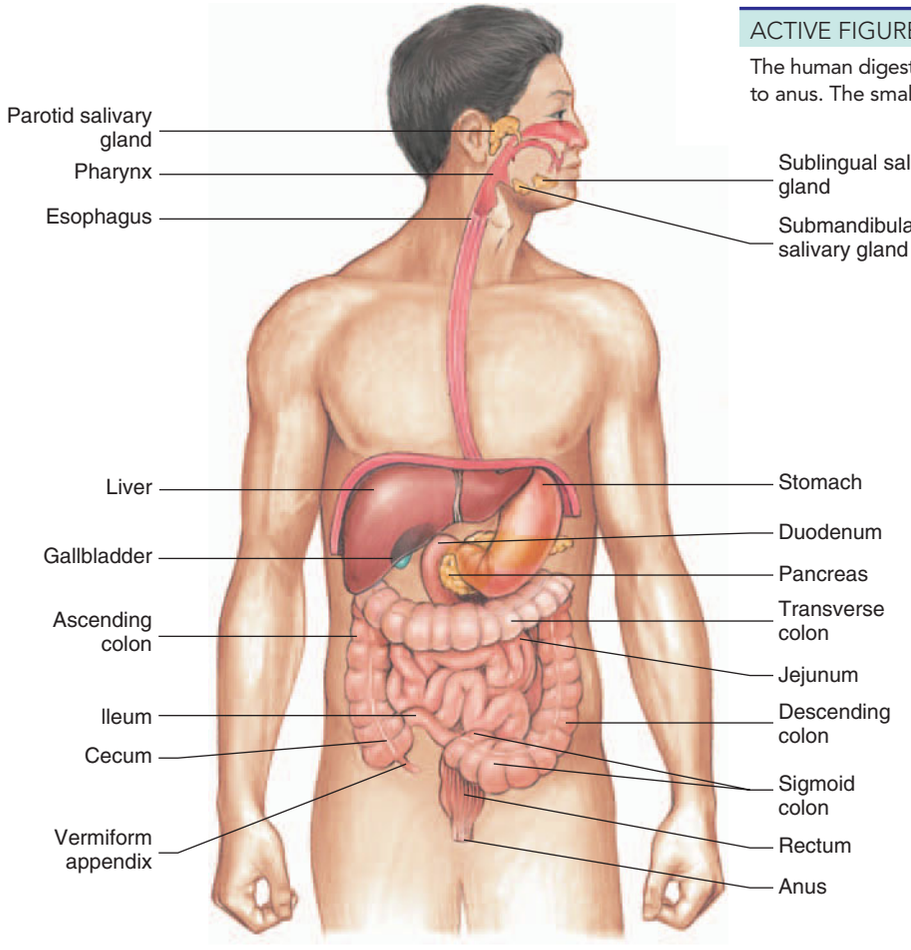
3 Describe the step-by-step digestion of carbohydrate, protein, and lipid.

4 Describe the structural adaptations that increase the surface area of the digestive tract.

5 Compare lipid absorption with absorption of other nutrients.

Various regions of the vertebrate digestive tract are specialized to perform specific functions (Fig. 45-4). Food passes in sequence through the following specialized regions:

Mouth ⟶ pharynx (throat) ⟶ esophagus ⟶ stomach ⟶ small intestine ⟶ large intestine ⟶ anus



ACTIVE FIGURE **45-4** **Human digestive system.**

The human digestive tract is a long, coiled tube extending from mouth to anus. The small intestine consists of the duodenum, jejunum, and ileum. The large intestine includes the cecum, colon, rectum, and anus. Locate the three types of accessory glands: the liver, pancreas, and salivary glands.

BiologyNow™ Learn more about **human digestion** by clicking on this figure on your BiologyNow CD-ROM.

Food processing begins in the mouth

Imagine you have just taken a big bite of a hamburger. The mouth is specialized for ingestion and for beginning the digestive process. Mechanical digestion begins as you bite, grind, and chew the meat and bun with your teeth. Unlike the simple, pointed teeth of fish, amphibians, and reptiles, the teeth of mammals vary in size and shape and are specialized to perform specific functions. The chisel-shaped **incisors** are used for biting, whereas the long, pointed **canines** are adapted for tearing food (Fig. 45-6). The flattened surfaces of the **premolars** and **molars** are specialized for crushing and grinding.

Each tooth is covered by **enamel,** the hardest substance in the body (Fig. 45-7). Most of the tooth consists of **dentin,** which resembles bone in composition and hardness. Beneath the dentin is the **pulp cavity,** a soft connective tissue containing blood vessels, lymph vessels, and nerves.

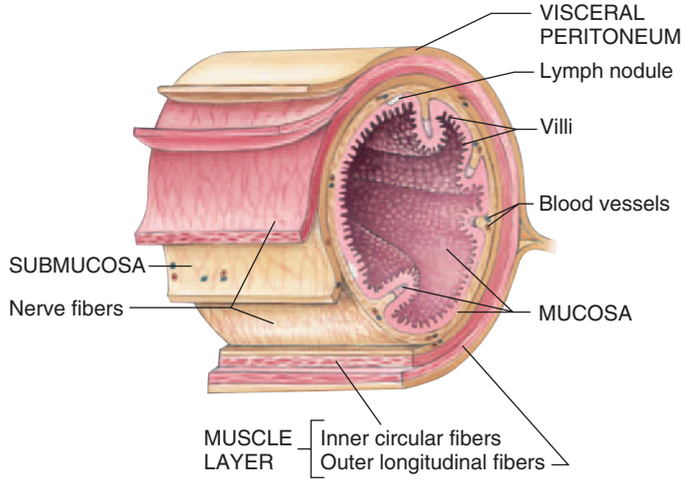
Vertebrates have accessory glands that secrete digestive juices into the digestive tract. These include the liver, the pancreas, and, in terrestrial vertebrates, the salivary glands.

The wall of the digestive tract has four layers. Although various regions differ somewhat in structure, the layers are basically similar throughout the digestive tract (Fig. 45-5). The **mucosa,** a layer of epithelial tissue and underlying connective tissue, lines the *lumen* (inner space) of the digestive tract. In the stomach and intestine, the mucosa is greatly folded to increase the secreting and absorbing surface. Surrounding the mucosa is the **submucosa,** a connective tissue layer rich in blood vessels, lymphatic vessels, and nerves.

A **muscle layer,** consisting of two sublayers of smooth muscle, surrounds the submucosa. In the inner sublayer, the muscle fibers are arranged circularly around the digestive tube. In the outer sublayer the muscle fibers are arranged longitudinally. Below the level of the diaphragm, the outer connective tissue coat of the digestive tract is called the **visceral peritoneum.** By various folds it is connected to the **parietal peritoneum,** a sheet of connective tissue that lines the walls of the abdominal and pelvic cavities. The visceral and parietal peritonea enclose part of the coelom called the **peritoneal cavity.** Inflammation of the peritoneum, called **peritonitis,** can be very serious, because infection can spread along the peritoneum to most of the abdominal organs.

FIGURE **45-5** **Wall of the digestive tract.**

From inside out, the layers of the wall are the mucosa, submucosa, muscle layer, and visceral peritoneum.



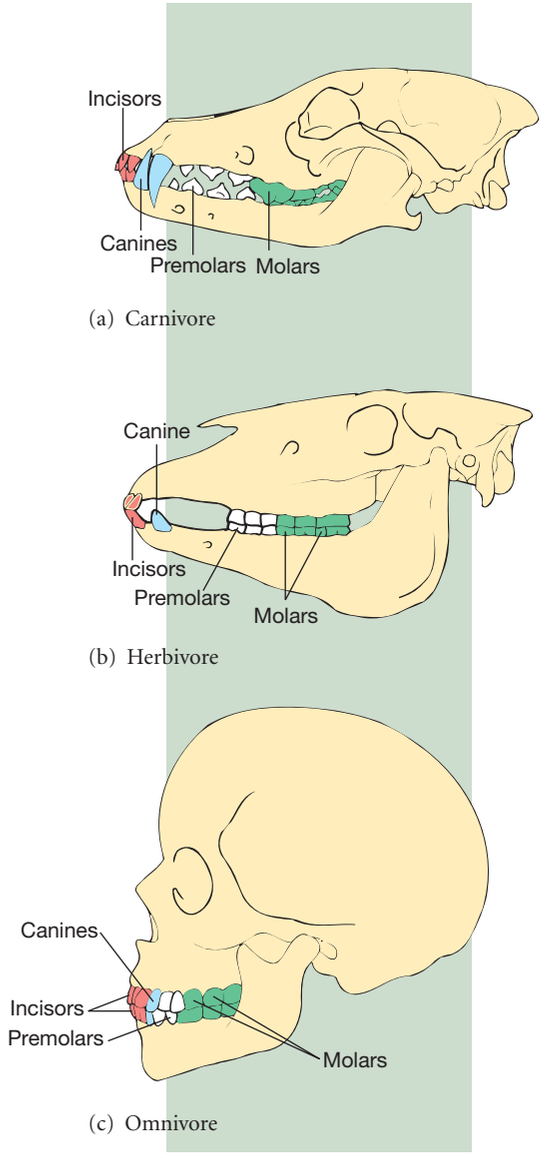


FIGURE **45-6** **Teeth and diet.**

(a) Skull of a coyote showing the pointed incisors and canines, adaptations for ripping flesh. **(b)** In contrast, herbivores, such as horses, have incisors (and sometimes canines) adapted for cutting off bits of vegetation. Canines are absent in some herbivores. The broad, ridged surfaces of the molars are adapted for grinding plant material. **(c)** The teeth of omnivores, such as humans, are adapted for chewing a variety of foods.

While food is being mechanically disassembled by the teeth, it is moistened by saliva. Some of the food molecules dissolve, enabling you to taste the food. Recall from Chapter 41 that taste buds are located on the tongue and other surfaces of the mouth. Three pairs of **salivary glands** secrete about a liter of saliva into the mouth cavity each day. Saliva contains an enzyme, **salivary amylase,** which begins the chemical digestion of starch into sugar.

The pharynx and esophagus conduct food to the stomach

After being chewed and fashioned into a lump called a **bolus,** the bite of food is swallowed—moved through the **pharynx** into the **esophagus.** The pharynx, or throat, is a muscular tube that serves as the hallway of both the respiratory system and the digestive system. During swallowing, a small flap of tissue, the **epiglottis,** closes the opening to the airway.

Waves of peristalsis sweep the bolus through the pharynx and esophagus toward the stomach (Fig. 45-8). Circular muscle fibers in the wall of the esophagus contract around the top of the bolus, pushing it downward. Almost at the same time, longitudinal muscles around the bottom of the bolus and below it contract, shortening the tube.

When the body is in an upright position, gravity helps move the food through the esophagus, but gravity is not essential. Astronauts eat in its absence, and even if you are standing on your head, food will reach your stomach.

Food is mechanically and enzymatically digested in the stomach

The entrance to the large, muscular **stomach** is normally closed by a ring of muscle at the lower end of the esophagus. When a peristaltic wave passes down the esophagus, the muscle relaxes, permitting the bolus to enter the stomach (Fig. 45-9). When empty, the stomach is collapsed and shaped almost like a hot dog. Folds of the stomach wall, called **rugae,** give the inner lining a wrinkled appearance. As food enters, the rugae gradually smooth out, expanding the capacity of the stomach to more than a liter.

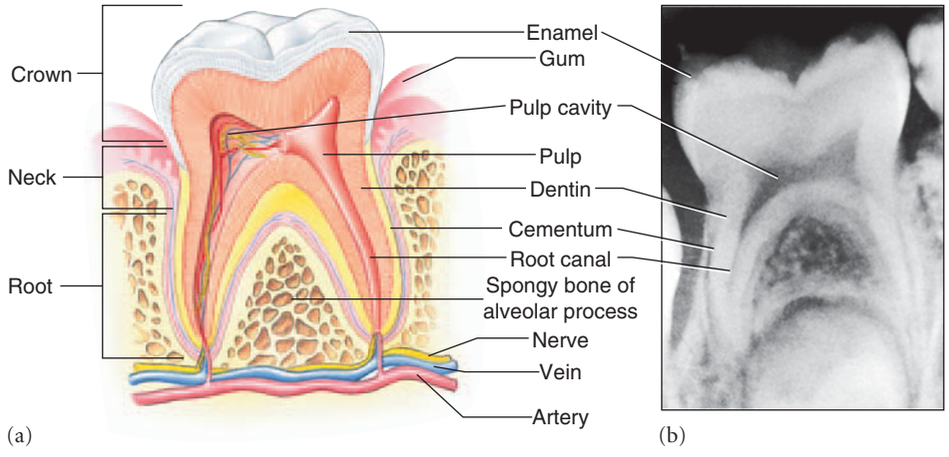

FIGURE **45-7** **Tooth structure.**

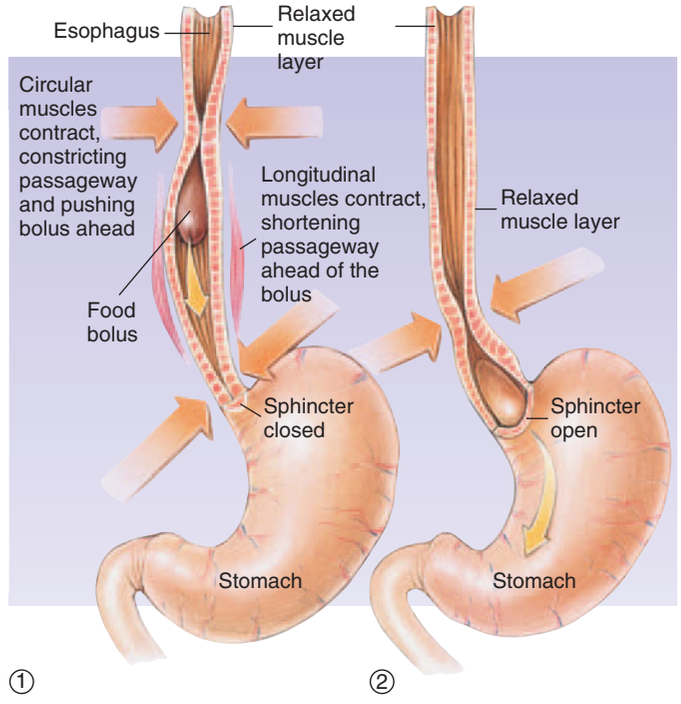
(a) Sagittal section through a human lower molar showing the crown, neck, and root. **(b)** X-ray of a healthy tooth.

FIGURE **45-8** **Peristalsis.**

Food is moved through the digestive tract by waves of muscular contractions known as *peristalsis*. ① A bolus is moved down through the esophagus by peristaltic contractions. ② When the sphincter (ring of muscle) at the entrance of the stomach opens, food enters the stomach.



The stomach is lined with a simple, columnar epithelium that secretes large amounts of mucus. Tiny pits mark the entrances to the millions of **gastric glands,** which extend deep into the stomach wall. **Parietal cells** in the gastric glands secrete hydrochloric acid and *intrinsic factor,* a substance needed for adequate absorption of vitamin B_{12}. **Chief cells** in the gastric glands secrete **pepsinogen,** an inactive enzyme precursor. When pepsinogen comes in contact with the acidic gastric juice in the stomach, it is converted to **pepsin,** the main digestive enzyme of the stomach. Pepsin hydrolyzes proteins, converting them to short polypeptides.

Several protective mechanisms prevent the gastric juice from digesting the wall of the stomach. Cells of the gastric mucosa secrete an alkaline mucus that coats the stomach wall and neutralizes the acidity of the gastric juice along the lining. In addition, the epithelial cells of the lining fit tightly together, preventing gastric juice from leaking between them and into the tissue beneath. If some of the epithelial cells become damaged, they are quickly replaced. In fact, about a half million of these cells are shed and replaced every minute!

Sometimes, these protective mechanisms malfunction and part of the stomach lining is digested, leaving an open sore, or **peptic ulcer.** Such ulcers often occur in the duodenum and sometimes in the lower part of the esophagus. The bacterium *Helicobacter pylori* has been implicated as a causative factor in ulcers. *H. pylori* infects the mucus-secreting cells of the stomach lining, decreasing the protective mucus, which can lead to peptic ulcers or cancer. *H. pylori* infection responds to antibiotic therapy.

What changes occur in a bite of hamburger during its three- to four-hour stay in the stomach? The stomach churns and chemically degrades the

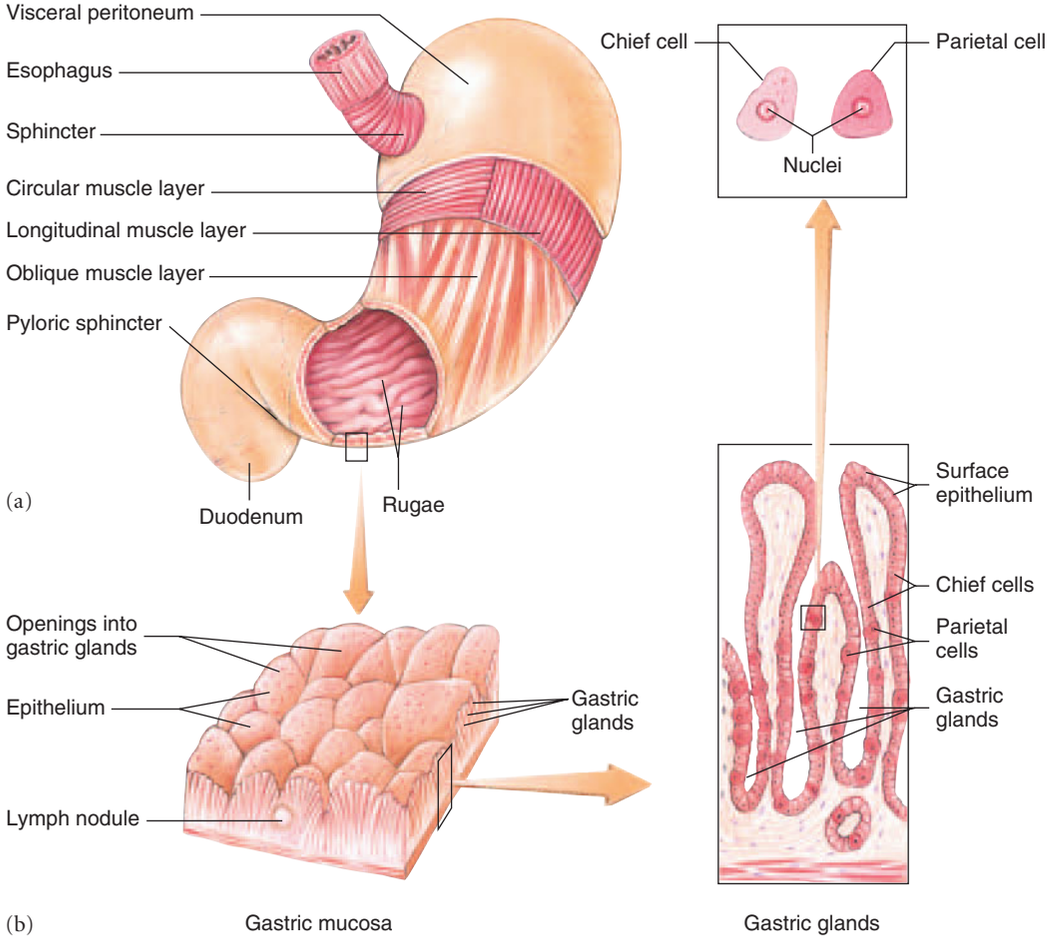


FIGURE **45-9**

Structure of the stomach.

From the esophagus, food enters the stomach, where it is mechanically and enzymatically digested. **(a)** The wall of the stomach has been progressively removed to show muscle layers and rugae. **(b)** Stomach lining and gastric glands.

food so that it assumes the consistency of a thick soup; this partially digested food is called **chyme.** Protein digestion then degrades much of the hamburger protein to polypeptides. Digestion of the starch in the bun to small polysaccharides and maltose continues until salivary amylase is inactivated by the acidic pH of the stomach. Over a period of several hours, peristaltic waves release the chyme in spurts through the stomach exit, the **pylorus,** and into the small intestine.

Most enzymatic digestion takes place in the small intestine

Digestion of food is completed in the **small intestine,** and nutrients are absorbed through its wall. The small intestine, which is 5 to 6 m (about 17 ft) in length, has three regions: the **duodenum, jejunum,** and **ileum.** Most chemical digestion takes place in the duodenum, the first portion of the small intestine, not in the stomach. Bile from the liver and enzymes from the pancreas are released into the duodenum and act on the chyme. Then enzymes produced by the epithelial cells lining the duodenum catalyze the final steps in the digestion of the major types of nutrients.

The lining of the small intestine appears velvety because of its millions of tiny finger-like projections, the intestinal **villi** (sing., *villus*) (Fig. 45-10). The villi increase the surface area of the small intestine for digestion and absorption of nutrients. The intestinal surface is further expanded by thousands of **microvilli,** folds of cytoplasm on the exposed surface of the simple columnar epithelial cells of the villi. About 600 microvilli protrude from the surface of each cell, giving the epithelial lining a fuzzy appearance when viewed with the electron microscope.

KEY CONCEPT: The digestive and absorptive surface area of the small intestine is vastly increased by millions of finger-like villi; the surface area is further increased by microvilli on the epithelial cells of the villi.

If the intestinal lining were smooth, like the inside of a water pipe, food would zip right through the intestine, and many valuable nutrients would not be absorbed. Folds in the wall of the intestine, the villi, and microvilli together increase the surface area of the small intestine by about 600 times. If we could unfold and spread out the lining of the small intestine of an adult human, its surface would approximate the size of a tennis court.

The liver secretes bile

The **liver,** the largest internal organ and also one of the most complex organs in the body, lies in the upper right part of the abdomen just under the diaphragm (Fig. 45-11). A single liver cell can carry on more than 500 separate, specialized metabolic activities. The liver:

1. Secretes **bile,** which is important in the mechanical digestion of fats
2. Helps maintain homeostasis by removing or adding nutrients to the blood
3. Converts excess glucose to glycogen and stores it
4. Converts excess amino acids to fatty acids and urea
5. Stores iron and certain vitamins
6. Detoxifies alcohol and other drugs and poisons

Bile consists of water, bile salts, bile pigments, cholesterol, salts, and lecithin (a phospholipid). The pear-shaped gallbladder stores and concentrates the bile, and releases it into the duodenum as needed. Bile mechanically digests fats by a detergent-like action (discussed in a later section). Because it contains no digestive enzymes, bile does not enzymatically digest food.

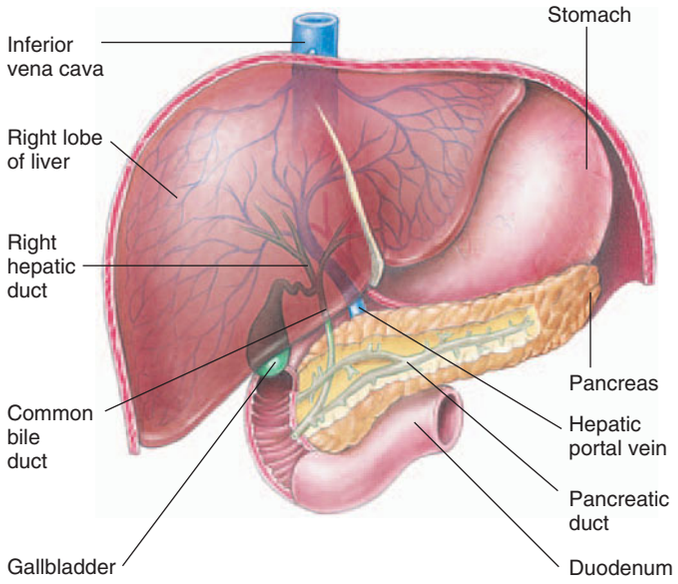

FIGURE **45-11** **The liver and pancreas.**
The gallbladder stores bile from the liver. Note the ducts that conduct bile to the gallbladder and the duodenum. The stomach has been displaced to expose the pancreas.

The pancreas secretes digestive enzymes

The **pancreas** is an elongated gland that secretes both digestive enzymes and hormones that help regulate the level of glucose in the blood. Among its enzymes are **trypsin** and **chymotrypsin,** which digest polypeptides to dipeptides; **pancreatic lipase,** which degrades fats; **pancreatic amylase,** which breaks down almost all types of carbohydrates, except cellulose, to disaccharides; and **ribonuclease** and **deoxyribonuclease,** which split the nucleic acids ribonucleic acid (RNA) and deoxyribonucleic acid (DNA) to free nucleotides.

Nutrients are digested as they move through the digestive tract

Chyme moves through the digestive tract by peristalsis, mixing contractions, and motions of the villi. Nutrients in the chyme come into contact with enzymes that digest them (Table 45-1).

TABLE **45-1** **Summary of Digestion**

	Carbohydrates	Proteins	Lipids
Mouth	Polysaccharides ↓ Salivary amylase Maltose and small polysaccharides		
Stomach	Action continues until acidic pH inactivates salivary amylase	Protein ↓ Pepsin Short polypeptides	
Small intestine	Undigested polysaccharides ↓ Pancreatic amylase Maltose and other disaccharides ↓ Maltase, sucrase, lactase Monosaccharides	Polypeptides ↓ Trypsin, chymotrypsin Small polypeptides and peptides ↓ Carboxypeptidase, Peptidases, Dipeptidases Amino acids	Glob of fat ↓ Bile salts Emulsified fat droplets ↓ Pancreatic lipase Fatty acids and glycerol

Carbohydrates are digested to monosaccharides

Polysaccharides, such as starch and glycogen, are important components of the food ingested by humans and most other animals. The glucose units of these large molecules are connected by glycosidic bonds linking carbon 4 (or 6) of one glucose molecule with carbon 1 of the adjacent glucose molecule. These bonds are hydrolyzed by **amylases** that digest polysaccharides to the disaccharide maltose. Although amylase can split the α-glycosidic linkages present in starch and glycogen, it cannot split the β-glycosidic linkages present in cellulose (see Figs. 3-9 and 3-10).

Amylase cannot split the bond between the two glucose units of maltose. Enzymes produced by the cells lining the small intestine break down disaccharides such as maltose to monosaccharides. **Maltase,** for example, splits maltose into two glucose molecules (see Fig. 3-8a). Hydrolysis occurs while the disaccharides are being absorbed through the epithelium of the small intestine.

Proteins are digested to amino acids

Several kinds of proteolytic enzymes are secreted into the digestive tract. Each breaks peptide bonds at one or more specific locations in a polypeptide chain. Trypsin, secreted in an inactive form by the pancreas, is activated by an enzyme called *enterokinase.* The trypsin then activates chymotrypsin and carboxypeptidase, as well as additional trypsin. Pepsin, trypsin, and chymotrypsin break certain internal peptide bonds of proteins and polypeptides. Carboxypeptidase removes amino acids with free terminal carboxyl groups from the end of polypeptide chains. **Dipeptidases** released by the duodenum then split the small peptides to amino acids.

Fats are digested to fatty acids and monoacylglycerols

Lipids are usually ingested as large masses of triacylglycerols (also called triglycerides). They are digested mainly within the duodenum by pancreatic lipase. Like many other proteins, lipase is water-soluble, but its substrates are not. Thus the enzyme can attack only the fat molecules at the surface of a mass of fat. Bile salts act like detergents, reducing the surface tension of fats. Their action, called **emulsification,** breaks large masses of fat into smaller droplets. Emulsification greatly increases the surface area of fat exposed to the action of pancreatic lipase and so increases the rate of lipid digestion.

Conditions in the intestine are usually not optimal for the complete hydrolysis of lipids to glycerol and fatty acids. Consequently, the products of lipid digestion include monoacylglycerols (monoglycerides) and diacylglycerols (diglycerides) as well as glycerol and fatty acids. Undigested triacylglycerols remain as well, and some of these are absorbed without digestion.

Nerves and hormones regulate digestion

Most digestive enzymes are produced only when food is present in the digestive tract. Salivary gland secretion is controlled entirely by the nervous system, but secretion of other digestive juices is regulated by both nerves and hormones. The wall of the digestive tract contains dense networks of neurons. This so-called *enteric nervous system* continues to regulate many motor and secretory activities of the digestive system even if sympathetic and parasympathetic nerves to these organs are cut. Many neuropeptides present in the brain are also released by neurons in the digestive tract and help regulate digestion. For example, *substance P* stimulates smooth muscle contraction of the digestive tract, and *enkephalin* inhibits it.

Several hormones, including **gastrin, secretin, cholecystokinin (CCK),** and **gastric inhibitory peptide (GIP),** help regulate the digestive system (Table 45-2). All these hormones are polypeptides secreted by endocrine cells in the mucosa of certain regions of the digestive tract. Investigators are studying several other messenger peptides that are important in regulating digestive activity.

As an example of the regulation of the digestive system, consider the secretion of gastric juice. Seeing, smelling, tasting, or even thinking about food causes the brain to send neural signals to the gastric glands in the stomach, stimulating them to secrete. In addition, when food distends the stomach, stretch receptors send neural messages to the medulla. The medulla then sends messages to endocrine cells in the stomach wall that secrete the

TABLE **45-2** Some Hormones That Regulate Digestion

Hormone	Source	Target Tissue	Actions	Factors That Stimulate Release
Gastrin	Stomach (mucosa)	Stomach (gastric glands)	Stimulates gastric glands to secrete pepsinogen	Distention of the stomach by food; certain substances such as partially digested proteins and caffeine
Secretin	Duodenum (mucosa)	Pancreas	Signals secretion of sodium bicarbonate	Acidic chyme acting on mucosa of duodenum
		Liver	Stimulates bile secretion	
Cholecystokinin (CCK)	Duodenum (mucosa)	Pancreas	Stimulates release of digestive enzymes	Presence of fatty acids and partially digested proteins in duodenum
		Gallbladder	Stimulates emptying of bile	
Gastric inhibitory peptide (GIP)	Duodenum (mucosa)	Stomach	Decreases stomach churning, thus slowing emptying	Presence of fatty acids or glucose in duodenum

hormone gastrin. Gastrin is absorbed into the blood; it stimulates the stomach to release gastric juice and also stimulates gastric emptying and intestinal motility.

Absorption takes place mainly through the villi of the small intestine

Only a few substances—water, simple sugars, salts, alcohol, and certain drugs—are small enough to be absorbed through the stomach wall. Absorption of nutrients is primarily the job of the intestinal villi. As illustrated in Figure 45-10, the wall of a villus is a single layer of epithelial cells. Inside each villus is a network of capillaries and a central lymph vessel, called a **lacteal.**

To reach the blood (or lymph), a nutrient molecule must pass through an epithelial cell lining the intestine and through a cell lining a blood or lymph vessel. Absorption occurs by a combination of simple diffusion, facilitated diffusion, and active transport. Because glucose and amino acids cannot diffuse through the intestinal lining, they must be absorbed by active transport. Absorption of these nutrients is coupled with the active transport of sodium (see Chapter 5). Fructose is absorbed by facilitated diffusion.

Amino acids and glucose are transported directly to the liver by the **hepatic portal vein.** In the liver this vein divides into a vast network of tiny blood sinuses, vessels similar to capillaries. As the nutrient-rich blood moves slowly through the liver, nutrients and certain toxic substances are removed from the circulation.

The products of lipid digestion are absorbed by a different process and different route. After free fatty acids and monoacylglycerols enter an epithelial cell in the intestinal lining, they are reassembled as triacylglycerols in the smooth endoplasmic reticulum. The triacylglycerols, along with absorbed cholesterol and phospholipids, are packaged into protein-covered fat droplets, called **chylomicrons.** After they are released into the interstitial fluid, chylomicrons enter the lacteal (lymph vessel) of the villus. Chylomicrons are transported in the lymph to the subclavian veins, where the lymph and its contents enter the blood. About 90% of absorbed fat enters the blood circulation in this indirect way. The rest, mainly short-chain fatty acids such as those in butter, are absorbed directly into the blood. After a meal rich in fats, the great number of chylomicrons in the blood may give the plasma a turbid, milky appearance for a few hours.

Most of the nutrients in the chyme are absorbed by the time it reaches the end of the small intestine. What is left (mainly waste) passes through a sphincter, the **ileocecal valve,** into the large intestine.

The large intestine eliminates waste

Undigested material, such as the cellulose of plant foods, along with unabsorbed chyme, passes into the **large intestine** (see Fig. 45-4). Although only about 1.3 m (about 4 ft) long, this part of the digestive tract is referred to as "large" because its diameter is greater than that of the small intestine. The small intestine joins the large intestine about 7 cm (2.8 in) from the end of the large intestine, forming a blind pouch, the **cecum.** The **vermiform appendix** projects from the end of the cecum. (Appendicitis is an inflammation of the appendix.) Herbivores such as rabbits have a large, functional cecum that holds food while bacteria digest its cellulose. In humans, the functions of the cecum and appendix are not known, and these structures are generally considered vestigial organs.

From the cecum to the **rectum** (the last portion of the large intestine), the large intestine is known as the **colon.** The regions of the large intestine are the cecum; ascending colon; transverse colon; descending colon; sigmoid colon; rectum; and **anus,** the opening for the elimination of wastes.

As chyme passes slowly through the large intestine, water and sodium are absorbed from it, and it gradually assumes the consistency of normal feces. Bacteria inhabiting the large intestine are nourished by the last remnants of the meal and benefit their host by producing vitamin K and certain B vitamins that can be absorbed and used.

A distinction should be made between elimination and excretion. *Elimination* is the process of getting rid of digestive wastes—materials that have not been absorbed from the digestive tract and did not participate in metabolic activities. In contrast, *excretion* is the process of getting rid of metabolic wastes, which in mammals is mainly the function of the kidneys and lungs. The large intestine, however, does excrete bile pigments.

When chyme passes through the intestine too rapidly, **defecation** (expulsion of feces) becomes more frequent, and the feces are watery. This condition, called *diarrhea,* may be caused by anxiety, certain foods, or disease organisms that irritate the intestinal lining. Prolonged diarrhea results in loss of water and salts and leads to dehydration—a serious condition, especially in infants. *Constipation* results when chyme passes through the intestine too slowly. Because more water than usual is removed from the chyme, the feces may be hard and dry. Constipation is often caused by a diet deficient in fiber.

In Western countries, colorectal cancer (cancer of the colon and rectum) is the third most common cancer (Fig. 45-12). Factors contributing to colon cancer are not yet understood, but high consumption of red meat increases the risk, perhaps from carcinogens produced during cooking.

Review

- Imagine you have just taken a bite of steak. List in sequence the structures through which it passes in its journey through the digestive system. What happens in each structure?
- What is the function of villi?
- What are chylomicrons?

BiologyNow™ Assess your understanding of **the vertebrate digestive system** by taking the pretest on your BiologyNow CD-ROM.

REQUIRED NUTRIENTS

Learning Objectives

6 Summarize the nutritional requirements for dietary carbohydrates, lipids, and proteins, and trace the fate of glucose, lipids, and amino acids after their absorption.

7 Describe the nutritional functions of vitamins, minerals, and phytochemicals.

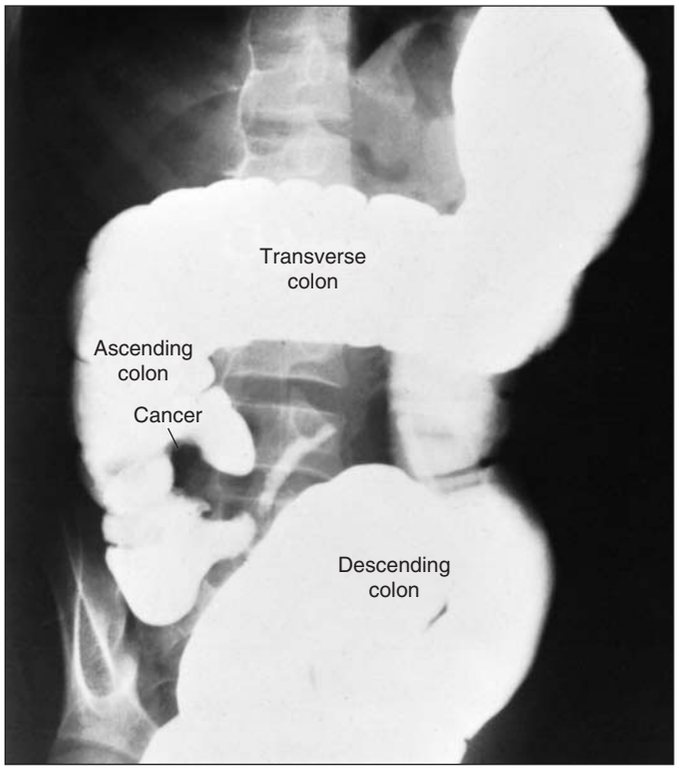

FIGURE **45-12** **Colon cancer.**

In this radiographic view of the large intestine, cancer is evident as a mass that projects into the lumen of the colon. The large intestine has been filled with a suspension of barium sulfate, which makes irregularities in the wall visible.

All animals require carbohydrates, lipids, proteins, vitamins, and minerals. In addition, nutritionists are investigating plant compounds, called *phytochemicals,* that appear important in nutrition. Although not considered a nutrient in a strict sense, water is a necessary dietary component. Enough fluid must be ingested to replace fluid lost in urine, sweat, feces, and breath.

Adequate amounts of essential nutrients are necessary for metabolic processes. Nutritionists are re-examining the *relative* amounts of various types of nutrients recommended for a healthy diet. Many long-held beliefs about nutrients and diet appear to be flawed. For example, high-carbohydrate diets are not necessarily healthy and not all fat is bad. The Institute of Medicine of the National Academies recently suggested that 20% to 35% of one's calories should come from carbohydrates, 45% to 65% from fat, and 10% to 35% from protein.

Recall from Chapter 1 that **metabolism** includes all the chemical processes that take place in the body. Metabolic processes include anabolism and catabolism. **Anabolism** includes the synthetic aspects of metabolism such as the production of proteins and nucleic acids. **Catabolism** includes breakdown processes such as hydrolysis. Nutritionists measure the energy value of food in kilocalories, or simply Calories. A Calorie, spelled with a capital *C,* is a **kilocalorie (kcal),** defined as the amount of heat required to raise the temperature of a kilogram of water 1 degree C.

Carbohydrates provide energy

Sugars and starches are important sources of energy in the human diet. Most carbohydrates are ingested in the form of starch and cellulose, both polysaccharides composed of long chains of glucose subunits. (You may want to review the discussion of carbohydrates in Chapter 3.) Nutritionists refer to polysaccharides as **complex carbohydrates.** Foods rich in complex carbohydrates include rice, potatoes, corn, and other cereal grains.

When we eat an excess of carbohydrate-rich food, the liver cells become fully packed with glycogen and convert excess glucose to fatty acids and glycerol. Liver cells convert these compounds to triacylglycerols and send them to the fat depots of the body for storage.

Refined carbohydrates, such as white bread and white rice, are unhealthy because the refining process removes fiber and many vitamins and minerals. The refining process also produces a form of starch that the digestive system rapidly breaks down to glucose. The resulting rapid increase in glucose concentration in the blood stimulates the pancreas to release a large amount of insulin, the hormone that stimulates the liver and muscles to remove glucose from the blood. Insulin lowers blood glucose level. When glucose and insulin levels are high, triglyceride levels increase and high-density lipoprotein (HDL; the good cholesterol) concentration decreases. These metabolic events can lead to cardiovascular disease and also increase the risk of type 2 diabetes (discussed in Chapter 47).

Dietary intake of fiber decreases cholesterol concentration in the blood and is associated with a lower risk for cardiovascular disease and diabetes. **Fiber** is mainly a complex mixture of cellulose and other indigestible carbohydrates. We obtain dietary fiber by eating fruits, vegetables, and whole grains. The U.S. diet is low in fiber because of low intake of fruits and vegetables and use of refined flour. Increasing fiber in the diet has a variety of health benefits. Fiber also stimulates the feeling of being satisfied (satiety) after food intake and thus is useful in treating obesity.

Lipids provide energy and are used to make biological molecules

Cells use ingested lipids as an energy source and to make a variety of lipid compounds, such as components of cell membranes, steroid hormones and bile salts. We ingest about 98% of our dietary lipids in the form of triacylglycerols (triglycerides). (Recall from Chapter 3 that a triacylglycerol is a glycerol molecule chemically combined with three fatty acids; see Fig. 3-12b.) Triacylglycerols may be saturated, that is, fully loaded with hydrogen atoms, or their fatty acids may be monounsaturated (containing one double bond) or polyunsaturated (containing two or more double bonds). Three polyunsaturated fatty acids (linoleic, linolenic, and arachidonic acids) are essential fatty acids that humans must obtain from food. Given these and sufficient nonlipid nutrients, the body can make all the lipid compounds (including fats, cholesterol, phospholipids, and prostaglandins) that it needs. The average U.S. diet provides far more cholesterol than the recommended daily max-

imum of 300 mg. High-cholesterol sources include egg yolks, butter, and meat.

Lipid transport and metabolism are complex. Recall that chylomicrons transport lipids from the intestine to the liver and to other tissues. As chylomicrons circulate in the blood, the enzyme **lipoprotein lipase** breaks down triacylglycerols. The fatty acids and glycerol can then be taken up by the cells. What is left of the chylomicron, a remnant made up mainly of cholesterol and protein, is taken up by the liver.

Liver cells repackage cholesterol and triacylglycerols. These lipids are bound to proteins and transported as large molecular complexes, called **lipoproteins.** Some plasma cholesterol is transported by **high-density lipoproteins,** or **HDLs** ("good" cholesterol), but most is transported by **low-density lipoproteins,** or **LDLs** ("bad" cholesterol). LDLs deliver cholesterol to the cells. For cells to take in LDLs, a protein (apolipoprotein B) on the LDL surface must bind with a protein **LDL receptor** on the plasma membrane (Fig. 5-20). After binding, the LDL enters the cell and its cholesterol and other components are used. When cholesterol levels are high, HDLs collect the excess cholesterol and transport it to the liver. HDLs decrease risk for cardiovascular disease

When needed, stored fats are hydrolyzed to fatty acids and released into the blood. Before cells can use these fatty acids as fuel, they are broken down into smaller compounds and combined with coenzyme A to form molecules of acetyl coenzyme A (acetyl CoA; Fig. 45-13). Acetyl CoA enters the citric acid cycle (see Chapter 7). The conversion of fatty acids to acetyl CoA is accomplished in the liver by a process known as *β-oxidation.*

For transport to the cells, acetyl coenzyme A is converted into one of three types of *ketone bodies* (four-carbon ketones). Normally, the level of ketone bodies in the blood is low, but in certain abnormal conditions, such as starvation and diabetes mellitus, fat metabolism is tremendously increased. Ketone bodies are then produced so rapidly that their level in the blood becomes excessive, which may make the blood too acidic. Such disrupted pH balance can lead to death. What is the relationship between fat and cholesterol intake and cardiovascular disease?

Lipids play a key role in the development of atherosclerosis, a progressive disease in which the arteries become clogged with fatty material (see Chapter 42). The type of fat consumed, as well as other dietary and lifestyle factors, is important. A healthy proportion of HDL to LDL can be promoted by a regular exercise program, healthy diet, appropriate body weight (obesity raises LDL and triacylglycerol levels), and by not smoking cigarettes.

In general, animal foods are rich in both saturated fats and cholesterol, whereas most plant foods contain unsaturated fats and no cholesterol. Butter contains mainly saturated fats. Commonly used polyunsaturated vegetable oils are corn, soy, cottonseed, and safflower oils. Monounsaturated fats raise HDL level, as does stearic acid, the saturated fat in chocolate. Olive, canola, and peanut oils contain large amounts of monounsaturated fats. A few plant oils, including palm oil and coconut oil, are high in saturated fats. **Omega-3 fatty acids** (found in fish and some plant oils) decrease LDL levels and play other protective roles in decreasing the risk for coronary heart disease.

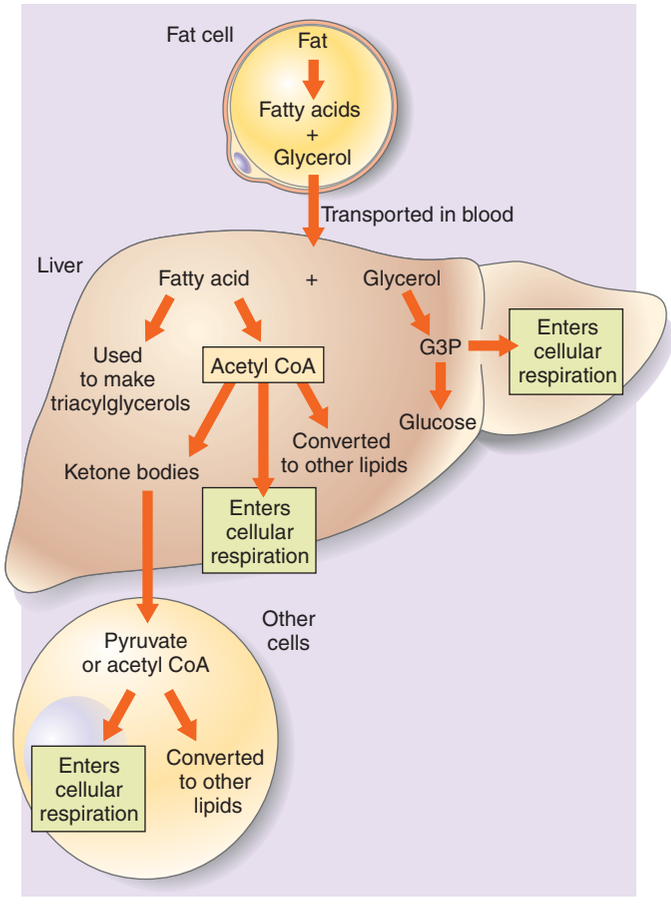

FIGURE **45-13** **How the body uses fat.**

The liver converts glycerol and fatty acids to compounds that are used as fuel in cellular respiration. Recall from Chapter 7 that G3P is glyceraldehyde-3-phosphate.

In about one third of the U.S. population, a diet high in saturated fats and cholesterol raises the blood cholesterol level by as much as 25%. Because polyunsaturated fats decrease the blood cholesterol level, many people now cook with vegetable oils rather than with butter and lard, drink skim milk rather than whole milk, and eat lowfat ice cream. Some use margarine instead of butter. However, during margarine production vegetable oils are partially hydrogenated (some of the carbons accept hydrogen to become fully saturated). During hydrogenation, some double bonds are transformed from a *cis* arrangement to a *trans* arrangement (see Fig. 3-3b), forming ***trans* fatty acids;** the harder the margarine, the higher the *trans* fatty acid content. Health concerns have been raised because trans fatty acids increase LDL cholesterol in the blood and also lower HDL. Many processed foods, including cookies, crackers, and potato chips, contain *trans* fatty acids.

If you have good genes, control your weight, and exercise regularly, your body may be able to process more unhealthy fat. It is important to remember that some fats, for example, *trans*-fatty acids and saturated fats are unhealthy, but others, such as omega-3 fatty acids and monounsaturated fat, are healthy. The

Inuits in Greenland eat diets extremely high in fat, but because their dietary fat is rich in omega-3 fatty acids, they have a low incidence of heart disease. These fatty acids decrease the probability of ventricular fibrillation, which can cause sudden death.

Proteins serve as enzymes and as structural components of cells

Proteins are essential building blocks of cells, serve as enzymes, and are also used to make compounds such as hemoglobin and myosin. Protein consumption is an index of a country's (or an individual's) economic status, because high-quality protein tends to be the most expensive and least available of the nutrients. In many parts of the world, protein poverty is one of the most pressing health problems.

Ingested proteins are degraded in the digestive tract to small peptides and amino acids. Of the 20 or so amino acids important in nutrition, approximately 9 (10 in children) cannot be synthesized by humans at all, or at least not in sufficient quantities to meet the body's needs. The diet must provide these **essential amino acids** (see Chapter 3).

Complete proteins, those that contain the most appropriate distribution of amino acids for human nutrition, are found in fish, meat, nuts, eggs, and milk. Some foods, such as gelatin and legumes (soybeans, beans, peas, peanuts) contain a high proportion of protein. However, they either do not contain all the essential amino acids, or they do not contain them in proper nutritional proportions. Most plant proteins are deficient in one or more essential amino acids. The healthiest sources of protein are fish, chicken, nuts, and legumes.

Amino acids circulating in the blood are taken up by cells and used for the synthesis of proteins. The liver removes excess amino acids from the circulation. Liver cells deaminate amino acids, that is, remove the amino group (Fig. 45-14). During deamination, ammonia forms from the amino group. Ammonia, which is toxic at high concentrations, is converted to urea and excreted from the body. The remaining carbon chain of the amino acid (called a *keto acid*) may be converted into carbohydrate or lipid and used as fuel or stored. Thus even people who eat high-protein diets can gain weight if they eat too much.

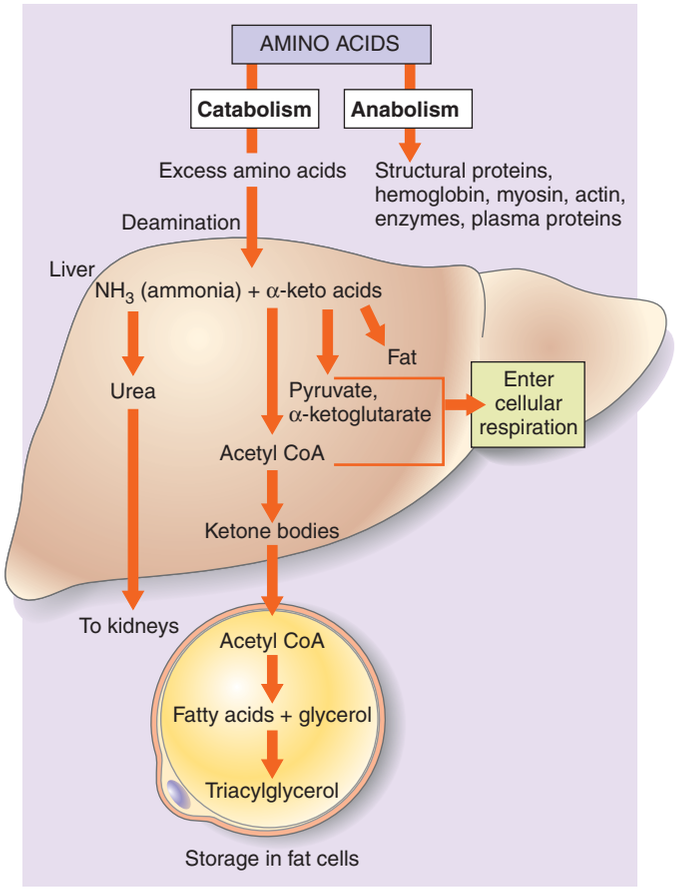

FIGURE **45-14** **How the body uses protein.**

The liver plays a central role in protein metabolism. Deamination of amino acids and conversion of the amino groups to urea take place there. In addition, many proteins are synthesized in the liver. Note that you can gain weight on a high-protein diet, because excess amino acids can be converted to fat.

Vitamins are organic compounds essential for normal metabolism

Vitamins are organic compounds required in the diet in relatively small amounts for normal biochemical functioning. Many are components of coenzymes (see Chapter 6). Nutritionists divide vitamins into two main groups. **Fat-soluble vitamins** include vitamins A, D, E, and K. **Water-soluble vitamins** are the B and C vitamins. Fruit and vegetables are rich sources of vitamins. Table 45-3 provides the sources, functions, and consequences of deficiency for most of the vitamins.

Health professionals debate the advisability of taking large amounts of certain specific vitamins, such as vitamin C to prevent colds or vitamin E to protect against vascular disease. Some studies suggest that vitamin A (found in yellow and green vegetables) and vitamin C (found in citrus fruit and tomatoes) help protect against certain forms of cancer. We do not yet understand all the biochemical roles played by vitamins or the interactions among various vitamins and other nutrients. We do know that large overdoses of vitamins, like vitamin deficiency, can be harmful. Moderate overdoses of the B and C vitamins are excreted in the urine, but surpluses of the fat-soluble vitamins are not easily excreted and can accumulate to harmful levels.

Minerals are inorganic nutrients

Minerals are inorganic nutrients ingested in the form of salts dissolved in food and water (Table 45-4). We need certain minerals, including sodium, chloride, potassium, calcium, phosphorus, magnesium, and sulfur, in amounts of 100 mg or more daily. Several others, such as iron, copper, iodide, fluoride, and selenium, are **trace elements,** minerals that we require in amounts of less than 100 mg per day.

Minerals are necessary components of body tissues and fluids. Salt content (about 0.9% in plasma) is vital in maintaining

TABLE **45-3** The Vitamins

Vitamins and U.S. RDA*	Actions	Effect of Deficiency	Sources
Fat soluble			
Vitamin A, retinol 5000 IU†	Converted to retinal; essential for normal vision; essential for normal growth and differentiation of cells; reproduction; immunity	Growth retardation; night blindness; worldwide 250 million children are at risk of blindness from vitamin A deficiency	Liver, fortified milk, yellow and green vegetables such as carrots and broccoli
Vitamin D, calciferol 400 IU	Promotes calcium and phosphorus absorption from digestive tract; essential to normal growth and maintenance of bone	Weak bones; bone deformities; rickets in children, osteomalacia in adults	Fish oils, egg yolk, fortified milk, butter, margarine
Vitamin E, tocopherols 30 IU	Antioxidant; protects unsaturated fatty acids and cell membranes	Increased catabolism of unsaturated fatty acids, so that not enough are available for maintenance of cell membranes; prevention of normal growth; nerve damage	Vegetable oils, nuts; leafy greens
Vitamin K, about 80 mcg‡	Synthesis of blood-clotting proteins	Prolonged blood clotting time	Normally supplied by intestinal bacteria; leafy greens, legumes
Water soluble			
Vitamin C, ascorbic acid 60 mg	Collagen synthesis; antioxidant; needed for synthesis of some hormones and neurotransmitters; important in immune function	Scurvy (wounds heal very slowly and scars become weak and split open; capillaries become fragile; bone does not grow or heal properly)	Citrus fruit, strawberries, tomatoes leafy vegetables, cabbage
B-complex vitamins			
Vitamin B_1, thiamine 1.5 mg	Active form is a coenzyme in many enzyme systems; important in carbohydrate and amino acid metabolism	Beriberi (weakened heart muscle, enlarged right side of heart, nervous system and digestive tract disorders); common in alcoholics	Liver, yeast, whole and enriched grains, meat, green leafy vegetables
Vitamin B_2, riboflavin 1.7 mg	Used to make coenzymes (e.g., FAD) essential in cellular respiration	Dermatitis, inflammation and cracking at corners of mouth; confusion	Liver, milk, eggs, green leafy vegetables, enriched grains
Niacin 20 mg	Component of important coenzymes (NAD^+ and $NADP^+$); essential to cellular respiration	Pellagra (dermatitis, diarrhea, mental symptoms, muscular weakness, fatigue)	Liver, chicken, tuna, milk, green leafy vegetables, enriched grains
Vitamin B_6, pyridoxine 2 mg	Derivative is coenzyme in many reactions in amino acid metabolism	Dermatitis, digestive tract disturbances; convulsions	Meat, whole grains, legumes, green leafy vegetables
Pantothenic acid 10 mg	Constituent of coenzyme A (important in cellular metabolism)	Deficiency extremely rare	Meat, whole grains, legumes
Folate 400 mcg	Coenzyme needed for nucleic acid synthesis and for maturation of red blood cells	A type of anemia; certain birth defects; increased risk of cardiovascular disease; deficiency in alcoholics, smokers, and pregnant women	Liver, legumes, dark green leafy vegetables, orange juice
Biotin 30 mcg	Coenzyme important in metabolism	—	Produced by intestinal bacteria; liver; chocolate, egg yolk
Vitamin B_{12} 6 mcg	Coenzyme important in metabolism; contains cobalt	A type of anemia	Liver, meat, fish

*RDA is the recommended dietary allowance, established by the Food and Nutrition Board of the National Research Council, to maintain good nutrition for healthy adults.

†International Unit: the amount that produces a specific biological effect and is internationally accepted as a measure of the activity of the substance.

‡mcg = micrograms.

the fluid balance of the body, and because salts are lost from the body daily in sweat, urine, and feces, they must be replaced by dietary intake. Sodium chloride (common table salt) is the salt needed in largest quantity in blood and other body fluids. A deficiency results in dehydration. Iron is the mineral most often deficient in the diet. In fact, iron deficiency is one of the most widespread nutritional problems in the world.

Antioxidants protect against oxidants

Normal cell processes that require oxygen produce **oxidants,** highly reactive molecules such as free radicals, peroxides, and superoxides. **Free radicals,** molecules or ions with one or more unpaired electrons, are also generated by ionizing radiation, to-

TABLE **45-4** Some Important Minerals and Their Functions

Mineral	Functions	Sources; Comments
Calcium	Main mineral of bones and teeth; essential for normal blood clotting, muscle function, nerve function, and regulation of cell activities	Milk and other dairy products, fish, green leafy vegetables; bones serve as calcium reservoir
Phosphorus	Performs more functions than any other mineral; structural component of bone; component of ATP, DNA, RNA, and phospholipids	Meat, dairy products, cereals
Sulfur	Component of many proteins and vitamins	High-protein foods such as meat, fish, legumes, nuts
Potassium	Principal positive ion within cells; important in muscle contraction and nerve function	Fruit, vegetables, grains
Sodium	Principal positive ion in interstitial fluid; important in fluid balance; neural transmission	Many foods, table salt; too much ingested in average American diet; excessive amounts may contribute to high blood pressure
Chloride	Principal negative ion of interstitial fluid; important in fluid balance and in acid–base balance	Many foods; table salt
Magnesium	Needed for normal muscle and nerve function	Nuts; whole grains; green, leafy vegetables
Copper	Component of several enzymes; essential for hemoglobin synthesis	Liver, eggs, fish, whole wheat flour, beans
Iodide	Component of thyroid hormones (hormones that increase metabolic rate); deficiency results in goiter (abnormal enlargement of thyroid gland)	Seafood, iodized salt, vegetables grown in iodine-rich soils
Manganese	Activates many enzymes	Whole-grain cereals, egg yolks, green vegetables; poorly absorbed from intestine
Iron	Component of hemoglobin, myoglobin, important respiratory enzymes (cytochromes), and other enzymes essential to oxygen transport and cellular respiration; deficiency results in anemia and may impair cognitive function	Mineral most likely to be deficient in diet. Good sources: meat (especially liver), fish, nuts, egg yolk, legumes, dried fruit
Fluoride	Component of bones and teeth; makes teeth resistant to decay; excess causes tooth mottling	Fish; in areas where it does not occur naturally, fluoride may be added to municipal water supplies (fluoridation)
Zinc	Cofactor for at least 70 enzymes; helps regulate synthesis of certain proteins; needed for growth and repair of tissues; deficiency may impair cognitive function	Meat, fish, milk, yogurt, grains, vegetables
Selenium	Antioxidant (part of a peroxidase that breaks down peroxides)	Seafood, eggs, meat, garlic, mushrooms, whole grains

bacco smoke, and other forms of air pollution. Oxidants damage DNA, proteins, and unsaturated fatty acids by snatching electrons. Damage to DNA causes mutations that lead to cancer, and injury to unsaturated fatty acids can damage cell membranes. Free radicals are thought to contribute to atherosclerosis by causing oxidation of LDL cholesterol. Oxidative damage to the body over many years contributes to the aging process.

Cells have **antioxidants** that destroy free radicals and other reactive molecules. Antioxidants in tissues include certain enzymes, for example, catalase, and peroxidase. Their action requires minerals such as selenium, zinc, manganese, and copper. Certain vitamins—vitamin C, vitamin E, and β-carotene—have strong antioxidant activity. Vitamins A and E protect cell membranes from free radicals. In addition, a variety of phytochemicals are potent antioxidants (discussed in next section).

Many antioxidants have more than one action. For example, vitamin E also helps prevent selenium deficiency. Nutritionists recommend that we increase the antioxidants in our diet by eating fruits, vegetables, and other foods high in antioxidants. We do not yet know whether antioxidant supplements are useful.

Phytochemicals play important roles in maintaining health

Diets rich in fruits and vegetables lower the incidence of heart disease and of certain types of cancer. Studies comparing diets in various countries suggest that intake of fruits and vegetables may be more important than differences in dietary fat. Yet, nutritionists estimate that in the United States only about 1 in 11 people eats the daily recommended three to five servings of vegetables and two to three of fruit. A diet that includes all the essential nutrients does not provide the same health benefits as one rich in fruit and vegetables. The missing ingredients appear to be **phytochemicals,** plant compounds that promote health. Some phytochemicals function as antioxidants. In Asian countries where diets are low in fat and high in soy and green tea, the incidence of breast, prostate, and colorectal cancer is low.

Nutritionists are just beginning to intensively investigate phytochemicals. Among the important classes of phytochemicals are the carotenoids, allium compounds, flavonoids, indoles, and isocyanates. Except for carotenoids, yellow-orange pigments that the body can convert into vitamin A, phytochemicals have

not been established as essential nutrients. Among the carotenoids are the *lycopenes,* powerful antioxidants that are responsible for the red color of tomatoes.

ENERGY METABOLISM

Learning Objectives

8 Contrast basal metabolic rate with total metabolic rate; write the basic energy equation for maintaining body weight, and describe the consequences of altering it in either direction.

9 In general terms, describe the effects of malnutrition, including both undernutrition and overnutrition.

10 Summarize current hypotheses about the regulation of food intake and energy homeostasis. (Include the roles of leptin and neuropeptide Y.)

The amount of energy liberated by the body per unit time is a measure of its **metabolic rate.** Much of the energy expended by the body is ultimately converted to heat. Metabolic rate may be expressed either in kilocalories of heat energy expended per day or as a percentage above or below a standard normal level.

The **basal metabolic rate (BMR)** is the rate at which the body releases heat as a result of breaking down fuel molecules. BMR is the body's basic cost of living, that is, the rate of energy used during resting conditions. This energy is required to maintain body functions such as heart contraction, breathing, and kidney function. A person's **total metabolic rate** is the sum of his or her BMR and the energy used to carry on all daily activities. For example, a laborer has a greater total metabolic rate than does an account executive whose job requirements do not include a substantial amount of physical activity and who does not exercise regularly.

An average-sized person who does not exercise and who sits at a desk all day expends about 2000 kcal daily. If the food the individual eats each day also contains about 2000 kcal, the body will be in a state of energy balance; that is, energy input will equal energy output. This is an extremely important concept, because body weight remains constant when

$$\text{Energy input} = \text{energy output}$$

When energy output is greater than energy input, stored fat is burned and body weight decreases. People gain weight when they take in more energy in food than they expend in daily activity, in other words, when

$$\text{Energy input} > \text{energy output}$$

Undernutrition can cause serious health problems

Millions of people do not have enough to eat, or do not eat a balanced diet. Individuals suffering from undernutrition are weak, easily fatigued, and highly susceptible to infection. Iron, calcium, and vitamin A are commonly deficient nutrients, but essential amino acids are the ones most often deficient in the diet. Millions of people suffer from poor health and lowered resistance to disease because of protein deficiency. Children's physical and mental development are retarded when these essential building blocks of cells are not provided in the diet. Because their bodies cannot manufacture antibodies (which are proteins) and cells needed to fight infection, common childhood diseases, such as measles, whooping cough, and chickenpox, are often fatal in children suffering from protein malnutrition.

In young children, severe protein malnutrition results in the condition known as **kwashiorkor.** This Ashanti (West African) word means "first-second." It refers to the situation in which a first child is displaced from its mother's breast when a younger sibling is born. The older child is then given a diet of starchy cereal or cassava that is deficient in protein. Growth becomes stunted, muscles are wasted, and edema develops (as displayed by a swollen belly); the child becomes apathetic and anemic, with an impaired metabolism (Fig. 45-15). Without essential

FIGURE **45-15** **Protein deficiency.**

Millions of children suffer from kwashiorkor, a disease caused by severe protein deficiency. Note the characteristic swollen belly, which results from fluid imbalance.

P. Pittet/United Nations Food and Agricultural Organization

amino acids, digestive enzymes cannot be manufactured, so what little protein is ingested cannot be digested.

Obesity is a serious nutritional problem

Obesity, the excess accumulation of body fat, is a serious form of malnutrition that has become a problem of epidemic proportions in affluent societies. The World Health Organization considers obesity among the top 19 global health problems. Approximately 30% of U.S. adults are obese and another 35% are overweight. An estimated 20% of U.S. children and adolescents are overweight. Obesity contributes to about 300,000 deaths annually in the United States and is the second leading preventable cause of death (second only to smoking). It is a major risk factor for heart disease, diabetes mellitus, osteoarthritis, and certain types of cancer, including breast and colon cancers. In the well-known Framingham study of more than 2000 men, those who were 20% overweight had a significantly higher mortality rate from all causes.

Body mass index (BMI), now used worldwide as a measure of body size, is an index of weight in relation to height. It is calculated by dividing the square of the weight (kg^2) by height (m). The English equivalent is 4.89 times the weight (lb) divided by the square of the height (ft^2). A person is considered obese if the BMI is 30 or more. Each of us appears to have a **set point,** or steady state, around which body weight is regulated. When BMI decreases below an individual's set point, energy-conserving mechanisms are activated and energy expenditure decreases.

Obesity can result from an increase in the size of fat cells or from an increase in the number of fat cells, or both. The number of fat cells in the adult is apparently determined mainly by the amount of fat stored during infancy and childhood. When we are overfed early in life, abnormally large numbers of fat cells are formed. Later in life, these fat cells may be fully stocked with excess lipids or may shrink in size, but they are always there. People with such increased numbers of fat cells are thought to be at greater risk for obesity than are those with normal numbers.

PROCESS OF SCIENCE

In their search for the causes of obesity, biologists are focusing on the genetic aspects of obesity and on signaling pathways. This research has its roots in the 1950s when a spontaneous recessive mutation in a strain of laboratory mice, produced mutant mice that were grossly obese. The increased adipose tissue in these mice is part of a syndrome that parallels morbid obesity in humans, a condition in which an individual's body weight is 100 lb (45.5 kg) or more above normal. In 1994, Jeffrey M. Friedman's research team at Rockefeller University isolated the (*ob* locus) that, when mutated, was responsible for the obese phenotype. Mice with the mutated allele apparently lacked some weight-regulating substance.

In 1995, three different research teams reported in *Science* that injections of the normal *ob* gene product, later named **leptin,** resulted in weight loss by obese and nonobese mice. When researchers injected leptin into grossly obese mice, their appetites decreased and their energy use increased, resulting in weight loss, mainly from loss of body fat. Friedman's team fed the same diet to obese mice that were injected with leptin and

ACTIVE FIGURE **45-16** **Mutant *Ob* mice before *(left)* and after *(right)* treatment with leptin.**

BiologyNow™ Learn more about **leptins and body weight** by clicking on this figure on your BiologyNow CD-ROM.

to a control group of obese mice that did not receive leptin. The mice in the treated group lost 50% more weight than the untreated animals (Fig. 45-16). Researchers have discovered that leptin is a hormone produced in adipose tissue. It signals centers in the brain about the status of energy stores. The brain then adjusts feeding behavior and energy metabolism. An *ob* gene has been identified in humans, indicating that this gene has been conserved during evolution. Unfortunately, most obese humans are resistant to the actions of leptin.

During the past few years, researchers have identified several gene mutations and signaling molecules that help regulate food intake and energy homeostasis. These signaling molecules form complex regulatory pathways involving genetic, neural, and endocrine mechanisms. Leptin and insulin are long-term regulators that stabilize the body's fat stores. During negative energy balance, the body's adipose tissue decreases, depressing both leptin and insulin secretion. When leptin levels and food intake are low, as during dieting or starvation, the hypothalamus increases secretion of the neurotransmitter **neuropeptide Y (NPY).** This neuropeptide increases appetite and slows metabolism, actions that help restore energy homeostasis.

Short-term appetite regulators signal us to eat or to stop eating. For example, when the stomach is empty it secretes the hormone *ghrelin,* which stimulates appetite. As the stomach fills, the gastrointestinal tract releases the hormone cholecystokinin and *PYY* (a peptide), which signal that we are full. The blood level of PYY rises after eating and remains high between meals. Investigators are testing this hormone for use as an appetite suppressant.

Although an estimated 40% to 70% of the factors involved in obesity are inherited, there is plasticity in the system that regulates body weight. High-calorie diets, overeating, and underexercising lead to obesity, and psychosocial factors influence these behaviors. A sedentary lifestyle combined with the ready availability of high-energy foods contributes to the problem.

One researcher cleverly described the roots of the obesity problem as the combination of "computer chips and potato chips." For every 9.3 kcal of excess food taken into the body, about 1 g of fat is stored. (An excess of about 140 kcal, less than a typical candy bar, per day for a month results in a 1-lb weight gain.)

As researchers discover the genetic and biochemical mechanisms that regulate energy metabolism, they provide potential targets for the development of pharmacological treatments for obesity. The following are among the many targets for drug action that are the focus of research: (1) Reduce appetite so that food intake is decreased; (2) block absorption of fat; (3) uncouple metabolism from energy production so that food energy is dissipated as heat (see *Focus On: Electron Transport and Heat* in Chapter 7); and (4) block receptors for molecules that send signals leading to increased energy storage.

Review

- Write an equation to describe energy balance, and explain what happens when the equation is altered in either direction.
- What is body mass index (BMI)?
- What is the function of leptin?

BiologyNow™ Assess your understanding of **energy metabolism** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Describe food processing, including ingestion, digestion, absorption, and egestion or elimination, and compare the digestive system of a cnidarian (such as *Hydra*) with that of an earthworm or vertebrate.

- **Nutrition** is the process of taking in and using food. Animals are **heterotrophs;** they must obtain their **nutrients** from the organic molecules manufactured by other organisms.
- **Feeding** is the selection, acquisition, and **ingestion** of food. The process of breaking down food mechanically and chemically is **digestion.** Nutrients pass through the lining of the digestive tract and into the blood by **absorption.** Food that is not digested and absorbed is discharged from the body by **egestion** or **elimination.**
- In cnidarians and flatworms, food is digested in the **gastrovascular cavity.** This cavity has only one opening that serves as both mouth and anus.
- In more complex invertebrates and in all vertebrates, the digestive tract is a complete tube with an opening at each end. Digestion takes place as food passes through the tube.
- Various parts of the digestive tract are specialized to perform specific functions. In vertebrates, food passes in sequence through the mouth, pharynx, esophagus, stomach, small intestine, large intestine, and anus.

2 Trace the pathway traveled by an ingested meal in the human digestive system, describing the structure and function of each organ involved.

- Mechanical and enzymatic digestion of carbohydrates begin in the mouth. Mammalian teeth include **incisors** for biting, **canines** for tearing food, and **premolars** and **molars** for crushing and grinding. Three pairs of **salivary glands** secrete saliva, a fluid containing the enzyme **salivary amylase** that digests starch.
- As food is swallowed, it is propelled through the **pharynx** and **esophagus.** A **bolus** of food is moved along through the digestive tract by **peristalsis,** waves of muscular contraction that push food along. The mixing and propulsive movements of the digestive tract are referred to as **motility.**
- In the **stomach,** food is mechanically digested by vigorous churning, and proteins are enzymatically digested by the action of **pepsin** in the gastric juice. **Rugae** are folds in the stomach wall that expand as the stomach fills with food. **Gastric glands** secrete hydrochloric acid and **pepsinogen,** the precursor of pepsin.
- After several hours, a soup of partly digested food, called **chyme,** leaves the stomach through the **pylorus** and enters the **small intestine** in spurts. Most enzymatic digestion takes place in the **duodenum,** which produces several digestive enzymes and also receives secretions from the liver and pancreas.
- The **liver** produces **bile,** which emulsifies fats.
- The **pancreas** releases enzymes that digest protein, lipid, and carbohydrate, as well as RNA and DNA. **Trypsin** and **chymotrypsin** digest polypeptides to dipeptides. **Pancreatic lipase** degrades fats, and **pancreatic amylase** digests complex carbohydrates.
- The **large intestine,** which consists of the **cecum, colon, rectum,** and **anus,** is responsible for eliminating undigested wastes. It also incubates bacteria that produce vitamin K and certain B vitamins.

3 Describe the step-by-step digestion of carbohydrate, protein, and lipid.

- Nutrients in chyme are enzymatically digested as they move through the digestive tract.
- Polysaccharides are digested to the disaccharide maltose by salivary and pancreatic amylases. Maltase in the small intestine splits maltose into glucose, the main product of carbohydrate digestion.
- Proteins are split by pepsin in the stomach and by proteolytic enzymes in the pancreatic juice. Dipeptidases then split the peptides and dipeptides produced. The end products of protein digestion are amino acids.
- Lipids are emulsified by bile salts and then hydrolyzed by pancreatic lipase.

4 Describe the structural adaptations that increase the surface area of the digestive tract.

- The surface area of the small intestine is greatly expanded by folds in its wall, by the intestinal **villi,** and by **microvilli.**

5 Compare lipid absorption with absorption of other nutrients.

- Nutrients are absorbed through the thin walls of the intestinal villi. The **hepatic portal vein** transports amino acids and glucose to the liver.
- Fatty acids and monacylglycerols enter epithelial cells in the intestinal lining where they are reassembled into triacylglycerols. They are packaged into **chylomicrons,** droplets that also contain cholesterol and phospholipids and are covered by a protein coat. The lymphatic system transports chylomicrons to the blood circulation.

SUMMARY WITH KEY TERMS *(continued)*

6 Summarize the nutritional requirements for dietary carbohydrates, lipids, and proteins, and trace the fate of glucose, lipids, and amino acids after their absorption.

- For a balanced diet, humans and other animals require carbohydrates, lipids, proteins, vitamins, and minerals.
- Most carbohydrates are ingested in the form of polysaccharides—starch and cellulose. Polysaccharides are referred to as **complex carbohydrates. Fiber** is mainly a mixture of cellulose and other indigestible carbohydrates. Carbohydrates are used mainly as an energy source. Glucose concentration in the blood is carefully regulated. Excess glucose is stored as glycogen and can also be converted to fat.
- Lipids are used as an energy source, as components of cell membranes, and to synthesize steroid hormones and other lipid substances. Most lipids are ingested in the form of triacyglycerols. Fatty acids are converted to molecules of acetyl coenzyme A which enter the citric acid cycle. Excess fatty acids are converted to triacylglycerol and stored as fat.
- Lipids are transported as large molecular complexes called **lipoproteins. Low-density lipoproteins (LDLs)** deliver cholesterol to the cells. **High-density lipoproteins (HDLs)** collect excess cholesterol and transport it to the liver.
- Proteins serve as enzymes and are essential structural components of cells. The best distribution of **essential amino acids** is found in the complete proteins of animal foods. Excess amino acids are deaminated by liver cells. Amino groups are converted to urea and excreted in urine; the remaining keto acids are converted to carbohydrate and used as fuel or converted to lipid and stored in fat cells.

7 Describe the nutritional functions of vitamins, minerals, and phytochemicals.

- **Vitamins** are organic compounds required in small amounts for many biochemical processes. Many serve as components of coenzymes. **Fat-soluble vitamins** include vitamins A, D, E, and K. **Water-soluble vitamins** are the B and C vitamins.
- **Minerals** are inorganic nutrients ingested as salts dissolved in food and water. **Trace elements** are minerals required in amounts less than 100 mg per day.
- **Phytochemicals** are plant compounds that promote health. Some phytochemicals are **antioxidants** that destroy **oxidants,** which are free radicals and other reactive molecules that damage DNA by snatching electrons.

8 Contrast basal metabolic rate with total metabolic rate; write the basic energy equation for maintaining body weight, and describe the consequences of altering it in either direction.

- **Basal metabolic rate (BMR)** is the body's cost of metabolic living. **Total metabolic rate** is the BMR plus the energy used to carry on daily activities.
- When energy (kilocalories) input equals energy output, body weight remains constant. When energy output is greater than energy input, body weight decreases. When energy input exceeds energy output, body weight increases.

9 In general terms, describe the effects of malnutrition, including both undernutrition and overnutrition.

- Millions of people suffer from undernutrition. Essential amino acids are the nutrients most often deficient in the diet.
- **Obesity** is a serious nutritional problem in which an excess amount of fat accumulates in adipose tissues. A person gains weight by taking in more energy, in the form of kilocalories, than is expended in activity.

10 Summarize current hypotheses about the regulation of food intake and energy homeostasis. (Include the roles of leptin and neuropeptide Y.)

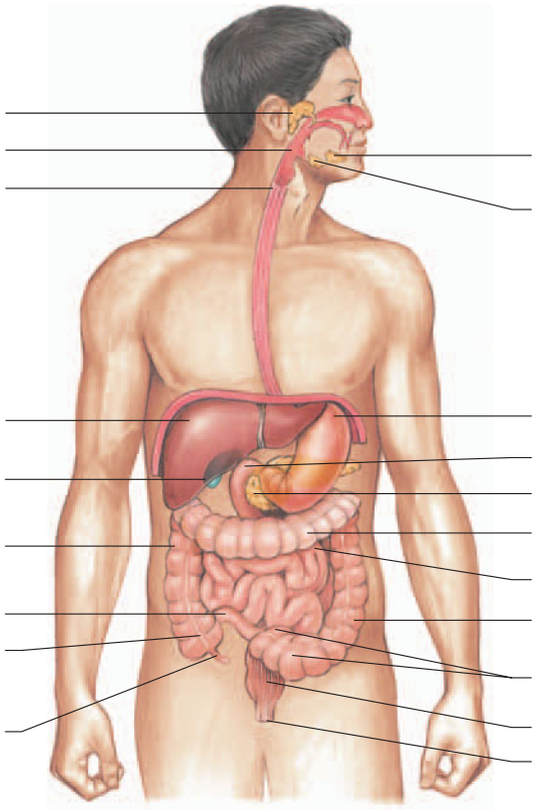
- Researchers are identifying signaling molecules that make up the complex pathways that regulate food intake and energy metabolism. The hormone **leptin** is produced by fat cells in proportion to body fat mass; it signals the brain about the status of energy stores. **Neuropeptide Y (NPY),** a neurotransmitter produced in the hypothalamus, increases appetite and slows metabolism when leptin levels and food intake are low.
- Short-term appetite regulators signal us to start and stop eating.

POST-TEST

1. The process of taking in and using food is (a) nutrition (b) chemical digestion (c) egestion (d) ingestion (e) absorption
2. Animals that feed mainly on producers are (a) herbivores (b) secondary consumers (c) animals with gastrovascular cavities (d) carnivores (e) secondary consumers and carnivores
3. Teeth adapted for crushing and grinding are (a) incisors (b) canines (c) premolars and molars (d) incisors and premolars (e) canines and molars
4. The layer of tissue that lines the lumen of the digestive tract is the (a) muscle layer (b) visceral peritoneum (c) parietal peritoneum (d) mucosa (e) submucosa
5. Which of the following are accessory digestive glands? (a) salivary glands (b) pancreas (c) liver (d) answers a, b, and c are correct (e) answers a and b only
6. Which of the following is the correct sequence? (a) pharynx ⟶ stomach ⟶ esophagus (b) stomach ⟶ large intestine ⟶ small intestine (c) esophagus ⟶ pharynx ⟶ stomach (d) cecum ⟶ colon ⟶ duodenum (e) pharynx ⟶ esophagus ⟶ stomach
7. Amylase is produced by the (a) liver and pancreas (b) stomach and pancreas (c) colon and salivary glands (d) liver and pancreas (e) pancreas and salivary glands
8. Pepsin is produced by the (a) liver (b) stomach (c) pancreas (d) duodenum (e) salivary glands
9. Which sequence most accurately describes the digestion of protein? (a) polypeptide ⟶ monoacylglycerol ⟶ amino acids (b) polypeptide ⟶ dipeptides ⟶ amino acids (c) protein ⟶ amylose ⟶ amino acid (d) protein ⟶ emulsified peptide ⟶ fatty acids and glycerol (e) protein ⟶ triacylglycerol ⟶ fatty acids and glycerol
10. The surface area of the small intestine is increased by (a) folds in its wall (b) villi (c) microvilli (d) a, b, and c are correct (e) a and b only

POST-TEST *(continued)*

11. Lipids are transported from the intestine to the cells of the body by (a) chylomicrons (b) neuropeptide Y (c) rugae (d) villi (e) leptin
12. Most vitamins are (a) inorganic compounds (b) components of coenzymes (c) used as fuel (d) electrolytes (e) required by herbivores and carnivores but not omnivores
13. When energy input is greater than energy output (a) weight loss occurs (b) weight remains stable (c) weight gain occurs (d) leptin prevents weight gain (e) the *ob* gene is activated
14. A hormone that stimulates gastric glands to secrete pepsinogen is (a) secretin (b) gastric inhibitory peptide (c) gastrin (d) cholecystokinin (CCK) (e) substance P
15. Neuropeptide Y (NPY) (a) increases appetite (b) increases metabolism (c) is encoded by the mutant *ob* gene (d) is a hormone produced by the pancreas (e) decreases bile production
16. Phytochemicals (a) are harmful to the body (b) cause high cholesterol levels (c) inhibit gastrin (d) are mainly used as energy sources (e) contain antioxidants
17. Label the diagram. Use Figure 45-4 to check your answers.



CRITICAL THINKING

1. If you were presented with an unfamiliar animal and asked to determine its nutritional lifestyle, how would you do so?
2. Design an experiment to test the hypothesis that the B vitamin pyridoxine is an essential nutrient in mice.
3. Why are proteolytic enzymes produced in an inactive form?
4. Investigators are unraveling the biochemical pathways that help regulate body weight. How might their work lead to a cure for obesity?

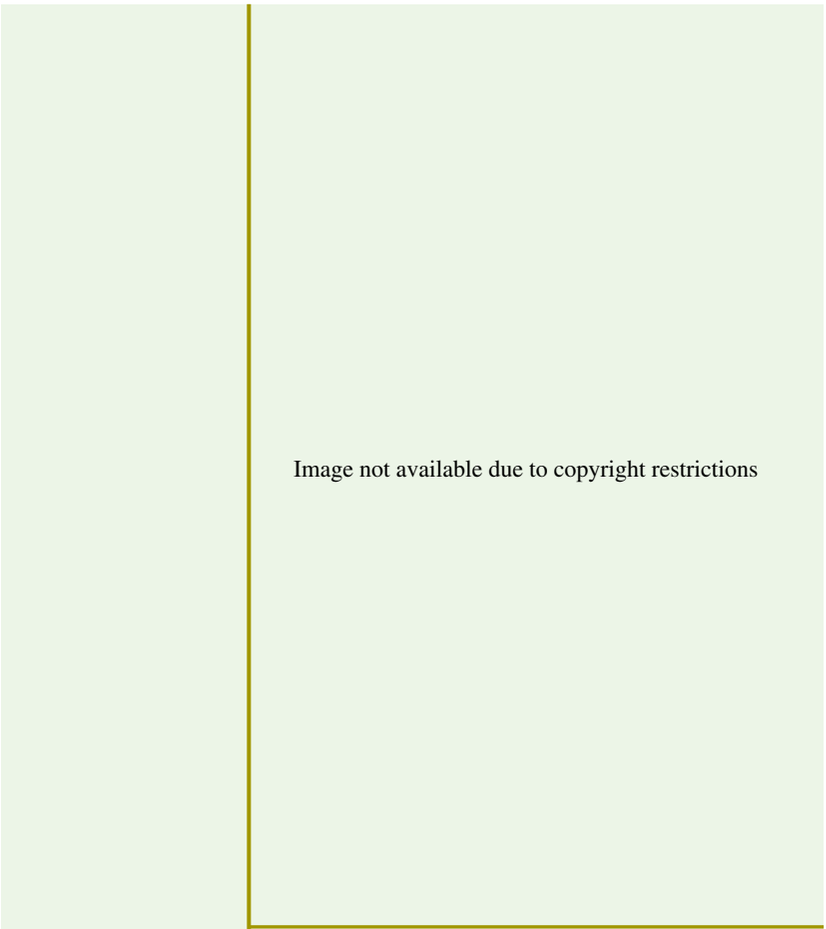
Osmoregulation and Disposal of Metabolic Wastes



CHAPTER OUTLINE

- Metabolic Waste Products
- Osmoregulation and Metabolic Waste Disposal in Invertebrates
- Osmoregulation and Metabolic Waste Disposal in Vertebrates
- The Urinary System

Water, the most abundant molecule both in the cell and on Earth, shapes life and the distribution of organisms on our planet. Water is the medium in which most metabolic reactions take place, and the osmotic and ionic composition of an animal's body fluids must be maintained within homeostatic limits. Natural selection has resulted in the evolution of a variety of homeostatic mechanisms that regulate the volume and composition of fluids in the internal environment. In this chapter we discuss some of these mechanisms.

Many small animals live in the ocean and get their food and oxygen directly from the seawater that surrounds them; they release waste products into the surrounding seawater. In larger, more complex animals and in most terrestrial animals, the extracellular fluid serves as an internal sea. **Extracellular fluid** includes the fluid outside of the cells, such as interstitial fluid (fluid between cells) and blood (or hemolymph). In vertebrates, blood plasma, which is mainly water, transports nutrients, gases, waste products, and other materials throughout the body. Interstitial fluid forms from the blood plasma and bathes all the cells. Excess water evaporates from the body surface or is excreted by specialized structures.

Terrestrial animals have a continuous need to conserve water. Its loss from the body must be carefully regulated, and water lost must be replaced. Water is taken in with food and drink and is also produced in metabolic reactions. Like the animals in the photograph, most animals need a dependable source of water with which to replenish their body fluids, and so they often live near water sources.

Two processes that maintain homeostasis of fluids in animals are osmoregulation and excretion of metabolic wastes. **Osmoregulation** is the active regulation of osmotic pressure of body fluids to keep them from becoming too dilute or too concentrated. **Excretion** is the process of ridding the body of metabolic wastes. Efficient **excretory systems** have evolved that function in osmoregulation and in disposal of metabolic wastes, excess water and ions, and harmful substances. As we discuss,

hormones are important signaling molecules in these regulatory processes.

Excretory systems maintain homeostasis by selectively adjusting the concentrations of salts and other substances in blood and other body fluids. Typically, an excretory system collects fluid, generally from the blood or interstitial fluid. It then adjusts the composition of this fluid by selectively returning needed substances to the body fluid. Finally, the body releases the adjusted excretory product containing excess or potentially toxic substances. ■

METABOLIC WASTE PRODUCTS

Learning Objective

1 Define *osmoregulation* and *excretion* and contrast the advantages and disadvantages of excreting ammonia, uric acid, or urea.

Metabolic wastes must be excreted so that they do not accumulate and reach concentrations that would disrupt homeostasis. The principal metabolic waste products in most animals are water, carbon dioxide, and **nitrogenous wastes,** those that contain nitrogen. Carbon dioxide is excreted mainly by respiratory structures (see Chapter 44). Water is also lost from respiratory surfaces in terrestrial animals. Excretory organs, such as kidneys, remove and excrete most of the water and nitrogenous wastes.

Nitrogenous wastes include ammonia, uric acid, and urea. Recall that amino acids and nucleic acids contain nitrogen. During the metabolism of amino acids, the nitrogen-containing amino group is removed (in a process known as deamination) and converted to **ammonia** (Fig. 46-1). However, ammonia is highly toxic. Some aquatic animals excrete it into the surrounding water before it can build up to toxic concentrations in their tissues. A few terrestrial animals, including some terrestrial snails and wood lice, vent it directly into the air. But many animals, humans included, convert ammonia to some less toxic nitrogenous waste such as uric acid or urea.

Uric acid is produced both from ammonia and by the breakdown of nucleotides from nucleic acids. Uric acid is insoluble in water and forms crystals that are excreted as a crystalline paste with little fluid loss. This is an important water-conserving adaptation in many terrestrial animals, including insects, certain reptiles, and birds. Also, because uric acid is not toxic and can be safely stored, its excretion is an adaptive advantage for species whose young begin their development enclosed in eggs.

Urea is the principal nitrogenous waste product of amphibians and mammals. It is produced in the liver from ammonia. Urea is synthesized from ammonia and carbon dioxide by a sequence of reactions known as the **urea cycle.** Like the formation of uric acid, these reactions require specific enzymes and the input of energy by the cells. Urea has the advantage of being far less toxic than ammonia and can accumulate in higher concentrations without causing tissue damage; thus, it can be excreted in more concentrated form. Because urea is highly soluble, however, it is dissolved in water, and more water is needed to excrete urea than to excrete uric acid.

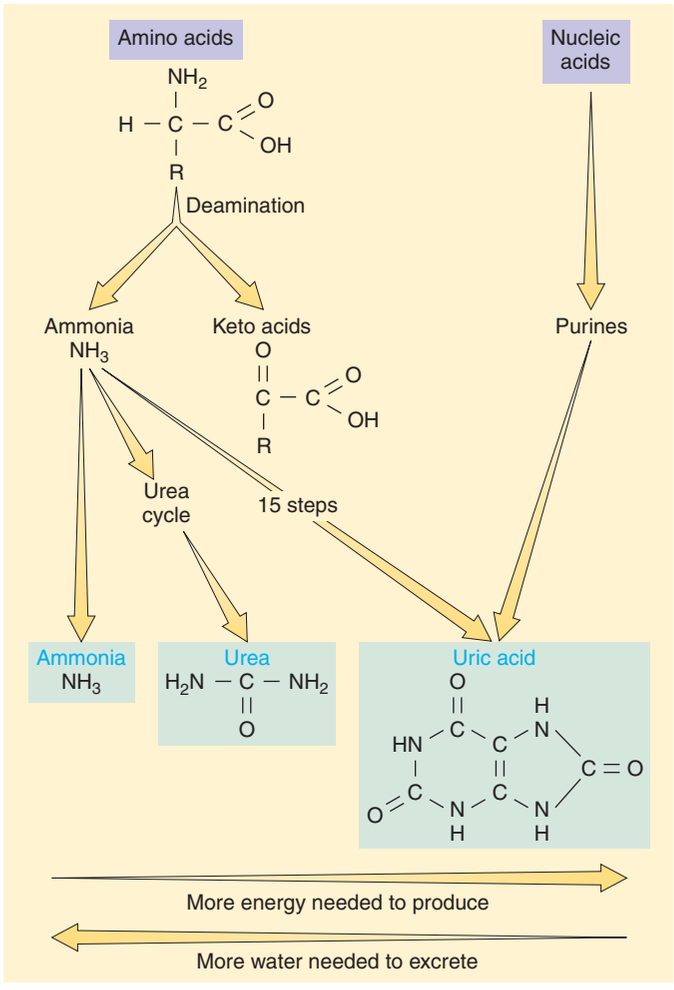


FIGURE **46-1** **Formation of nitrogenous wastes.**
Deamination of amino acids and metabolism of nucleic acids produce nitrogenous wastes. Ammonia is the first metabolic product of deamination. Many aquatic animals excrete ammonia, but terrestrial animals convert it to the less toxic urea and uric acid. Most amphibians and mammals convert ammonia to urea via the urea cycle. Insects, many reptiles, and birds convert ammonia to uric acid. Energy is required to convert ammonia to urea and uric acid, but less water is required to excrete these wastes.

Review

- What are the principal types of nitrogenous wastes? Give examples of animals that excrete each type.
- What are the advantages of excreting nitrogenous wastes in the form of uric acid?
- What is an advantage of excreting nitrogenous wastes in the form of urea? What is a disadvantage?

BiologyNow™ Assess your understanding of **metabolic waste products** by taking the pretest on your BiologyNow CD-ROM.

OSMOREGULATION AND METABOLIC WASTE DISPOSAL IN INVERTEBRATES

Learning Objective

2 Compare osmoconformers and osmoregulators, and describe protonephridia, metanephridia, and Malpighian tubules.

The ocean is a stable environment, and its salt concentration does not vary much. The body fluids of most marine invertebrates are in osmotic equilibrium with the surrounding seawater. These animals are known as **osmoconformers,** because the concentration of their body fluids varies along with changes in the seawater. Even so, many osmoconforming marine animals regulate some ions in their body fluids.

Coastal habitats, such as estuaries that contain brackish water, are much less stable environments than is the open ocean. Salt concentrations change frequently with shifting tides. Many invertebrates (as well as vertebrates) that inhabit these environments are **osmoregulators,** which maintain an optimal salt concentration in their tissues regardless of changes in the salt concentration of their surroundings.

In a coastal environment where fresh water enters the ocean, the water may have a lower salt concentration than the body fluids of the animal. Water osmotically moves into the body, and salt diffuses out. An animal adapted to this environment has excretory structures that remove the excess water. Certain polychaete worms and the blue crab are among the animals that can be osmoconformers or osmoregulators depending on environmental conditions.

Dehydration is a constant threat to terrestrial animals. Because their fluid concentration is higher than that of the air around them, they tend to lose water by evaporation from both the body surface and respiratory surfaces and may also lose water as wastes are excreted. As animals moved onto the land, natural selection favored the evolution of structures and processes that conserve water.

Nephridial organs are specialized for osmoregulation and/or excretion

Marine sponges and cnidarians need no specialized excretory structures, and they expend little or no energy to excrete wastes. Their wastes pass by diffusion from their cells to the external environment and are washed away by water currents. When water stagnates and currents do not wash away wastes, aquatic environments, such as coral reefs, are damaged by their accumulation.

Nephridial organs, or nephridia, are osmoregulatory structures that evolved in many invertebrates, including flatworms, nemerteans, rotifers, annelids, mollusks, and lancelets. Each nephridial organ consists of simple or branching tubes that typically open to the outside of the body through excretory pores, called *nephridiopores.* Two types of nephridial organs are protonephridia and metanephridia.

In flatworms and nemerteans, metabolic wastes pass through the body surface by diffusion, but these animals also have **protonephridia** (Fig. 46-2). These nephridial organs are composed of tubules with no internal openings. Their enlarged blind ends consist of **flame cells** with brushes of cilia, so named because their constant motion reminded early biologists of flickering flames. The flame cells lie in the interstitial fluid that bathes the body cells. Fluid enters the flame cells, and the beating of the cilia propels the fluid through the tubules. Excess fluid leaves the body through nephridiopores.

Most annelids and mollusks have more complex nephridial organs called **metanephridia** (Fig. 46-3). Each segment of an earthworm has a pair of metanephridia. A metanephridium is a tubule open at both ends. The inner end opens into the coelom as a ciliated funnel, and the outer end opens to the outside through a nephridiopore. Around each tubule is a network of capillaries. Fluid from the coelom passes into the tubule, bringing with it whatever it contains—glucose, salts, or wastes. As fluid moves through the tubule, needed materials (such as water and glucose) are removed from the fluid by the tubule and are reabsorbed by the capillaries, leaving the wastes behind. In this way, urine is produced that contains concentrated wastes.

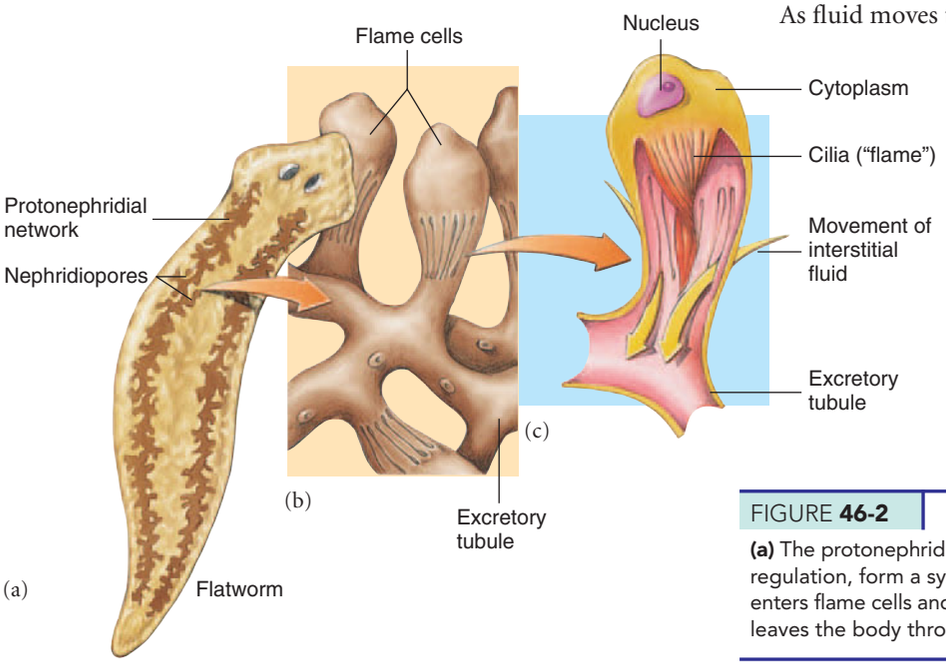

FIGURE **46-2** **Protonephridia of a flatworm.**

(a) The protonephridia of a planarian, which function mainly in osmoregulation, form a system of branching tubules. **(b)** Interstitial fluid enters flame cells and passes through a series of tubules. Excess fluid leaves the body through nephridiopores. **(c)** A single flame cell.

Malpighian tubules conserve water

The excretory system of insects and spiders consists of several hundred **Malpighian tubules** (Fig. 46-4). Malpighian tubules are

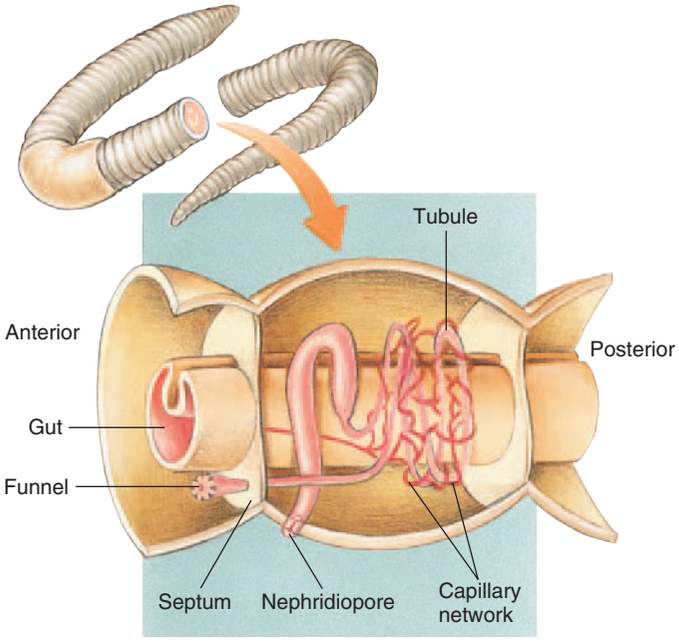

FIGURE **46-3** **Metanephridium of an earthworm.**

slender extensions of the gut wall. Their blind ends lie in the hemocoel (blood cavity) and are bathed in hemolymph. Cells of the tubule wall actively transport uric acid, potassium ions, and some other substances from the hemolymph into the tubule lumen. Other solutes and water follow by diffusion. The Malpighian tubules empty into the gut. Water, some salts, and other solutes are reabsorbed into the hemolymph by a specialized epithelium in the rectum.

Uric acid, the major waste product, is excreted as a semidry paste with a minimum of water. Because Malpighian tubules effectively conserve body fluids, they have contributed to the success of insects in terrestrial environments.

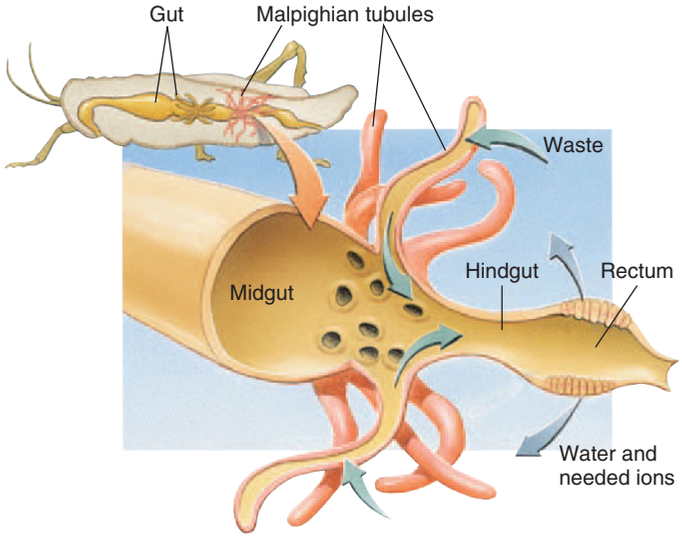

FIGURE **46-4** **Malpighian tubules of an insect.**

The slender Malpighian tubules have blind ends that extend into the hemocoel. Their cells transfer uric acid and some ions from the hemolymph to the cavity of the tubule. Water follows by diffusion. The wastes are discharged into the gut. The epithelium lining the rectum (part of the hindgut) actively reabsorbs most of the water and needed ions.

Review

- How are nephridial organs and Malpighian tubules alike? How are they different?

OSMOREGULATION AND METABOLIC WASTE DISPOSAL IN VERTEBRATES

Learning Objectives

3 Compare adaptations to the challenges of osmoregulation in the following animals: freshwater fishes, marine bony fishes, sharks, marine mammals, and terrestrial vertebrates.

4 Relate the function of the vertebrate kidney to the success of vertebrates in a wide variety of habitats.

Vertebrates live successfully in a wide range of habitats—in fresh water, the ocean, tidal regions, and on land, even in extreme environments such as deserts. In response to the requirements of these diverse environments, adaptations have evolved for regulating salt and water content and for excreting wastes. The main osmoregulatory and excretory organ in most vertebrates is the **kidney.** The kidneys excrete most nitrogenous wastes and help maintain fluid balance by adjusting the salt and water content of the urine. The skin, lungs or gills, and digestive system also help maintain fluid balance and dispose of metabolic wastes.

Freshwater vertebrates must rid themselves of excess water

As fishes began to move into freshwater habitats about 460 million years ago (mya), there was strong selection for the evolution of adaptations for effective osmoregulation. Evolution of body fluids more dilute than seawater is one of their chief adaptations. However, the salt concentration of their body fluids is still higher than that of the fresh water that surrounds them, and so they are hypertonic to their watery environment. As a result, water passes into them osmotically, and they are in constant danger of becoming waterlogged.

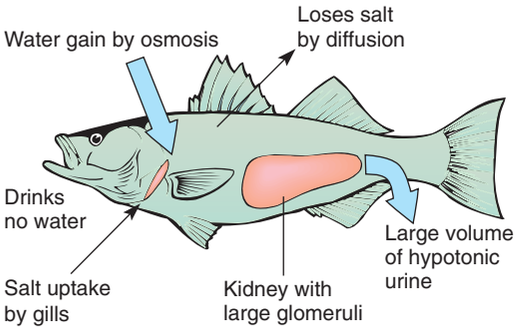
Freshwater fishes are covered by scales and a mucous secretion that retard the passage of water into the body. However, water enters through the gills. Some water leaves the body through the gills, and the kidneys of these fishes are adapted to excrete large amounts of dilute urine (Fig. 46-5a). The kidneys have large

glomeruli (capillary clusters that filter the blood and produce urine).

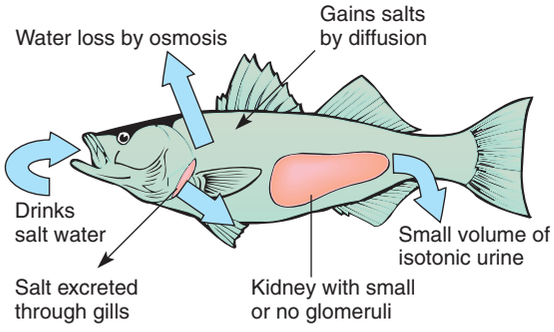
Water entry is only part of the challenge of osmoregulation in freshwater fishes. These animals also tend to lose salts by diffusion through the gills into the surrounding water. To compensate, special gill cells have evolved that actively transport salts (mainly sodium chloride) from the water into the body.

The gills excrete most of the nitrogenous wastes, but the kidneys are also important excretory organs. Ammonia is the main nitrogenous waste of freshwater fishes. About 10% of nitrogenous wastes are excreted as urea.

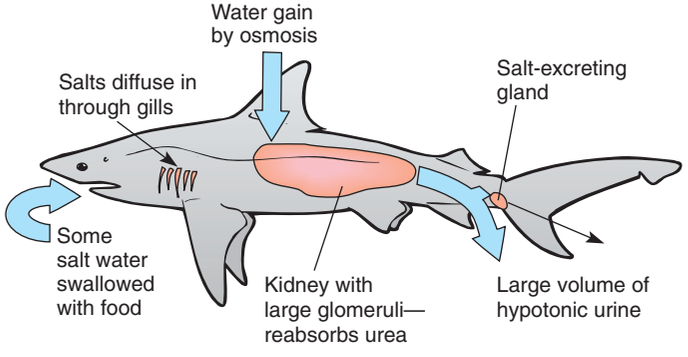
Most amphibians are at least semiaquatic, and their mechanisms of osmoregulation are similar to those of freshwater fishes. They, too, produce large amounts of dilute urine. In its urine and through its skin, a frog can lose an amount of water equivalent to one third of its body weight in one day. Active transport of salt inward by special cells in the skin compensates for loss of salt through skin and in urine.



(a) Freshwater fish



(b) Marine bony fish



(c) Cartilaginous fish (shark)

FIGURE **46-5** **Osmoregulation in fishes.**

(a) Freshwater fishes live in a hypotonic medium, so water continuously enters the body by osmosis, and salts diffuse out. These fishes excrete large quantities of dilute urine and actively transport salts in through the gills. **(b)** Marine fishes live in a hypertonic medium and therefore lose water by osmosis. They gain salts from the seawater they drink and by diffusion. To compensate, the fish drinks water, excretes the salt, and produces a small volume of urine. **(c)** In contrast, the shark kidney reabsorbs urea in high enough concentration that its tissues become hypertonic to the surrounding medium. As a result, water enters the shark by osmosis. A large quantity of dilute urine is excreted.

Marine vertebrates must replace lost fluid

Freshwater fishes adapted very successfully to their aquatic habitats. Thus, when some freshwater fishes returned to the sea about 200 mya, their blood and body fluids were less salty than (hypotonic to) their surroundings. They tended to lose water osmotically and to take in salt. To compensate for fluid loss, many marine bony fishes drink seawater (Fig. 46-5b). They retain the water and excrete salt by the action of specialized cells in their gills. Very little urine is excreted by the kidneys; the kidneys have only small (or no) glomeruli.

Marine cartilaginous fishes (sharks and rays) have different osmoregulatory adaptations that allow them to tolerate the salt concentrations of their environment. These animals accumulate and tolerate urea (Fig. 46-5c). Their tissues are adapted to function at concentrations of urea that would be toxic to most other animals. The high urea concentration makes the body fluids slightly hypertonic to seawater, resulting in a net inflow of water. Their well-developed kidneys excrete a large volume of urine. Excess salt is excreted by the kidneys and, in many species, by a rectal salt gland.

The heads of certain reptiles and marine birds have salt glands that excrete salt that enters the body with ingested seawater or in salty food. Salt glands are usually inactive; they function only in response to osmotic stress.

Whales, dolphins, and other marine mammals ingest seawater along with their food. Their kidneys produce a concentrated urine, much saltier than seawater. This is an important physiological adaptation, especially for marine carnivores. The high-protein diet of these animals results in the production of large amounts of urea, which must be excreted in urine without losing much water.

Terrestrial vertebrates must conserve water

Adult amphibians generally inhabit moist environments. They excrete urea, and reabsorb some water from the urinary bladder. Amniotes (reptiles, birds, and mammals) have more effective adaptations for life on land. Their skin minimizes water loss by evaporation, and many amniotes excrete uric acid, which requires very little water.

Because they are endothermic (maintain a constant body temperature) and have a high rate of metabolism, birds and mammals produce a relatively large volume of nitrogenous wastes. They have numerous adaptations, including very efficient kidneys, for conserving water. An extreme example is the desert-dwelling kangaroo rat, which obtains most of its water from its own metabolism (recall from Chapter 7 that aerobic respiration produces water). Its kidneys are so efficient that it loses little fluid as urine.

Birds conserve water by excreting nitrogen as uric acid and by efficiently reabsorbing water from the cloaca and intestine. Mammals excrete urea. Their kidneys produce a very concentrated (hypertonic) urine.

In terrestrial vertebrates, the lungs, skin, and digestive system are important in osmoregulation and waste disposal (Fig. 46-6). Most carbon dioxide is excreted by the lungs. In birds and mammals, some water is lost from the body as water vapor in exhaled air. Although primarily concerned with the regulation of body temperature, the sweat glands of humans and some other mammals excrete 5% to 10% of all metabolic wastes.

The liver produces both urea and uric acid, which are transported by the blood to the kidneys. Most of the bile pigments produced by the breakdown of red blood cells are normally excreted by the liver into the intestine. From the intestine they pass out of the body with the feces.

Review

- What type of osmoregulatory challenge is faced by marine fishes? By freshwater fishes? What adaptations have evolved that meet these challenges?
- What adaptations have evolved in birds and mammals to meet the challenges of osmoregulation and metabolic waste disposal?

(a) The vertebrate kidney conserves water by reabsorbing it. **(b)** Disposal of metabolic wastes in humans and other terrestrial mammals. To conserve water, a small amount of hypertonic urine is produced. Nitrogenous wastes are produced by the liver and transported to the kidneys. All cells produce carbon dioxide and some water during cellular respiration.

THE URINARY SYSTEM

Learning Objectives

5 Describe (or label on a diagram) the organs of the mammalian urinary system, and give the functions of each.

6 Describe (or label on a diagram) the structures of a nephron (including associated blood vessels), and give the functions of each structure.

7 Trace a drop of filtrate from Bowman's capsule to its release from the body as urine.

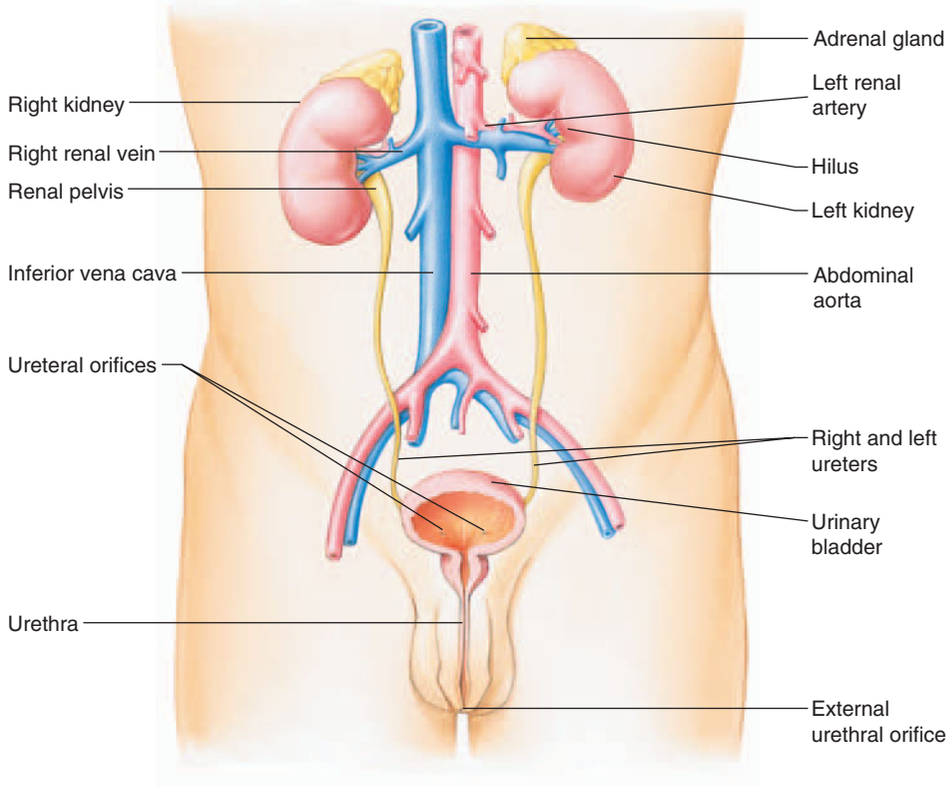
8 Describe the hormonal regulation of fluid balance by antidiuretic hormone (ADH), aldosterone, angiotensin II, and atrial natriuretic peptide (ANP).

The mammalian **urinary system** consists of the kidneys, the urinary bladder, and associated ducts. The overall structure of the human urinary system is shown in Figure 46-7. Located just below the diaphragm in the "small of the back," the kidneys look like a pair of giant, dark-red lima beans, each about the size of a fist. Each kidney is covered by a connective tissue capsule (Fig. 46-8). The outer portion of the kidney is called the **renal cortex;** the inner portion is the **renal medulla.** The renal medulla contains 8 to 10 cone-shaped structures called **renal pyramids.** The tip of each pyramid is a **renal papilla.** Each papilla has several pores, the openings of **collecting ducts.**

As urine is produced, it flows from collecting ducts through a renal papilla and into the **renal pelvis,** a funnel-shaped chamber. Urine then flows into one of the paired **ureters,** ducts that

FIGURE **46-7** **The human urinary system.**

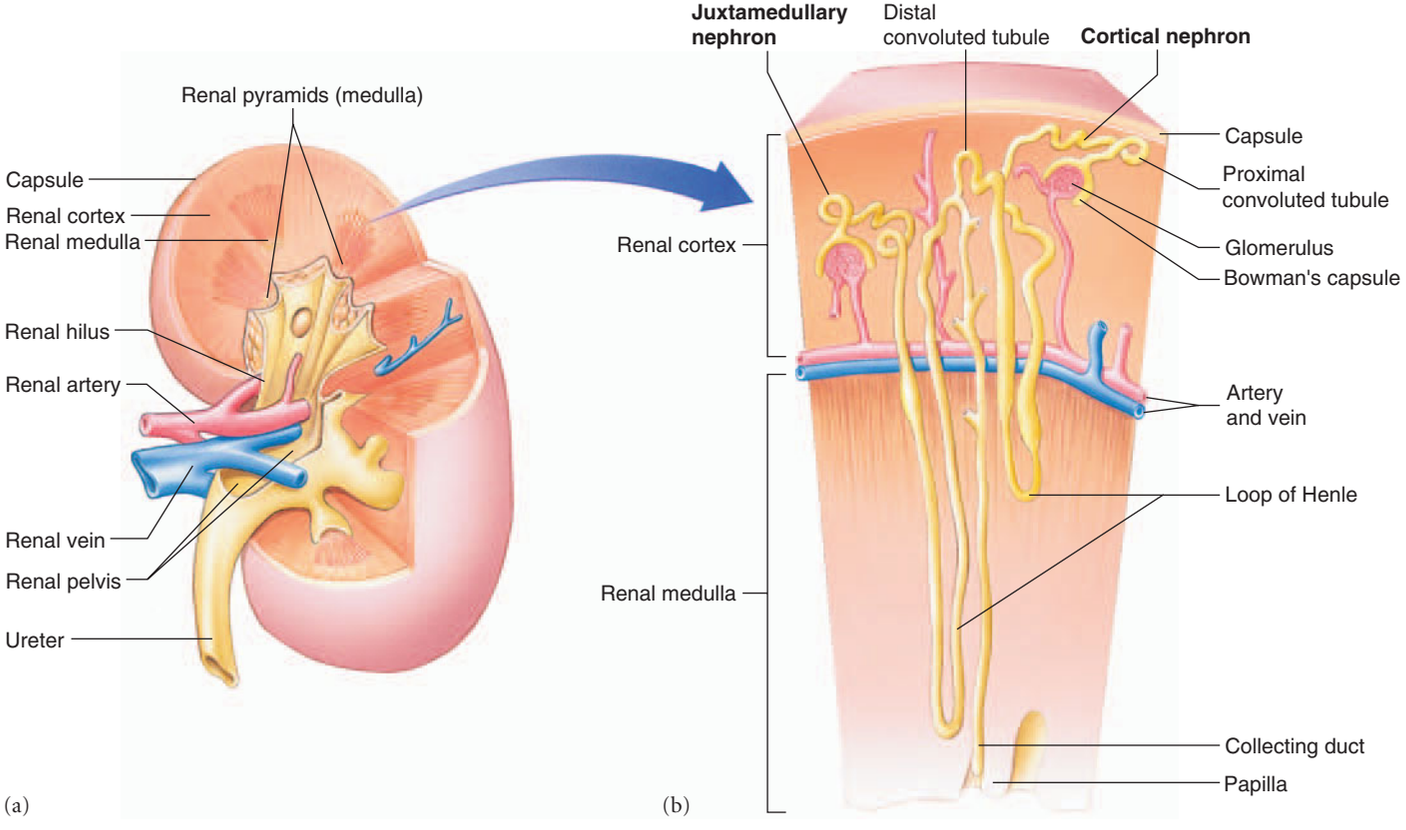
The kidneys produce urine, which is conveyed by the ureters to the urinary bladder for temporary storage. The urethra then conducts urine from the bladder to the outside of the body.

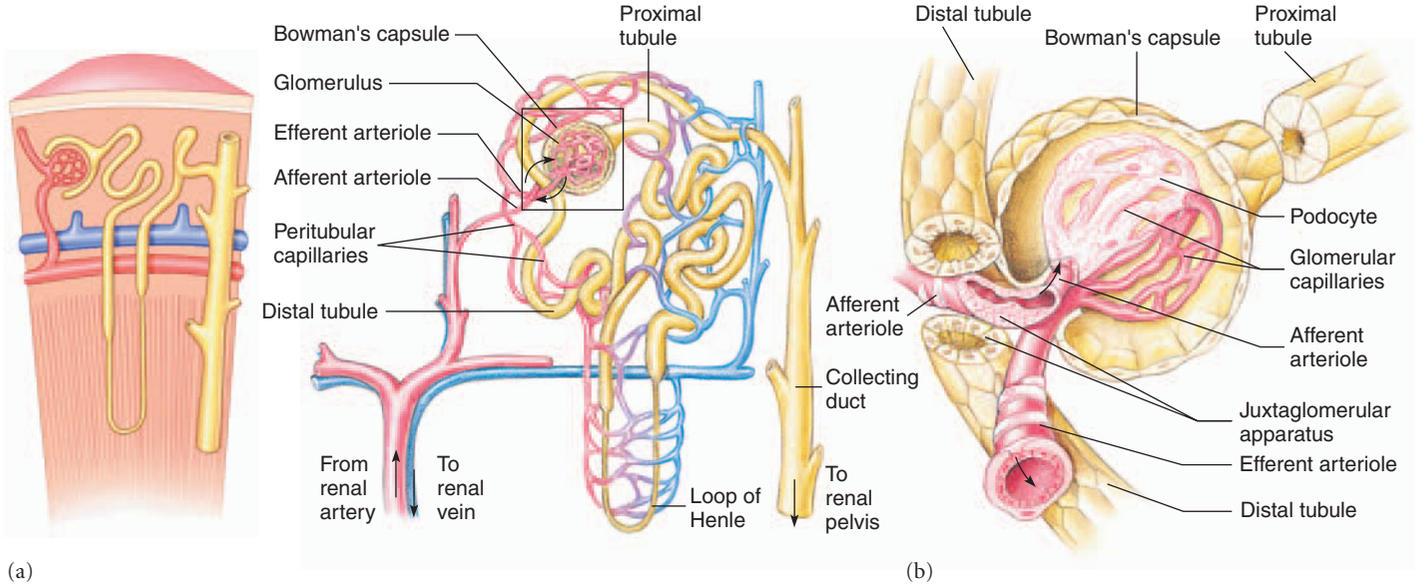


ACTIVE FIGURE **46-8** **Structure of the kidney.**

(a) The kidney is covered by a fibrous capsule. The outer region of the kidney is the cortex; the inner region is the medulla. When urine is produced, it flows into the renal pelvis and leaves the kidney through the ureter. **(b)** Longitudinal section showing the location of the two main types of nephrons: the juxtamedullary nephron and the cortical nephron.

BiologyNow™ Explore **kidney structure** by clicking on this figure on your BiologyNow CD-ROM.





connect the kidney with the **urinary bladder.** The urinary bladder is a remarkable organ capable of holding (with practice) up to 800 mL (about a pint and a half) of urine. Emptying the bladder changes it from the size of a small melon to that of a pecan. This feat is made possible by the smooth muscle and specialized epithelium of the bladder wall, which is capable of great shrinkage and stretching.

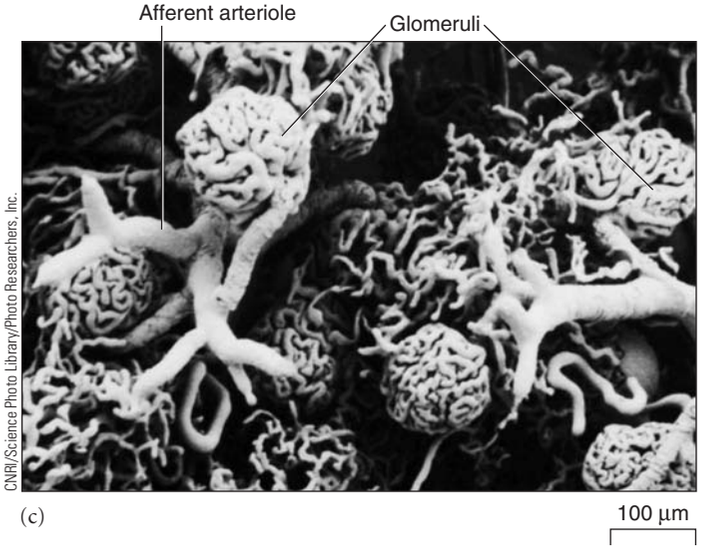
During **urination,** urine is released from the bladder and flows through the **urethra,** a duct leading to the outside of the body. In the male, the urethra is lengthy and passes through the penis. Semen, as well as urine, passes through the male urethra. In the female, the urethra is short and transports only urine. Its opening to the outside is just above the opening of the vagina. The length of the male urethra discourages bacterial invasions of the bladder. This length difference helps explain why bladder infections are more common in females than in males. In summary, urine flows through the following structures:

Kidney (through renal pelvis) ⟶ ureter ⟶ urinary bladder ⟶ urethra

The nephron is the functional unit of the kidney

The kidneys produce the enzyme *renin* which helps regulate fluid balance and blood pressure (discussed later in this chapter). The kidneys also produce at least two hormones: *erythropoietin,* which stimulates red blood cell production, and *1,25-dihydroxyvitamin D_3,* which stimulates calcium absorption by the intestine. The principal function of the kidneys is to help maintain homeostasis by regulating fluid balance and excreting metabolic wastes.

Each kidney has more than one million functional units called **nephrons.** A nephron consists of a cuplike **Bowman's capsule** connected to a long, partially coiled **renal tubule** (Fig. 46-9). Positioned within Bowman's capsule is a cluster of capillaries called a **glomerulus.**



CNRI/Science Photo Library/Photo Researchers, Inc.

FIGURE **46-9** **Nephron structure.**

(a) The location and the basic structure of a nephron. Urine forms by filtration of the blood in the glomeruli and by adjustment of the filtrate as it passes through the tubules that drain the glomeruli. **(b)** Detailed view of Bowman's capsule. Note that the distal tubule is adjacent to the afferent and efferent arterioles. The juxtaglomerular apparatus (discussed later in the chapter) is a small group of cells located in the walls of the tubule and arterioles. **(c)** Low-power SEM of a portion of the kidney cortex. The tissue was treated to remove some structures and to show glomeruli and associated blood vessels.

Three main regions of the renal tubule are the **proximal convoluted tubule,** which conducts the filtrate from Bowman's capsule; the **loop of Henle,** an elongated, hairpin-shaped portion; and the **distal convoluted tubule,** which conducts the filtrate to a collecting duct. Thus, filtrate passes through the following structures:

Bowman's capsule ⟶ proximal convoluted tubule ⟶ loop of Henle ⟶ distal convoluted tubule ⟶ collecting duct

The human kidney has two types of nephrons: the more numerous (85%) cortical nephrons and the more internal juxtamedullary nephrons (see Fig. 46-8b). **Cortical nephrons** have relatively small glomeruli and are located almost entirely within the cortex or outer medulla. **Juxtamedullary nephrons** have large glomeruli, and their very long loops of Henle extend deep into the medulla. The loop of Henle consists of a *descending limb* that receives filtrate from the proximal convoluted tubule and an *ascending limb,* through which the filtrate passes on its way to the distal convoluted tubule. The juxtamedullary nephrons contribute to the ability of the mammalian kidney to concentrate urine. Excretion of urine that is hypertonic to body fluids is an important mechanism for conserving water.

Blood is delivered to the kidney by the **renal artery.** Small branches of the renal artery give rise to **afferent arterioles.** (Afferent means "to carry toward.") An afferent arteriole conducts blood into the capillaries that make up each glomerulus. As blood flows through the glomerulus, some of the plasma is forced into Bowman's capsule.

You may recall that in a typical circulatory route, capillaries deliver blood into veins. Circulation in the kidneys is an exception, because blood flowing from the glomerular capillaries next passes into an **efferent arteriole.** Each efferent arteriole conducts blood *away* from a glomerulus. The efferent arteriole delivers blood to a second capillary network, the **peritubular capillaries** surrounding the renal tubule.

As blood flows through the first set of capillaries, those of the glomerulus, it is filtered. The peritubular capillaries receive materials returned to the blood by the renal tubule. Blood from the peritubular capillaries enters small veins that eventually lead to the **renal vein.** In summary, blood circulates through the kidney in the following sequence:

Renal artery ⟶ afferent arterioles ⟶ capillaries of glomerulus ⟶ efferent arterioles ⟶ peritubular capillaries ⟶ small veins ⟶ renal vein

Urine is produced by filtration, reabsorption, and secretion

Urine, the watery discharge of the urinary system, is produced by a combination of three processes: filtration, reabsorption, and tubular secretion (Fig. 46-10).

Filtration is not selective with regard to ions and small molecules

Blood flows through the glomerular capillaries under high pressure, forcing more than 10% of the plasma out of the capillaries and into Bowman's capsule. **Filtration** is similar to the mechanism whereby interstitial fluid is formed as blood flows through other capillary networks in the body. However, blood flow through glomerular capillaries is at much higher pressure, so more plasma is filtered in the kidney.

Several factors contribute to filtration. First, the hydrostatic blood pressure in the glomerular capillaries is higher than in other capillaries. This high pressure is mainly due to the high resistance to outflow presented by the efferent arteriole, which is smaller in diameter than the afferent arteriole (see Fig. 46-9b).

KEY CONCEPT: The glomerulus filters blood. As the filtrate moves through the renal tubule, its composition is adjusted by selective reabsorption and secretion. The adjusted filtrate is urine.

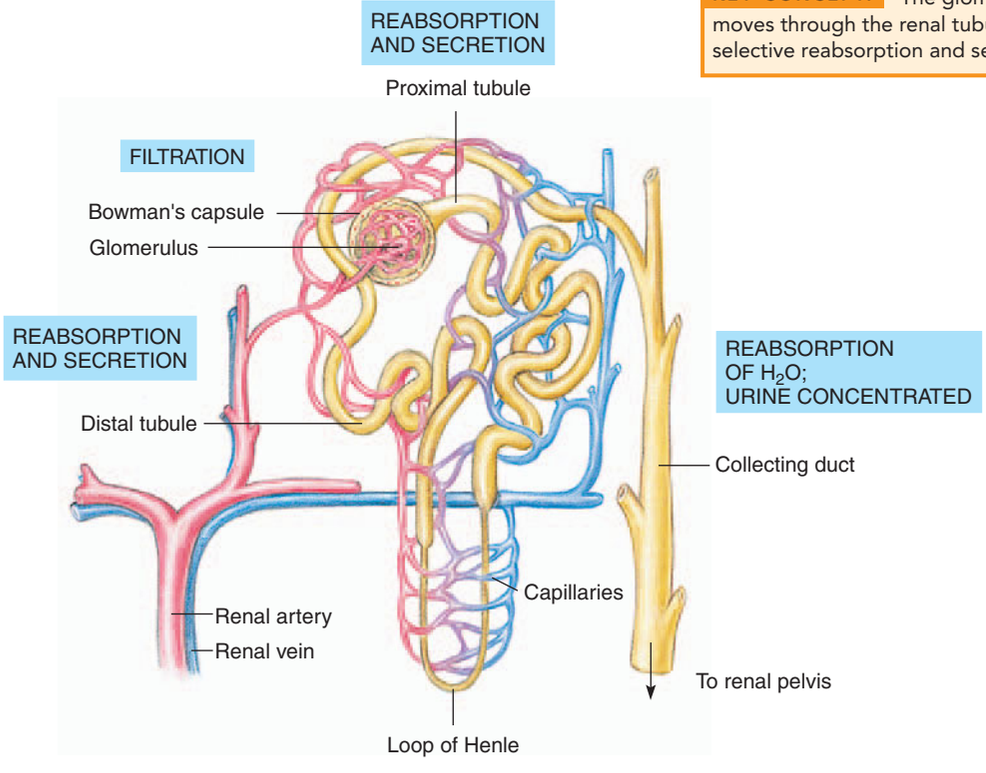


FIGURE **46-10**

General regions of filtration, reabsorption, and secretion.

A second factor contributing to the large amount of **glomerular filtrate** is the large surface area for filtration provided by the highly coiled glomerular capillaries. A third factor is the great permeability of the glomerular capillaries. Numerous small pores between the endothelial cells that form their walls make the glomerular capillaries more porous than typical capillaries.

The wall of Bowman's capsule in contact with the capillaries consists of specialized epithelial cells called **podocytes.** These cells have numerous cytoplasmic extensions called *foot processes* that cover most of the surfaces of the glomerular capillaries (Fig. 46-11). Foot processes of adjacent podocytes are separated by narrow gaps called **filtration slits.** The porous walls of the glomerular capillaries and the filtration slits of the podocytes form a **filtration membrane** that permits fluid and small solutes dissolved in the plasma, such as glucose, amino acids, sodium, potassium, chloride, bicarbonate, other salts, and urea, to pass through and become part of the filtrate. This filtration membrane holds back blood cells, platelets, and most of the plasma proteins.

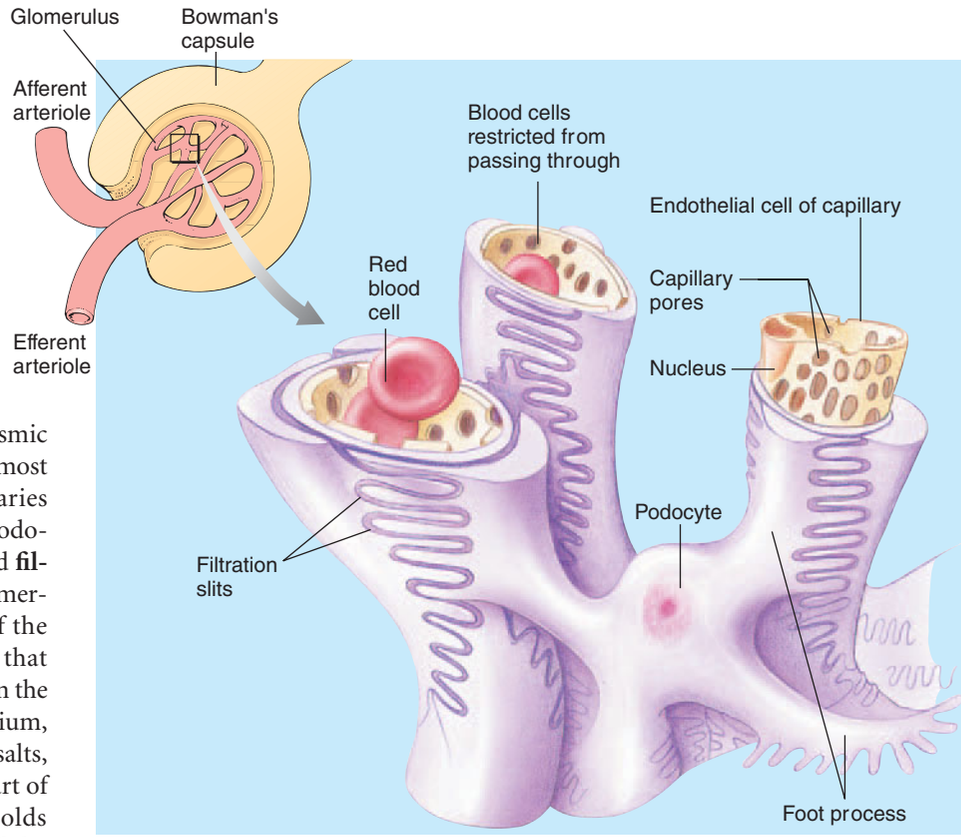

FIGURE **46-11** **Filtration membrane of the kidney.**

The porous walls of the glomerular capillaries and the filtration slits between podocytes form a filtration membrane that is highly permeable to water and small molecules but restricts the passage of blood cells and large molecules.

The total volume of blood passing through the kidneys is about 1200 mL per minute, or about one fourth of the entire cardiac output. As plasma passes through the glomerulus, it loses more than 10% of its volume to the glomerular filtrate. The normal glomerular filtration rate amounts to about 180 L (about 45 gal) each 24 hours. This is four and a half times the amount of fluid in the entire body! Common sense tells us that urine could not be excreted at that rate. Within a few moments, dehydration would become life threatening.

Reabsorption is highly selective

The threat to homeostasis posed by the vast amounts of fluid filtered by the kidneys is avoided by **reabsorption.** The renal tubules reabsorb about 99% of the filtrate into the blood, leaving only about 1.5 L to be excreted as urine during a 24-hour period. Reabsorption permits precise regulation of blood chemistry by the kidneys. Wastes, excess salts, and other materials remain in the filtrate and are excreted in the urine, whereas needed substances such as glucose and amino acids are returned to the blood. Each day the tubules reabsorb more than 178 L of water, 1200 g (2.6 lb) of salt, and about 250 g (0.5 lb) of glucose. Most of this, of course, is reabsorbed many times over.

The simple epithelial cells lining the renal tubule are well adapted for reabsorbing materials. Their abundant microvilli increase the surface area for reabsorption. These epithelial cells contain numerous mitochondria that provide the energy for running the cell pumps that actively transport materials.

Most (about 65%) of the filtrate is reabsorbed as it passes through the proximal convoluted tubule. Glucose, amino acids, vitamins, and other substances of nutritional value are entirely reabsorbed there. Many ions, including sodium, chloride, bicarbonate, and potassium, are partially reabsorbed. Some of these ions are actively transported; others are reabsorbed by diffusion. Reabsorption continues as the filtrate passes through the loop of Henle and the distal convoluted tubule. Then the filtrate is further concentrated as it passes through the collecting duct that leads to the renal pelvis.

Normally, substances that are useful to the body, such as glucose or amino acids, are reabsorbed from the renal tubules. If the concentration of a particular substance in the blood is high, however, the tubules may not be able to reabsorb it all. The maximum rate at which a substance can be reabsorbed is called its **tubular transport maximum (Tm).** When that rate is reached, the binding sites are saturated on the membrane proteins that transport the substance. For example, the tubular load of glucose is about 125 mg per minute, and almost all of it is normally reabsorbed. However, in a person with uncontrolled diabetes mellitus, the concentration of glucose in the blood exceeds its Tm (glucose concentration in excess of 320 mg per minute). The excess glucose cannot be reabsorbed and is excreted in the urine (glucosuria), a symptom of this disorder (see Chapter 47).

Some substances are actively secreted from the blood into the filtrate

Tubular **secretion** is the passage of substances across the tubule epithelium in a direction opposite to that of reabsorption. Secretion occurs mainly in the region of the distal convoluted tubule. Potassium, hydrogen ions, and ammonium ions, as well as some organic ions such as creatinine (a metabolic waste), are secreted into the filtrate. Certain drugs, such as penicillin, are also removed from the blood by secretion.

Secretion of hydrogen ions by the collecting ducts is an important homeostatic mechanism for regulating the pH of the blood. Carbon dioxide, which diffuses from the blood into the cells of the distal tubules and collecting ducts, combines with water, producing carbonic acid. This acid then dissociates, forming hydrogen ions and bicarbonate ions. When the blood becomes too acidic, more hydrogen ions are secreted into the urine:

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$$

Potassium secretion is another important homeostatic mechanism. When potassium concentration is too high, nerve impulses are not effectively transmitted, and the strength of muscle contraction decreases. The heart rhythm becomes irregular, and cardiac arrest can occur. When potassium concentration is too high, potassium ions are secreted from the blood into the renal tubules and then excreted in the urine. Secretion results partly from a direct effect of the potassium ions on the tubules. In addition, the adrenal cortex increases its output of the hormone aldosterone, which further stimulates secretion of potassium.

Urine becomes concentrated as it passes through the renal tubule

We can survive with limited fluid intake because the kidneys can produce highly concentrated urine—more than four times as concentrated as blood. The osmolarity of human blood is about 300 milliosmols per liter (mOsm/L).[1] The kidneys can produce urine with an osmolarity of about 1400 mOsm/L.

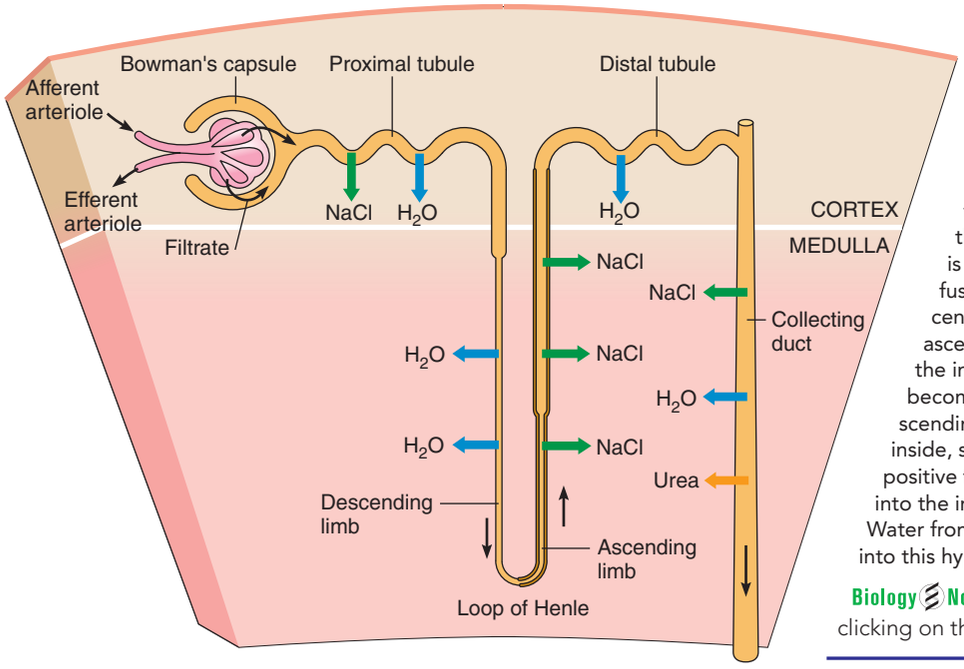
As the filtrate passes through various regions of the renal tubule, salt (NaCl) is reabsorbed and a salt concentration gradient is established (Figs. 46-12 and 46-13). The gradient is used to produce a concentrated urine.

When filtrate flows from Bowman's capsule to the proximal tubule, its osmolarity is the same as that of blood (about 300 mOsm/L). The proximal tubule reabsorbs water and salt. Sodium ions are actively transported out of the proximal tubule, and chloride follows passively. As salt passes into the interstitial fluid, water follows osmotically.

The loop of Henle is specialized to highly concentrate sodium chloride in the medulla. It maintains a highly hypertonic interstitial fluid in the medulla near the bottom of the loop, which in turn lets the kidneys produce a concentrated urine. The walls of the descending limb of the loop of Henle are relatively permeable to water but relatively impermeable to sodium and urea. The interstitial fluid has a high concentration of Na^+, so as the filtrate passes down the loop of Henle water moves out by osmosis. This concentrates the filtrate inside the loop of Henle.

At the turn of the loop of Henle, the walls become more permeable to salt and less permeable to water. As the concentrated filtrate begins to move up the ascending limb (the thin region), salt diffuses out into the interstitial fluid. This contributes to the high salt concentration of the interstitial fluid in the medulla surrounding the loop of Henle. Further along the ascending limb (the thick region), sodium is actively transported out of the tubule.

[1] An osmol is a unit of osmotic pressure equal to the molarity of the solution divided by the number of particles produced when the solute dissolves. For example, glucose dissolves to give only one kind of particle, but NaCl produces two. A milliosmol is 1/1000 of an osmol.

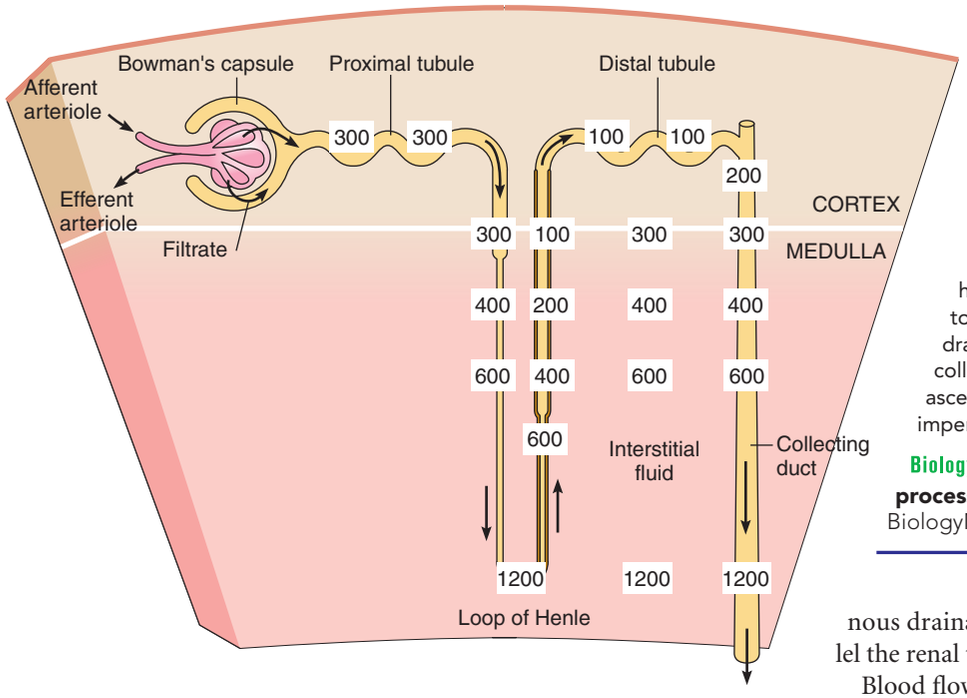


ACTIVE FIGURE **46-12**

Movement of water, ions, and urea through the renal tubule and collecting duct.

Water passes out of the descending limb of the loop of Henle, leaving a more concentrated filtrate inside. The heavy outline along the ascending limb indicates that this region is relatively impermeable to water. NaCl diffuses out from the lower (thin) part of the ascending limb. In the upper (thick) part of the ascending limb, NaCl is actively transported into the interstitial fluid. The saltier the interstitial fluid becomes, the more water moves out of the descending limb. This leaves a concentrated filtrate inside, so more salt passes out. Note that this is a positive feedback system. Some urea also moves out into the interstitial fluid through the collecting ducts. Water from the collecting ducts moves out osmotically into this hypertonic interstitial fluid.

BiologyNow™ Watch **renal processes in action** by clicking on this figure on your BiologyNow CD-ROM.



ACTIVE FIGURE **46-13**

Concentration of the filtrate as it moves through the nephron.

This figure shows the relative concentration of ions, mainly Na^+ and Cl^-, during formation of a very concentrated urine. Numbers indicate the concentration of salt in the filtrate expressed in milliosmols per liter. The more hypertonic a solution is, the higher its osmotic pressure. The very hypertonic interstitial fluid near the renal pelvis draws water osmotically from the filtrate in the collecting ducts. The heavy outline along the ascending loop indicates this region is relatively impermeable to water.

BiologyNow™ Learn more about **filtrate processing** by clicking on this figure on your BiologyNow CD-ROM.

Because water passes out of the descending limb of the loop of Henle, the filtrate at the bottom of the loop has a high salt concentration. However, because salt (but not water) is removed in the ascending limb, by the time the filtrate moves into the distal tubule its osmolarity may be the same or even lower than that of blood.

As it passes through the distal tubule, the filtrate may become even more dilute. The distal tubule is relatively impermeable to water but actively transports salt out into the interstitial fluid. The filtrate passes from the renal tubule into a larger collecting duct that eventually empties into the renal pelvis.

Note that there is a *counterflow* of fluid through the two limbs of the loop of Henle. Filtrate passing down through the descending limb is flowing in a direction opposite the filtrate moving upward through the ascending limb. The filtrate becomes concentrated as it moves down the descending limb and diluted as it moves up the ascending limb. This countercurrent mechanism helps maintain a high salt concentration in the interstitial fluid of the medulla. The hypertonic interstitial fluid draws water osmotically from the filtrate in the collecting ducts.

The inner medullary collecting ducts are permeable to urea, allowing the concentrated urea in the filtrate to diffuse out into the interstitial fluid. This urea contributes to the high solute concentration of the inner medulla and so helps in the process of concentrating urine.

The collecting ducts pass through the zone of very salty interstitial fluid. As the filtrate moves through the collecting duct, water passes osmotically into the interstitial fluid, where it is collected by capillaries. Sufficient water can leave the collecting ducts to produce highly concentrated urine. A hypertonic urine conserves water.

Some of the water that diffuses from the filtrate into the interstitial fluid is removed by the **vasa recta,** long, straight capillaries that extend from the efferent arterioles of the juxtamedullary nephrons. The vasa recta extend deep into the medulla, only to negotiate a hairpin curve and return to the cortical venous drainage of the kidney. These capillaries parallel the renal tubules.

Blood flows in opposite directions in the ascending and descending regions of the vasa recta, just as filtrate flows in opposite directions in the ascending and descending limbs of the loop of Henle. As a consequence of this countercurrent flow, much of the salt and urea that enter the blood through the descending region of the vasa recta leave again from the ascending region. As a result, the solute concentration of the blood leaving the vasa recta is only slightly higher than that of the blood entering. This mechanism helps maintain the high solute concentration of the interstitial fluid in the renal medulla.

Urine consists of water, nitrogenous wastes, and salts

By the time the filtrate reaches the renal pelvis, its composition has been precisely adjusted. The adjusted filtrate, called *urine,* consists of approximately 96% water, 2.5% nitrogenous wastes (mainly urea), 1.5% salts, and traces of other substances, such as bile pigments, that may contribute to the characteristic color and odor. Healthy urine is sterile and has been used to wash battlefield wounds when clean water was not available. However, when exposed to bacterial action, urine swiftly decomposes, forming ammonia and other products. Ammonia produces the diaper rash of infants.

The composition of urine yields many clues to body function and malfunction. **Urinalysis,** the physical, chemical, and microscopic examination of urine, is a very important diagnostic tool that has been used to monitor diabetes mellitus and many other disorders. Urinalysis is also extensively used in drug testing, because breakdown products of some drugs can be identified in the urine for several days or weeks after the drugs are taken.

Kidney function is regulated by hormones

Several hormones regulate urine volume and concentration, and additional hormones that help maintain fluid homeostasis

remain to be identified (Table 46-1). The amount of urine produced depends on the body's need to retain or rid itself of water. We have seen that salt reabsorption in the loops of Henle establishes a very salty interstitial fluid that draws water osmotically from the collecting ducts.

When fluid intake is low, the body begins to dehydrate, causing the blood volume to decrease. As blood volume decreases, the concentration of salts dissolved in the blood becomes greater, causing an increase in osmotic pressure. Certain receptors in the hypothalamus are sensitive to this osmotic change and stimulate the posterior lobe of the pituitary to release **antidiuretic hormone (ADH).** This hormone is actually produced in the hypothalamus, but it is stored in the posterior pituitary and released as needed. A thirst center in the hypothalamus also responds to dehydration, stimulating an increase in fluid intake.

ADH regulates the permeability of the collecting ducts to water. When the body needs to conserve water, the posterior pituitary gland increases its release of ADH (Fig. 46-14). This hormone makes the collecting ducts more permeable to water so that more water is reabsorbed and a small volume of concentrated urine is produced. ADH acts on aquaporin-2, a membrane protein that forms gated water channels in the wall of the collecting ducts (see Chapter 5). These channels allow water to pass rapidly through the plasma membrane.

When you drink a large volume of water, your blood becomes diluted and its osmotic pressure falls. Release of ADH by the pituitary gland decreases, lessening the amount of water reabsorbed from the collecting ducts. The kidneys produce a large volume of dilute urine.

Occasionally the pituitary gland malfunctions and does not produce enough ADH. The resulting condition is called *diabetes insipidus* (not to be confused with the more common disorder, diabetes mellitus). Diabetes insipidus also results from an acquired insensitivity of the kidney to ADH. In diabetes insipidus, water is not efficiently reabsorbed from the ducts, so the body produces a large volume of urine. A person with severe diabetes insipidus may excrete up to 25 quarts of urine each day, a serious water loss. The affected individual becomes dehydrated and must

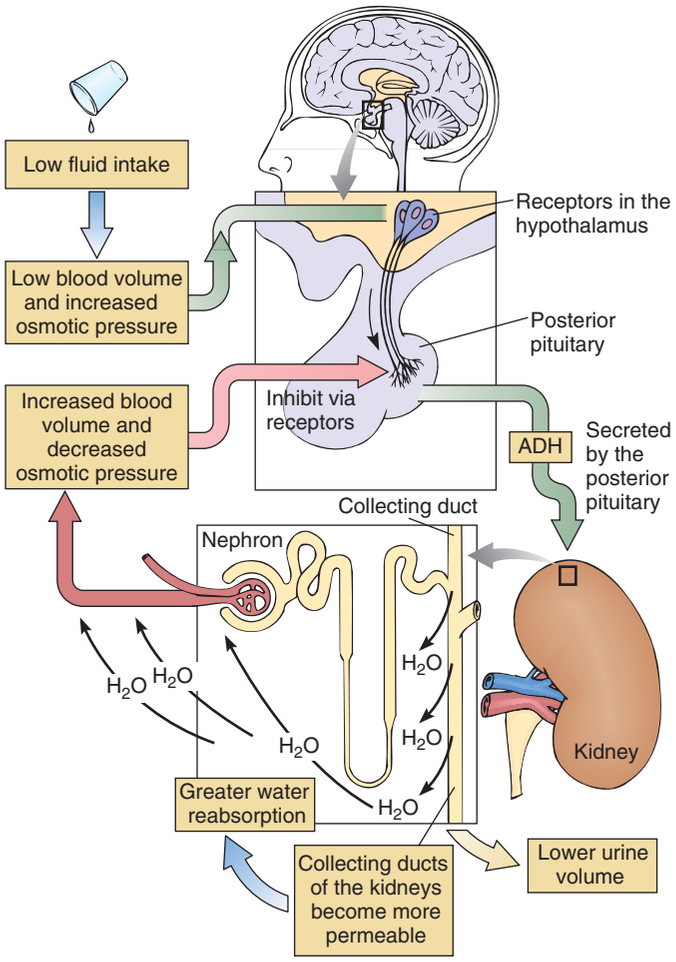


FIGURE **46-14** **Regulation of urine volume by antidiuretic hormone (ADH).**

When the body is dehydrated, the hormone ADH increases the permeability of the collecting ducts to water. More water is reabsorbed, and only a small volume of concentrated urine is produced.

TABLE **46-1** **Hormonal Control of Kidney Function**

Hormone	Source	Target Tissue	Actions	Factors that Stimulate Release
Antidiuretic hormone (ADH)	Produced in hypothalamus; released by posterior pituitary gland	Collecting ducts	Increases permeability of collecting ducts to water, increasing reabsorption and decreasing water excretion	Low fluid intake decreases blood volume and increases osmotic pressure of blood; receptors in hypothalamus stimulate posterior pituitary
Aldosterone	Adrenal glands (cortex)	Distal tubules and collecting ducts	Increases sodium reabsorption	Angiotensin II (when blood pressure decreases)
Angiotensin II	Produced from angiotensin I	Blood vessels and adrenal glands	Constricts blood vessels, which raises blood pressure; stimulates aldosterone secretion	Decrease in blood pressure causes renin secretion; renin catalyzes conversion of angiotensinogen to angiotensin I, which is then converted to angiotensin II by ACE
Atrial natriuretic peptide (ANP)	Atrium of heart	Afferent arterioles; collecting ducts	Dilates afferent arterioles; inhibits sodium reabsorption by collecting ducts; inhibits aldosterone secretion	Stretching of atria due to increased blood volume

drink almost continually to offset fluid loss. Injections of ADH or use of an ADH nasal spray can often control diabetes insipidus.

Sodium is the most abundant extracellular ion, accounting for about 90% of all positive ions in the extracellular fluid. The actions of several hormones precisely regulate sodium concentration. **Aldosterone,** which is secreted by the cortex of the adrenal glands, stimulates the distal tubules and collecting ducts to increase sodium reabsorption. When researchers remove the adrenal glands of experimental animals, too much sodium is excreted, leading to serious depletion of the extracellular fluid.

Aldosterone secretion is stimulated by a decrease in blood pressure (which is caused by a decrease in volume of blood and interstitial fluid). When blood pressure falls, cells of the **juxtaglomerular apparatus** secrete the enzyme **renin** and activate the **renin-angiotensin-aldosterone pathway.** The juxtaglomerular apparatus is a small group of cells in the region where the renal tubule contacts the afferent and efferent arterioles (see Fig. 46-9b). Renin acts on a plasma protein (angiotensinogen), converting it to angiotensin I. *Angiotensin-converting enzyme (ACE)* converts angiotensin I into its active form, **angiotensin II,** a peptide hormone that stimulates aldosterone secretion. ACE is produced by the endothelial cells of capillary walls, especially by those in the lung.

Angiotensin II not only increases the synthesis and release of aldosterone but also raises blood pressure directly by constricting blood vessels. Angiotensin II also stimulates sodium reabsorption by the proximal convoluted tubules and may stimulate the posterior pituitary to release ADH. All these actions help increase extracellular fluid volume and raise blood pressure. In individuals with hypertension, *ACE inhibitors* are sometimes used to block the production of angiotensin II. We can summarize the renin-angiotensin-aldosterone pathway as follows:

Blood volume decreases ⟶ blood pressure decreases ⟶ cells of juxtaglomerular apparatus secrete renin ⟶ angiotensinogen ⟶ angiotensin I ⟶ angiotensin II ⟶ constricts blood vessels and stimulates aldosterone secretion ⟶ aldosterone increases sodium reabsorption ⟶ blood pressure increases

Atrial natriuretic peptide (ANP), a hormone produced by the heart, increases sodium excretion and decreases blood pressure. ANP is stored in granules in atrial muscle cells. When blood volume increases, the atria stretch and respond by releasing ANP into the circulation. ANP dilates afferent arterioles, thereby increasing glomerular filtration rate. It inhibits sodium reabsorption by the collecting ducts directly and also indirectly by inhibiting aldosterone secretion. ANP also reduces plasma aldosterone concentration by inhibiting renin release. These actions of ANP raise urine output and lower blood volume and blood pressure.

Blood volume increases ⟶ blood pressure increases ⟶ atria of heart stretched ⟶ atria release ANP ⟶ directly inhibits sodium reabsorption and inhibits aldosterone secretion (which also inhibits sodium reabsorption) ⟶ larger urine volume ⟶ blood volume decreases ⟶ blood pressure decreases

The renin-angiotensin system and ANP work antagonistically in regulating fluid balance, salt (electrolyte) balance, and blood pressure.

Review

- Which structure(s) in the mammalian body is/are associated with each of the following: (a) urea formation (b) urine formation (c) temporary storage of urine (d) conduction of urine out of the body?
- Which part(s) of the nephron is/are associated with the following? (a) filtration (b) reabsorption (c) secretion
- Through what sequence of structures does a drop of filtrate pass as it moves from Bowman's capsule to the urinary bladder?
- Through what sequence of blood vessels does a drop of blood pass as it is conducted to and from a nephron?
- How is urine volume regulated? Explain.
- What are the actions of the renin-angiotensin-aldosterone pathway?

BiologyNow™ Assess your understanding of **the urinary system** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Define *osmoregulation* and *excretion,* and contrast the advantages and disadvantages of excreting ammonia, uric acid, or urea.

- **Osmoregulation** is the active regulation of osmotic pressure of body fluids so that homeostasis is maintained. **Excretion** is the process of ridding the body of metabolic wastes. **Excretory systems** help maintain homeostasis by regulating the concentration of body fluids through osmoregulation and excretion of metabolic wastes.
- The principal waste products of animal metabolism are water; carbon dioxide; and **nitrogenous wastes,** including ammonia, urea, and uric acid. **Ammonia** is toxic and is excreted mainly by aquatic animals.
- **Urea** and **uric acid** are far less toxic than ammonia, but their synthesis requires energy. Urea excretion requires water. Uric acid can be excreted as a semisolid paste, a water-conserving adaptation.

2 Compare osmoconformers and osmoregulators, and describe protonephridia, metanephridia, and Malpighian tubules.

- Most marine invertebrates are **osmoconformers**—the salt concentration of their body fluids varies with changes in the seawater. Some marine invertebrates, especially those inhabiting coastal habitats, are **osmoregulators** that maintain an optimal salt concentration despite changes in salinity of their surroundings.
- **Nephridial organs,** which include protonephridia and metanephridia, function in osmoregulation and waste disposal. **Protonephridia,** found in flatworms and nemerteans, are tubules with no internal openings. Interstitial fluid enters their blind

ends, which consist of **flame cells,** cells with brushes of cilia. Beating of the cilia propels fluid through the tubules; excess fluid leaves through nephridiopores.

- Most annelids and mollusks have excretory tubules called **metanephridia,** which are open at both ends. As fluid from the coelom moves through the tubule, needed materials are reabsorbed by capillaries. Urine, containing wastes, exits the body through nephridiopores.
- **Malpighian tubules,** extensions of the insect gut wall, have blind ends that lie in the hemocoel. Cells of the tubule actively transport uric acid and some other substances from the hemolymph into the tubule, and water follows by diffusion. The contents of the tubule pass into the gut, and water and some solutes are reabsorbed in the rectum. Malpighian tubules effectively conserve water and have contributed to the success of insects as terrestrial animals.

3 Compare the adaptations to the challenges of osmoregulation in the following animals: freshwater fishes, marine bony fishes, sharks, marine mammals, and terrestrial vertebrates.

- Freshwater fishes take in water osmotically; they excrete a large volume of dilute urine.
- Marine bony fishes lose water osmotically. They compensate by drinking seawater and excreting salt through their gills; they produce only a small volume of urine.
- Sharks and other marine cartilaginous fishes retain large amounts of urea, allowing them to take in water osmotically through the gills. They excrete a large volume of urine.
- Marine mammals ingest seawater with their food. They produce a concentrated urine.
- Terrestrial vertebrates must conserve water. Endotherms have a high metabolic rate and produce a large volume of nitrogenous wastes. They have numerous adaptations for conserving water, including efficient kidneys.

4 Relate the function of the vertebrate kidney to the success of vertebrates in a wide variety of habitats.

- The vertebrate **kidney** functions in excretion and osmoregulation and is vital in maintaining homeostasis. Its structure and function are adapted to the lifestyle of the animal.

5 Describe (or label on a diagram) the organs of the mammalian urinary system, and give the functions of each.

- The kidney is the key organ of the **urinary system,** the principal excretory system in humans and other vertebrates. In mammals, the kidneys produce urine, which passes through the **ureters** to the **urinary bladder** for storage. During urination, the urine is released from the body through the **urethra.**
- The outer portion of each kidney is the **renal cortex;** the inner portion is the **renal medulla.** The renal medulla contains 8 to 10 **renal pyramids.** The tip of each pyramid is a **renal papilla.** As urine is produced, it flows into **collecting ducts,** which empty through a renal papilla into a funnel-shaped chamber, the **renal pelvis.** Each kidney has more than a million functional units called *nephrons.*

6 Describe (or label on a diagram) the structures of a nephron (including associated blood vessels), and give the functions of each structure.

- Each **nephron** consists of a cluster of capillaries, called a **glomerulus,** surrounded by a **Bowman's capsule** that opens into a long, coiled **renal tubule.** The renal tubule consists of a **proximal convoluted tubule, loop of Henle,** and **distal convoluted tubule.**
- **Cortical nephrons,** located almost entirely within the cortex or outer medulla, have small glomeruli. **Juxtamedullary nephrons** have large glomeruli and long loops of Henle that extend deep into the medulla. These nephrons are important in concentrating urine.
- Blood flows from small branches of the **renal artery** to **afferent arterioles** and then to glomerular capillaries. Blood then flows into an **efferent arteriole** that delivers blood into a second set of capillaries, the **peritubular capillaries** that surround the renal tubule. Blood leaves the kidney through the **renal vein.**

7 Trace a drop of filtrate from Bowman's capsule to its release from the body as urine.

- Urine formation is accomplished by the **filtration** of plasma, **reabsorption** of needed materials, and **secretion** of a few substances such as potassium and hydrogen ions into the renal tubule.
- Plasma filters through the glomerular capillaries and into Bowman's capsule. The permeable walls of the capillaries and **filtration slits** between **podocytes,** specialized epithelial cells that make up the inner wall of Bowman's capsule, serve as a **filtration membrane.** Filtration is nonselective with regard to small molecules; glucose and other needed materials, as well as metabolic wastes, become part of the filtrate.
- About 99% of the filtrate is reabsorbed from the renal tubules into the blood. Reabsorption is a highly selective process that returns usable materials to the blood but leaves wastes and excesses of other substances to be excreted in the urine. The maximum rate at which a substance can be reabsorbed is its **tubular transport maximum (Tm).**
- In secretion, hydrogen ions, certain other ions, and some drugs are actively transported into the renal tubule to become part of the urine.
- Production of a concentrated urine depends on a high salt and urea concentration in the interstitial fluid of the kidney medulla. The interstitial fluid in the medulla has a concentration gradient in which the salt is most concentrated around the bottom of the loop of Henle. This gradient is maintained, in part, by salt reabsorption from various parts of the renal tubule. A counterflow of fluid through the two limbs of the loop of Henle concentrates filtrate as it moves down the descending loop and dilutes it as it moves up the ascending loop.
- Water is drawn by osmosis from the filtrate as it passes through the collecting ducts. This concentrates urine in the collecting ducts.
- Some of the water that diffuses from the filtrate into the interstitial fluid is removed by the **vasa recta,** a system of capillaries that extend from the efferent arterioles.
- **Urine** is a watery solution of nitrogenous wastes, excess salts, and other substances not needed by the body.

8 Describe the hormonal regulation of fluid balance by antidiuretic hormone (ADH), aldosterone, angiotensin II, and atrial natriuretic peptide (ANP).

- Urine volume is regulated by **antidiuretic hormone (ADH),** which is released by the posterior lobe of the pituitary gland in

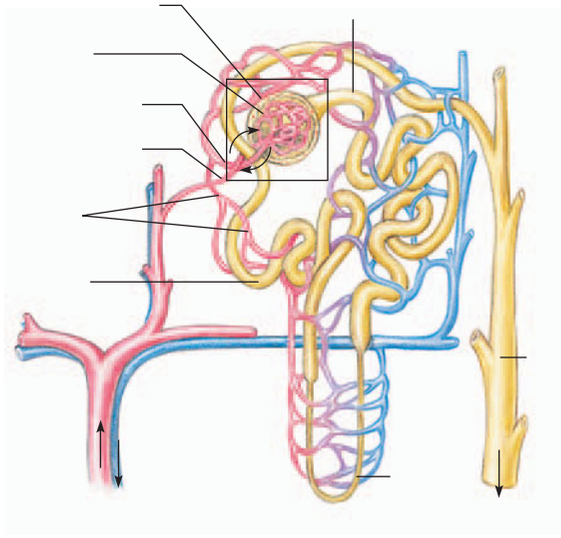
SUMMARY WITH KEY TERMS *(continued)*

response to an increase in osmotic concentration of the blood (caused by dehydration). ADH increases the permeability of the collecting ducts to water. As a result, more water is reabsorbed and only a small volume of urine is produced.

- Aldosterone and atrial natriuretic peptide work antagonistically. When blood pressure decreases, cells of the **juxtaglomerular apparatus** secrete the enzyme **renin,** which activates a pathway leading to production of **angiotensin II.** This hormone stimulates aldosterone release. **Aldosterone** increases sodium reabsorption, raising blood pressure.
- When blood pressure increases, **atrial natriuretic peptide (ANP)** increases sodium excretion and inhibits aldosterone secretion. These actions increase urine output and lower blood pressure.

POST-TEST

1. The process that maintains homeostasis of body fluids, keeping them from becoming too dilute or too concentrated is called (a) excretion (b) elimination (c) osmoregulation (d) glomerular filtration (e) tubular secretion
2. The main nitrogenous waste product of insects and birds is (a) urea (b) uric acid (c) ammonia (d) carbon dioxide (e) nitrate
3. The main nitrogenous waste product of amphibians and mammals is (a) urea (b) uric acid (c) ammonia (d) carbon dioxide (e) nitrate
4. Osmoconformers (a) maintain an optimal salt concentration despite fluctuations in salt concentration of their surroundings (b) include many animals that inhabit coastal habitats (c) experience variation in concentration of their body fluids along with changes in salinity of the seawater (d) typically have cells in their gills that remove salts from the surrounding water (e) answers (a) and (b) are correct
5. Which of the following is *not* a correct pair? (a) protonephridia/flatworm (b) metanephridia/annelid (c) flame cell/flatworm (d) Malpighian tubule/ mollusk (e) kidney/vertebrate
6. To compensate for fluid loss, many marine bony fishes (a) accumulate urea (b) have glands that excrete glucose (c) eat a low-protein diet (d) excrete a large volume of hypertonic urine (e) drink seawater
7. Arrange the following structures into an accurate sequence through which urine passes. (1) urethra (2) urinary bladder (3) kidney (4) ureter (a) 4, 3, 2, 1 (b) 3, 4, 2, 1 (c) 1, 2, 3, 4 (d) 4, 2, 1, 3 (e) 3, 1, 2, 4
8. Arrange the following structures into an accurate sequence through which filtrate passes. (1) proximal convoluted tubule (2) loop of Henle (3) collecting duct (4) distal convoluted tubule (5) Bowman's capsule (a) 5, 4, 3, 2, 1 (b) 3, 4, 2, 5, 1 (c) 1, 5, 2, 3, 4 (d) 5, 4, 2, 3, 1 (e) 5, 1, 2, 4, 3
9. The afferent arteriole delivers blood to the (a) renal artery (b) efferent arteriole (c) renal vein (d) capillaries of the glomerulus (e) peritubular capillaries
10. Which of the following does *not* contribute to the process of filtration? (a) high hydrostatic blood pressure in glomerular capillaries (b) large surface area for filtration (c) permeability of glomerular capillaries (d) active transport by epithelial cells lining renal tubules (e) podocytes
11. Tubular transport maximum is (a) the maximum concentration of a substance in the plasma that can be reabsorbed by the kidney (b) the most rapid rate at which urine can be transported through the ureter (c) the maximum rate at which a substance can be reabsorbed from the filtrate in the renal tubules (d) the maximum rate at which a substance can pass through the loop of Henle (e) the maximum rate at which a substance can be secreted into the filtrate
12. Which of the following does *not* contribute to the high salt concentration in the interstitial fluid in the medulla of the kidney? (a) reabsorption of salt from various regions of Bowman's capsule (b) diffusion of salt from the ascending limb of the loop of Henle (c) active transport of sodium from the upper part of the ascending limb (d) counterflow of fluid through the two limbs of the loop of Henle (e) diffusion of urea out of the collecting duct
13. Which of the following is *not* normally present in urine? (a) urea (b) glucose (c) salts (d) water (e) traces of bile pigments
14. Which is *not* true of ADH? (a) released by posterior lobe of the pituitary gland (b) increases water reabsorption (c) secretion increases when osmotic pressure in body increases (d) increases urine volume (e) secretion decreases when you drink a lot of water
15. Aldosterone (a) is released by the posterior pituitary gland (b) decreases sodium reabsorption (c) secretion is stimulated by an increase in blood pressure (d) is an enzyme that converts angiotensin into angiotensin II (e) secretion increases in response to angiotensin II
16. Label the diagram. Use Figure 46-9a to check your answers.



CRITICAL THINKING

1. The number of protonephridia in a planarian is related to the salinity of its environment. Planaria inhabiting slightly salty water develop fewer protonephridia, but the number quickly increases when the concentration of salt in the environment is lowered. Explain why.
2. What types of osmoregulatory challenges do humans experience? Explain. What mechanisms do we have to meet these challenges?
3. Why is glucose normally not present in urine? Why is it present in the urine of individuals with diabetes mellitus? Why do you suppose diabetics experience an increased output of urine?
4. The kangaroo rat's diet consists of dry seeds, and it drinks no water. Speculate about the adaptations this animal needs in order to survive.

Endocrine Regulation

Shark Song/M. Kazmers/Dembinsky Photo Associates

This juvenile Puget Sound king crab (*Lopholithodes mandtii*) changes color to blend with its background. Caused by changes in the distribution of pigment in its cells, color changes are regulated by hormones.

CHAPTER OUTLINE

- Cell Signaling
- Regulation of Hormone Secretion
- Mechanisms of Hormone Action
- Invertebrate Neuroendocrine Systems
- The Vertebrate Endocrine System

A caterpillar becomes a butterfly. A crustacean changes color to blend with its background (see photograph). A young girl develops into a woman. An adult copes with chronic stress. These physiological processes and many other adjustments of metabolism, fluid balance, growth and development, and reproduction are regulated by the **endocrine system.** This system works closely with the nervous system to maintain homeostatis, the steady state of the body. **Endocrinology,** the study of endocrine activity, is a very active and exciting field of biomedical research.

The endocrine system is a diverse collection of cells, tissues, and organs, including specialized **endocrine glands** that produce and secrete **hormones,** chemical messengers responsible for the regulation of many body processes. The term *hormone* is derived from a Greek word meaning "to excite." Hormones excite, or stimulate, changes in specific tissues.

Endocrine glands have no ducts; they secrete hormones directly into the interstitial fluid or blood. Hormones are typically transported by the blood and produce a characteristic response only after they reach target cells and bind with specific receptors. Target cells, the cells influenced by a particular hormone, may be in another endocrine gland or in an entirely different type of organ, such as a bone or the kidney. Target cells may be located far from the endocrine gland. For example, the vertebrate thyroid gland secretes hormones that stimulate metabolism in tissues throughout the body. Several types of hormones may be involved in regulating the metabolic activities of a particular type of cell. In fact, many hormones produce a synergistic effect in which the presence of one hormone enhances the effects of another.

Endocrinology has its roots in experiments performed by German physiologist A.A. Berthold in the 1840s. Berthold removed the testes from young roosters and observed that their combs (a male secondary sex characteristic) did not grow as large as those in normal roosters. He then transplanted testes into some of the birds and observed that the combs grew to normal size.

Berthold's methods became a model for subsequent studies in endocrinology and are still used by researchers today. To test the hypothesis that a particular tissue is endocrine, an investigator removes the tissue. Does removal of the tissue produce deficiency symptoms in the experimental animal? Investigators then replace the suspected endocrine tissue by transplanting similar tissue from another animal. They typically transplant the new tissue to a different location in the body to determine whether the effects depend on a signal that moves throughout the body in the blood. As with Berthold's roosters, the changes induced by removing the tissue should be reversed by replacing it.

Endocrinologists extract the suspected compound from the endocrine tissue of one animal and inject it into an experimental animal from which the tissue producing the compound has been removed. Deficiency symptoms should be relieved by replacing the suspected hormone. Researchers then isolate the active compound and determine its chemical structure. Finally, the compound is synthesized in the laboratory and injected into experimental animals. If its effects are those predicted, the researchers have data to support their hypothesis.

Using such procedures, endocrinologists have identified about 10 discrete endocrine glands. More recently investigators have identified specialized cells in the digestive tract, heart, kidneys, and many other parts of the body that also release hormones. In addition, some neurons release hormones. As a result of these discoveries, the scope of endocrinology has been broadened to include the production and actions of chemical messengers produced by a wide variety of organs, tissues, and cells.

One active focus of research is the study of the mechanisms of hormone action, which includes characterizing receptors and identifying the molecules involved in *signal transduction.* Some endocrinologists now use a reverse strategy for discovering new hormones and signaling pathways within the cell. They focus on "orphan" nuclear receptors, those for which ligands (the molecules that bind with them) are not yet known. Some of these "orphan" receptors are receptors for hormones that have not yet been identified. Using this strategy, researchers have identified intracellular signaling pathways for steroids, fatty acids, and several other compounds.

In this chapter we discuss the actions of a variety of hormones. We also examine how overproduction or deficiency of various hormones interferes with normal functioning. ■

CELL SIGNALING

Learning Objectives

1. Describe three main types of chemical signals used by cells, and compare types of endocrine signaling.
2. Identify four main chemical groups to which hormones are assigned, and give two examples for each group.

Cells signal one another with neurotransmitters, hormones, and local regulators. Some chemical compounds function as all three of these types of signals. Thus a neuron, endocrine gland, or some other cell type all may secrete the same chemical message. However, the same message can have different meanings for various target cells. We discussed neurotransmitters in Chapters 39 through 41. In this chapter we focus on hormones and local regulators, compounds that act on nearby cells.

Pheromones are chemical messengers that animals produce for communication with other animals of the same species. Because pheromones are generally produced by exocrine glands and do not regulate metabolic activities within the animal that produces them, most biologists do not classify them as hormones. Their role in regulating behavior is discussed in Chapter 50.

In classical endocrine signaling, hormones are secreted by endocrine glands

Endocrine glands differ from **exocrine glands** (such as sweat glands and gastric glands) that release their secretions into ducts. Endocrine glands have no ducts, and secrete their hormones into the surrounding interstitial fluid or blood. Typically, hormones diffuse into capillaries and are transported by the blood to target cells (Fig. 47-1a). Biologists have discovered that in addition to the discrete classical endocrine glands, specialized cells in many tissues and organs (such as the kidneys and heart) also release hormones or hormone-like substances.

The complexity of animal physiology challenges simplistic definitions. As new chemical signals and their modes of action have been discovered, the traditional definition of a hormone as a substance secreted by an endocrine gland and transported by the blood has become inadequate.

Neurohormones are transported in the blood

Certain neurons, known as **neuroendocrine cells,** are an important link between the nervous and endocrine systems. Neuroendocrine cells produce **neurohormones** that are transported down axons and released into the interstitial fluid. They typically diffuse into capillaries and are transported by the blood (Fig. 47-1b). Invertebrate endocrine systems are largely neuroendocrine. In vertebrates, the hypothalamus produces several neurohormones that link the nervous system with the pituitary gland, an endocrine gland that secretes several hormones.

Many endocrinologists include some local regulators as hormones

A **local regulator** is a signaling molecule that diffuses through the interstitial fluid and acts on nearby cells. Certain chemical compounds that are indisputably hormones because they are typically transported by the blood, under some conditions act as local regulators. In **autocrine regulation,** a hormone, or other

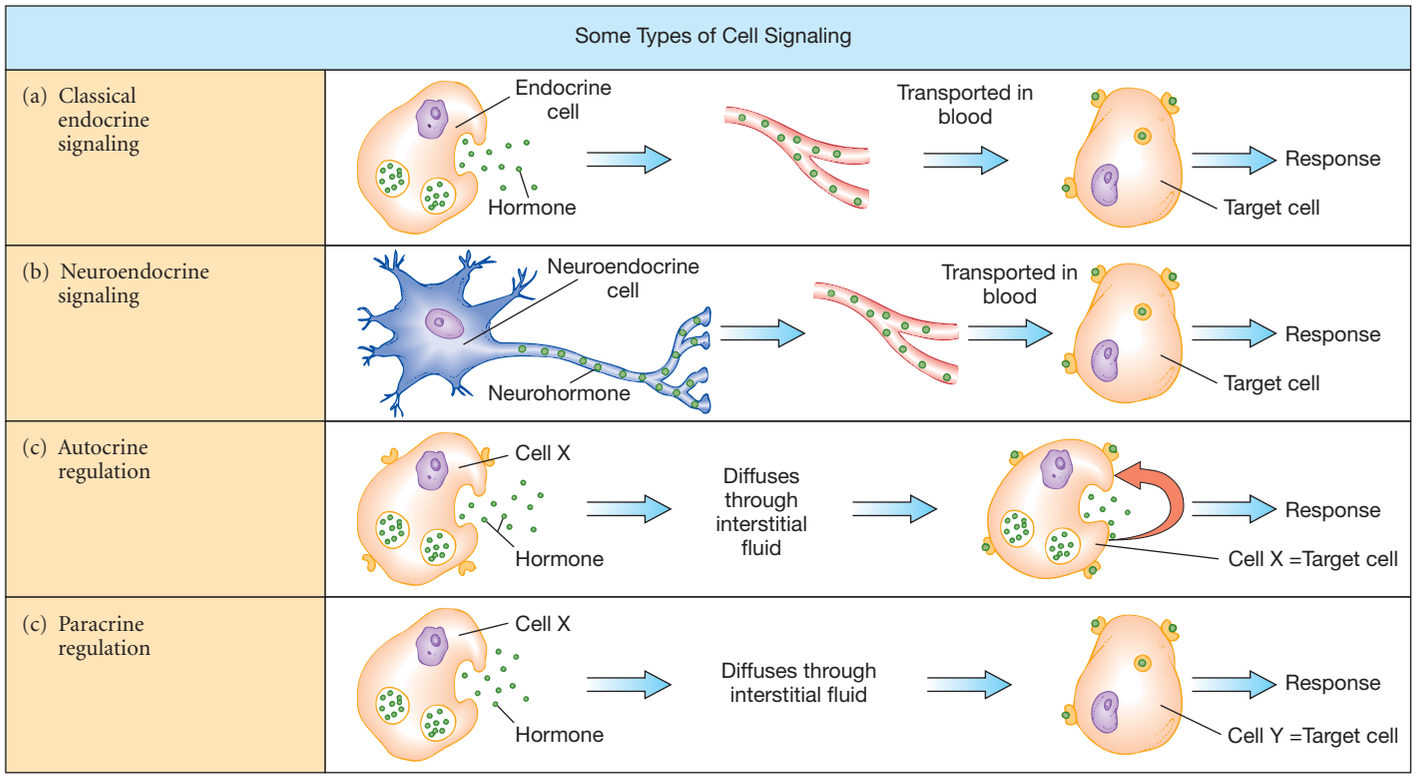

FIGURE **47-1** **Some types of endocrine signaling.**

(a) In classical endocrine signaling, endocrine cells release hormones that are transported to target cells by the blood. **(b)** In neuroendocrine signaling, neurons release neurohormones, which are transported by blood or diffuse through interstitial fluid. **(c)** In autocrine regulation, a hormone acts on the very cells that produce it. **(d)** In paracrine regulation, hormones diffuse through the interstitial fluid and act on nearby target cells.

regulator, acts on the very cells that produce it (Fig. 47-1c). For example, the female hormone estrogen, which functions as a classical hormone, may also exert an autocrine effect that stimulates additional estrogen secretion. Estrogen can also act on nearby cells, a type of local regulation known as **paracrine regulation** (Fig. 47-1d).

Local regulators include local chemical mediators such as histamine, growth factors, and prostaglandins. Recall from Chapter 43 that **histamine** is stored in mast cells and is released in response to allergic reactions, injury, or infection. Histamine causes blood vessels to dilate and capillaries to become more permeable. More than 50 **growth factors,** typically peptides, stimulate cell division and normal development in specific types of cells. Growth factors have autocrine or paracrine effects. **Nitric oxide** (NO), another local regulator, is produced by many types of cells, including those lining blood vessels. It relaxes nearby smooth muscle fibers, dilating the blood vessel.

Prostaglandins are modified fatty acids released continuously by the cells of most tissues. Biologists have grouped them into nine different classes. Although present in very small quantities, these local regulators affect a wide range of body processes. Prostaglandins are paracrine regulators that act on cells in their immediate vicinity. They modify cyclic adenosine monophosphate (cAMP) levels (discussed later in the chapter) and interact with other hormones to regulate various metabolic activities.

The major prostaglandin target is smooth muscle. Some prostaglandins stimulate smooth muscle to contract, whereas others cause relaxation. Thus some reduce blood pressure, whereas others raise it. Prostaglandins synthesized in the temperature-regulating center of the hypothalamus cause fever. In fact, nonsteroidal anti-inflammatory drugs (NSAIDs) such as aspirin and ibuprofen reduce fever and decrease inflammation by inhibiting prostaglandin synthesis.

Because prostaglandins are involved in the regulation of so many metabolic processes, they have great potential for a variety of clinical uses. Physicians use them to induce labor in pregnant women, to induce abortion, and to promote the healing of ulcers in the stomach and duodenum. Prostaglandins may someday be used to treat a wide variety of illnesses, including asthma, arthritis, kidney disease, certain cardiovascular disorders, and some forms of cancer.

Hormones are assigned to four chemical groups

Although hormones are chemically diverse, they generally belong to one of four different chemical groups: (1) fatty acid derivatives, (2) steroids, (3) amino acid derivatives, or (4) peptides or proteins (Fig. 47-2).

Focus On Anabolic Steroids and Other Abused Hormones

An estimated 1 million people in the United States, half of them adolescents, abuse anabolic steroids, a group of synthetic hormones. Anabolic steroids are synthetic androgens (male reproductive hormones) that were developed in the 1930s to prevent muscle atrophy in patients with diseases that prevented them from moving about. In the 1950s, anabolic steroids became popular with professional athletes, who used them to increase muscle mass, physical strength, endurance, and aggressiveness. In truth, their athletic performance was probably enhanced, at least in part, by drug-induced euphoria and increased enthusiasm for training.

As with other hormones, the concentration of steroids circulating in the body is precisely regulated, so use of anabolic steroids interferes with normal physiological processes. Even during short-term use and at relatively low doses, anabolic steroids have a significant effect on mood and behavior. At higher doses, users experience disturbed thought processes, forgetfulness, and confusion, and often find themselves easily distracted. The term "steroid rage" refers to the mood swings, unpredictable anger, increased aggressiveness, and irrational behavior exhibited by many users.

Anabolic steroids elevate blood pressure, damage the liver, and increase low-density lipoprotein (LDL) concentration, raising the risk of cardiovascular disease. In adolescents, these steroids cause severe acne and stunt growth by prematurely closing the growth plates in bones. Abuse of these hormones reduces sexual function and can shrink the testes, leading to sterility. These drugs remain in the body for a long time. Their metabolites (breakdown products) can be detected in the urine for up to six months.

When their serious side effects became known in the 1960s, anabolic steroid use became controversial, and in 1973 the Olympic Committee banned their use. They are now prohibited worldwide by amateur and professional sports organizations. However, according to the U.S. Drug Enforcement Administration, a multimillion-dollar black market exists for these synthetic hormones. They are both injected and taken in pill form. Steroid abusers who share needles or use nonsterile techniques when they inject steroids are at risk for contracting hepatitis, HIV, and other serious infections.

The typical anabolic steroid user is a male (95%) athlete (65%), most often a football player, weight lifter, or wrestler. Surprisingly, though, about 10% of male high school students have used anabolic steroids and about one third of these students are not even on a high school team. These adolescents use the hormone only to change their physical appearance—to pump up their muscles ("bulk up")—and increase endurance. Many anabolic steroid users have difficulty realistically perceiving their body images. They remain unhappy even after dramatic increases in muscle mass.

People also abuse other hormones, including human growth hormone (GH) and erythropoietin. Human growth hormone, like anabolic steroids, helps build muscle mass but also causes acromegaly. Erythropoietin increases the concentration of red blood cells. Although increased oxygen transport enhances the performance of an endurance athlete up to 10%, abnormally high concentrations of red blood cells can cause serious cardiovascular problems. Erythropoietin abuse has caused the deaths of several athletes.

Prostaglandins and the juvenile hormones of insects are **fatty acid derivatives** (Fig. 47-2a). Prostaglandins are synthesized from arachidonic acid, a 20-carbon fatty acid. A prostaglandin has a five-carbon ring in its structure.

The molting hormone of insects is a **steroid hormone** (Fig. 47-2b). In vertebrates, the adrenal cortex, testis, ovary, and placenta secrete steroid hormones synthesized from cholesterol. Examples of steroid hormones are cortisol, secreted by the adrenal cortex, the male hormone testosterone secreted by the testis, and the female hormones progesterone and estrogens produced by the ovary. Athletes (and others) sometimes abuse synthetic hormones known as anabolic steroids (see *Focus On: Anabolic Steroids and Other Abused Hormones*).

Chemically, the simplest hormones are **amino acid derivatives** (Fig. 47-2c). The thyroid hormones (T_3 and T_4) are synthesized from the amino acid tyrosine and iodide. Epinephrine (also known as adrenaline) and norepinephrine (also known as noradrenaline), produced by the medulla of the adrenal gland, are also derived from tyrosine. Melatonin is synthesized from the amino acid tryptophan.

The water-soluble **peptide hormones** are the largest hormone group. (Endocrinologists include protein hormones in this group.) **Neuropeptides** are a large group of signaling molecules produced by neurons. Oxytocin and antidiuretic hormone (ADH), produced by neuroendocrine cells in the hypothalamus, are short neuropeptides, each composed of nine amino acids (Fig. 47-2d). Seven of the amino acids are identical in the two hormones, but the actions of these hormones are quite different. The hormones glucagon (see Fig. 3-19), secretin, adrenocorticotropic hormone (ACTH), and calcitonin are somewhat longer peptides consisting of about 30 amino acids.

Insulin is a small protein consisting of two peptide chains joined by disulfide bonds. Growth hormone, thyroid-stimulating hormone, and the gonadotropic hormones, all secreted by the anterior lobe of the pituitary gland, are large proteins with molecular weights of 25,000 or more.

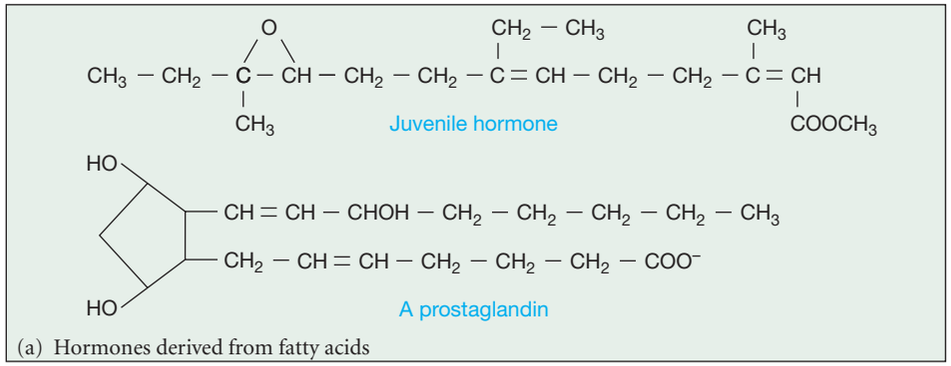
Review

- How has the definition of the term *hormone* changed in recent years? Explain your answer.
- How are neuroendocrine and paracrine signaling different?
- What are the four major chemical groups of hormones?

BiologyNow™ Assess your understanding of **cell signaling** by taking the pretest on your BiologyNow CD-ROM.

FIGURE **47-2**

Major chemical groups of hormones.



(a) Hormones derived from fatty acids

(d) Peptide hormones

REGULATION OF HORMONE SECRETION

Learning Objective

3 Summarize the regulation of endocrine glands by negative feedback mechanisms.

Although present in minute amounts, more than 50 different hormones may be circulating in the blood of a vertebrate at any time. Steroid hormones and thyroid hormones are transported bound to plasma proteins. Peptide hormones are water soluble and are transported dissolved in the plasma. Hormone molecules continuously move out of the circulation, and bind with target cells. They are removed from the blood by the liver, which inactivates some hormones, and by the kidneys, which excrete them.

Hormone secretion is typically regulated by **negative feedback mechanisms,** in which a hormone is released in response to some change in a steady state and triggers a response that counteracts the changed condition, restoring homeostasis (see Chapter 37). Information about the concentration of hormone in the blood or interstitial fluid is fed back to the gland, which then responds to restore homeostasis. The parathyroid glands, located in the neck of tetrapod vertebrates, provide a good example of how negative feedback works (Fig. 47-3).

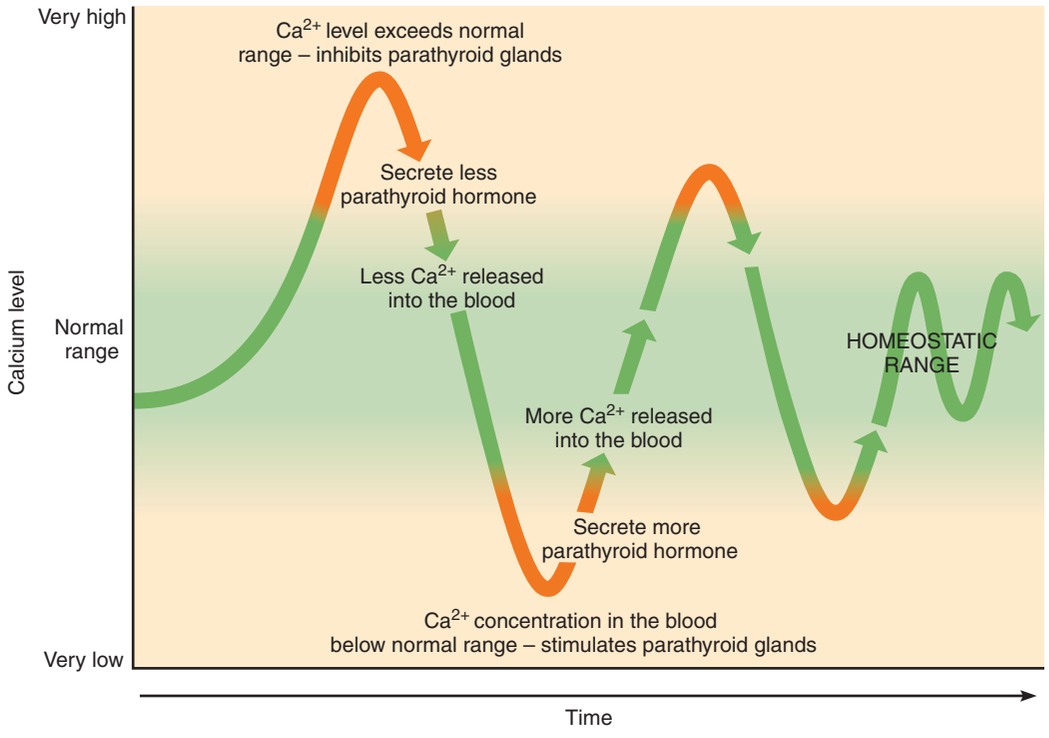
The parathyroid glands regulate the calcium concentration of the blood. When the calcium concentration is not within homeostatic limits, nerves and muscles cannot function properly. For example, when too few calcium ions are present, neurons fire spontaneously, causing muscle spasms. When calcium concentration varies too far from the steady state (either too high or too low), negative feedback mechanisms restore homeostasis.

A decrease in the calcium concentration in the plasma signals the parathyroid glands to release more parathyroid hormone. This hormone increases the concentration of calcium in the blood. (The details of parathyroid action are discussed later in this chapter.) When the calcium concentration rises above normal limits, the parathyroid glands slow their output of hormone. Both responses are negative feedback mechanisms. An increase in calcium concentration results in decreased release of parathyroid hormone, whereas a decrease in calcium leads to increased

FIGURE **47-3**

Regulation by negative feedback.

When calcium concentration exceeds its normal range in the blood, the parathyroid glands are inhibited and slow their release of parathyroid hormone. When the blood calcium concentration falls below its normal range, the parathyroid glands release more parathyroid hormone. This hormone acts on target tissues that increase the calcium concentration in the blood, thus restoring homeostasis.



hormone secretion. In each case, the response counteracts the inappropriate change, restoring the steady state.

Review

- How does the body respond when the concentration of calcium in the blood is below the homeostatic level?
- How does negative feedback work?

MECHANISMS OF HORMONE ACTION

Learning Objective

4 Compare the mechanisms of action of steroid and protein-type hormones; include the role of second messengers, such as cyclic AMP.

A hormone present in the extracellular fluid, remains "unnoticed" until it reaches its target cells. The **target cells** of a particular hormone have receptors that recognize and bind it. Hormone receptors are large proteins or glycoproteins. The receptor site is similar to a lock, and the hormones are like different keys. Only the hormone that fits the specific receptor can influence the metabolic machinery of the cell. Receptors are responsible for the specificity of the endocrine system.

Receptors are continuously synthesized and degraded. Their numbers are increased or decreased by **receptor up-regulation** and **receptor down-regulation.** For example, when the concentration of the hormone insulin is too high for an extended period, cells decrease the number of their insulin receptors. This down-regulation dampens insulin's ability to stimulate cells to take in glucose. Down-regulation suppresses the sensitivity of target cells to the hormone. Up-regulation occurs in response to low hormone concentrations. A greater number of receptors on the plasma membrane amplifies the hormone's effect on the cell. Receptor up-regulation and down-regulation is triggered by signals to genes that code for the receptors, as well as by several other mechanisms.

Some hormones enter target cells and activate genes

Steroid hormones and thyroid hormones are relatively small, lipid-soluble (hydrophobic) molecules that easily pass through the plasma membrane of the target cell. Specific protein receptors in the cytoplasm or in the nucleus bind with the hormone to form a hormone-receptor complex (Fig. 47-4). This complex combines with specific acceptor sites on the nuclear DNA, and turns specific genes on or off, activating or repressing transcription of messenger RNA molecules that code for specific proteins. These proteins produce the changes in structure or metabolic activity responsible for the hormone's action. Interestingly, some target cells have plasma membrane receptors, as well as intracellular receptors, for steroid hormones.

Many hormones bind to cell-surface receptors

Because peptide hormones are hydrophilic and not soluble in the lipid layer of the plasma membrane, they do not enter the target cell. Instead, they bind to a specific cell-surface receptor in

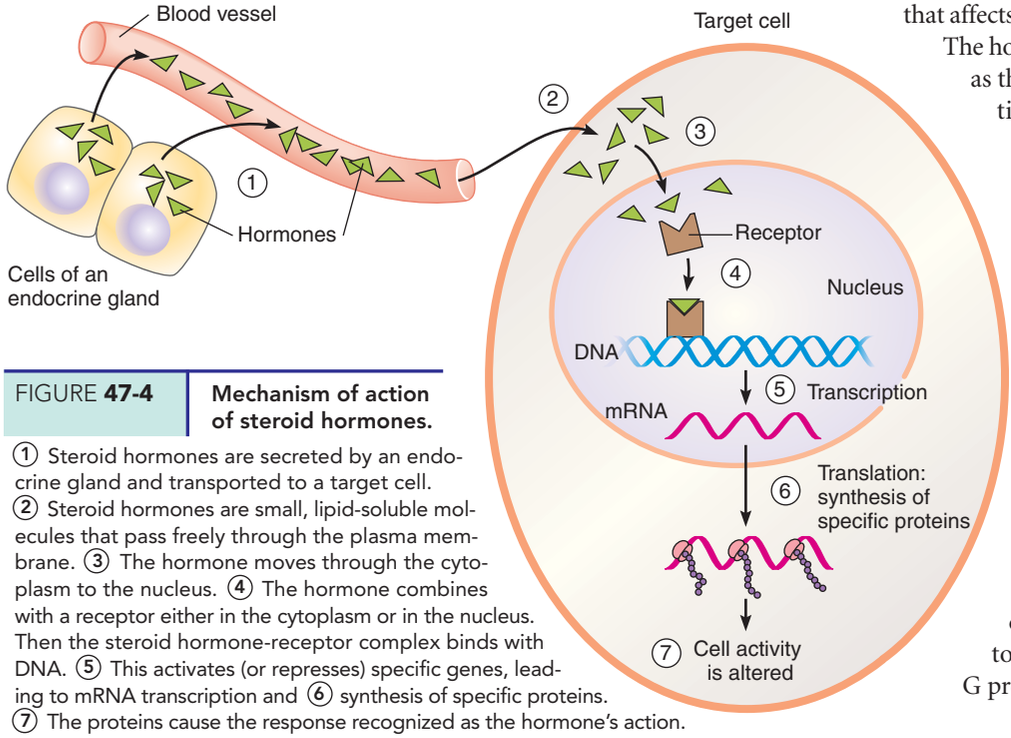

FIGURE 47-4 **Mechanism of action of steroid hormones.**

① Steroid hormones are secreted by an endocrine gland and transported to a target cell. ② Steroid hormones are small, lipid-soluble molecules that pass freely through the plasma membrane. ③ The hormone moves through the cytoplasm to the nucleus. ④ The hormone combines with a receptor either in the cytoplasm or in the nucleus. Then the steroid hormone-receptor complex binds with DNA. ⑤ This activates (or represses) specific genes, leading to mRNA transcription and ⑥ synthesis of specific proteins. ⑦ The proteins cause the response recognized as the hormone's action.

that affects some intracellular process (Fig. 47-5). The hormone does not enter the cell. It serves as the first messenger and relays information to a **second messenger,** or intracellular signal. The second messenger then signals effector molecules that carry out the action. Thus, many hormones activate a series of molecular events that comprise a *signaling cascade.*

G protein–linked receptors activate **G proteins,** a group of integral regulatory proteins (Fig. 47-6). The G indicates that they bind **guanosine triphosphate (GTP),** which, like ATP, is an important molecule in energy reactions. When the system is inactive, G protein binds to **guanosine diphosphate (GDP),** which is similar to ADP, the hydrolyzed form of ATP. G proteins shuttle a signal between the receptor and the effector.

the plasma membrane. Two main types of cell-surface receptors are G protein–linked receptors and enzyme-linked receptors.

Cell signaling through G protein–linked receptors

G protein–linked receptors are transmembrane proteins that loop back and forth through the plasma membrane seven times. These receptors initiate **signal transduction;** that is, they convert an extracellular hormone signal into an intracellular signal

FIGURE 47-5 **Overview of peptide hormone action.**

① Peptide hormones bind with receptors on the plasma membrane of a target cell. The receptor is a signal transducer that converts the hormone signal to an intracellular signal. ② The signal is relayed by a second messenger. Typically, a sequence of several signaling molecules relays the message. ③ Some cell activity is altered.

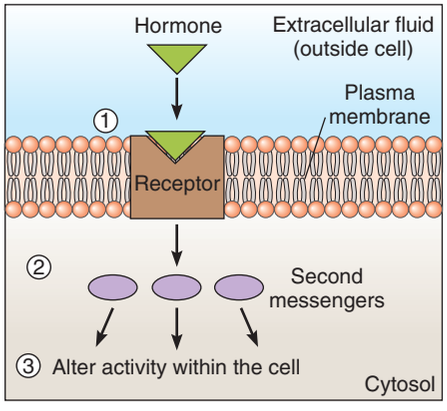

FIGURE 47-6

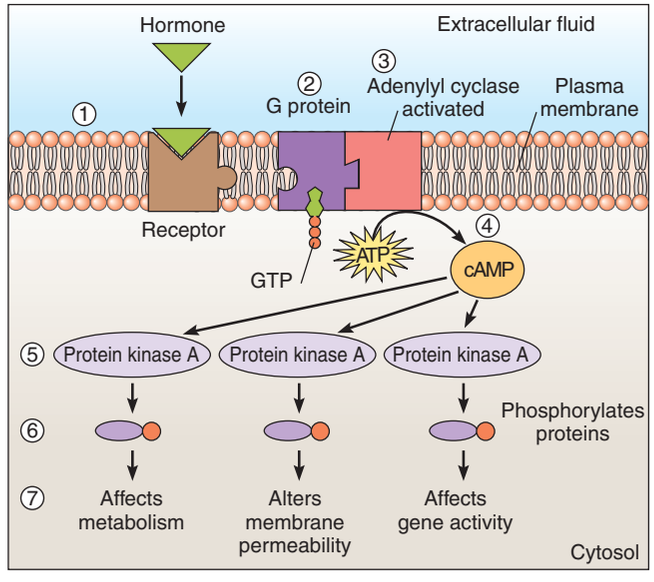
Mechanism of action of hormones that use G protein–linked receptors and second messengers.

① A hormone binds with a G protein–linked receptor in the plasma membrane of a target cell, ② activating a G protein (GDP on the G protein is replaced by GTP). ③ The G protein activates adenylyl cyclase. ④ ATP is converted to cAMP, a second messenger, which ⑤ activates protein kinase A. ⑥ This enzyme phosphorylates proteins ⑦ altering their function. (GTP, guanosine triphosphate; cAMP, cyclic AMP).

KEY CONCEPT: Many hormones signal target cells by way of a G protein–linked receptor. Cyclic AMP (or some other second messenger) relays the signal as part of a cascade of reactions that changes some cell process (the hormone action).



ceptor and a second messenger. Hundreds of different G protein–linked receptors have been identified.

Cyclic AMP is a common second messenger

When a hormone-bound receptor binds to it, a stimulatory G protein releases GDP and replaces it with GTP. The G protein undergoes a conformational change (change in shape), allowing it to bind with and activate **adenylyl cyclase,** an enzyme on the cytoplasmic side of the plasma membrane. Adenylyl cyclase catalyzes the conversion of ATP to cAMP. Note that a G protein couples adenylyl cyclase action to the hormone-receptor complex (Fig. 47-6). One type of G protein, G_s, stimulates adenylyl cyclase, and another, G_i, inhibits it.

Once activated, adenylyl cyclase catalyzes the conversion of ATP to **cyclic AMP (cAMP).** By coupling the hormone-receptor complex to an enzyme that generates a signal, G proteins amplify hormone effects and many second-messenger molecules are rapidly produced. In the 1960s, Earl Sutherland identified cAMP as a second messenger, and for his pioneering work he received the 1971 Nobel Prize in Medicine. Cyclic AMP is a common second messenger in prokaryotic and animal cells.

Cyclic AMP activates **protein kinase A,** an enzyme that phosphorylates (adds a phosphate group to) certain specific proteins. When a protein is phosphorylated, its function is altered, and it triggers a chain of reactions leading to some metabolic change. The substrates for protein kinase A are different in various cell types, so the effect of the enzyme varies. In skeletal muscle cells, protein kinase A triggers the breakdown of glycogen to glucose, whereas in cells of the hypothalamus the same enzyme activates the gene that encodes a growth-inhibiting hormone.

Any increase in cAMP is temporary. Cyclic AMP is rapidly inactivated by **phosphodiesterases,** which convert it to AMP. Thus the concentration of cAMP depends on the activity of both adenylyl cyclase, which produces it, and of phosphodiesterase, which breaks it down.

Phospholipid products and calcium ions can act as second messengers

Certain hormone-receptor complexes activate a G protein that then activates the membrane-bound enzyme phospholipase C (Fig. 47-7). This enzyme splits a membrane protein, PIP_2 (phosphotidylinositol 4,5-bisphosphate), into two products, **inositol trisphosphate (IP_3)** and **diacylglycerol (DAG);** both act as second messengers. DAG remains in the plasma membrane where (in combination with calcium ions) it activates **protein kinase C.** This enzyme phosphorylates a variety of proteins.

IP_3 opens calcium channels in the endoplasmic reticulum, releasing calcium ions into the cytosol. Calcium ions have important functions in many cell processes, including muscle contraction, neural signaling, microtubule disassembly, blood clotting, and activation of some enzymes. However, calcium ions do not act alone; they exert their effects by binding to certain proteins such as **calmodulin,** which is found in all eukaryotic cells. The calmodulin molecules change shape and then activate certain proteins, altering their activity.

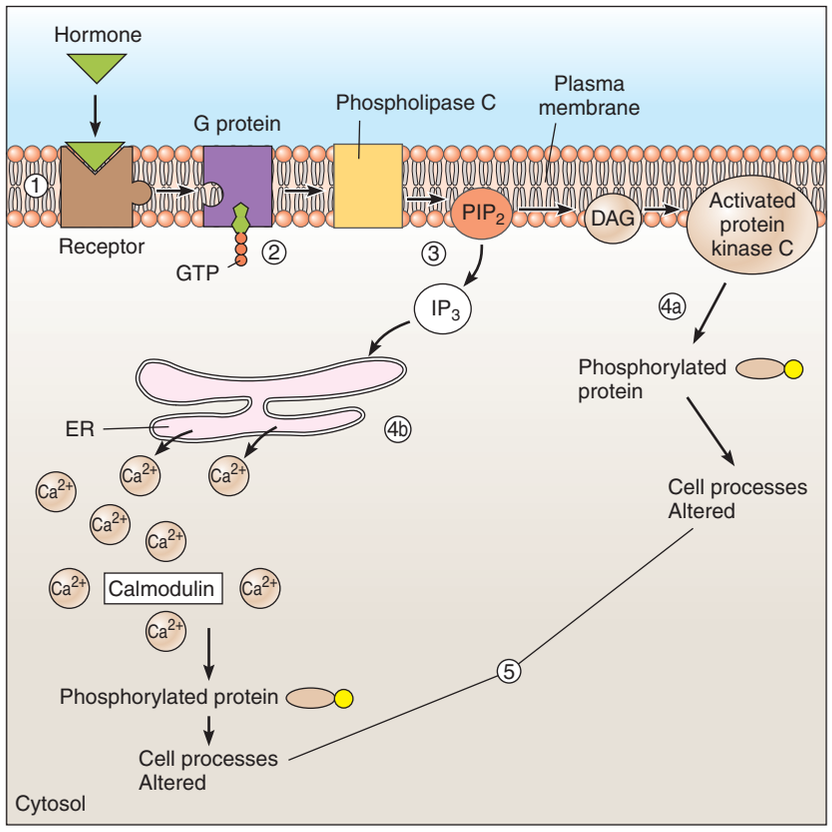


FIGURE **47-7** **Phospholipid products as second messengers.**

① A hormone binds with a cell-surface receptor, which ② activates a G protein that activates phospholipase C. ③ This enzyme splits PIP_2 into two products, DAG and IP_3. ④a DAG activates protein kinase C, which phosphorylates proteins. ④b IP_3 opens calcium channels in the ER. Calcium ions combine with calmodulin, which activates proteins. ⑤ Cell processes are altered by the actions of both DAG and IP_3. (GTP, guanosine trisphosphate; PIP_2, phosphotidylinositol 4,5-bisphosphate; DAG, diacylglycerol; IP_3, inositol trisphosphate).

Enzyme-linked receptors function directly

Enzyme-linked receptors are transmembrane proteins with a hormone-binding site outside the cell and an enzyme site inside the cell. These receptors are not linked to G proteins. They function directly as enzymes or are directly linked to enzymes. Most enzyme-linked receptors are **receptor tyrosine kinases.** These receptors bind signal molecules known as *growth factors,* including insulin and nerve growth factor. When the growth factor

binds to the receptor, the receptor is activated and phosphorylates the amino acid tyrosine in specific cell proteins.

Hormone signals are amplified

Although hormones are present in very small amounts, they effectively regulate many physiological processes. This is in large part the result of **signal amplification,** an increase in signal strength. For example, a single hormone molecule activates up to 100 G proteins. Each adenylyl cyclase molecule produces many cAMP molecules. In turn, each cAMP activates a protein kinase that phosphorylates many protein molecules. Thus, through a cascade of signals and reactions, a single hormone molecule activates many proteins.

Review

- What are the roles of receptors and second messengers in hormone action?
- How are the mechanisms of action of steroid and peptide hormones different?
- What is the mechanism of action of a hormone that uses cyclic AMP as a second messenger?

INVERTEBRATE NEUROENDOCRINE SYSTEMS

Learning Objective

5 Identify four functions of hormones in invertebrates, and describe the hormonal regulation of insect development.

Among invertebrates, hormones are secreted mainly by neurons rather than by endocrine glands. These **neurohormones** regulate regeneration in hydras, flatworms, and annelids; color changes in crustaceans; and growth, development, metabolic rate, gamete production, and reproduction, including reproductive behavior in many other groups. Trends in the evolution of invertebrate endocrine systems include a larger number of both neurohormones and hormones secreted by endocrine glands, and a greater role of hormones in physiological processes.

Insects have endocrine glands as well as neuroendocrine cells. Their various hormones and neurohormones interact with one another to regulate metabolism, growth, and development, including molting and metamorphosis. Hormonal control of development in insects varies among species. Generally, some environmental factor (such as temperature change) activates neuroendocrine cells in the brain. These cells then produce a neurohormone referred to as **brain hormone (BH),** which is transported down axons and stored in the paired **corpora cardiaca** (sing., *corpus cardiacum;* Fig. 47-8). When released from the corpora cardiaca, BH stimulates the **prothoracic glands,** endocrine glands in the prothorax, to produce **molting hormone (MH),** also called **ecdysone.** Molting hormone, a steroid hormone, stimulates growth and molting.

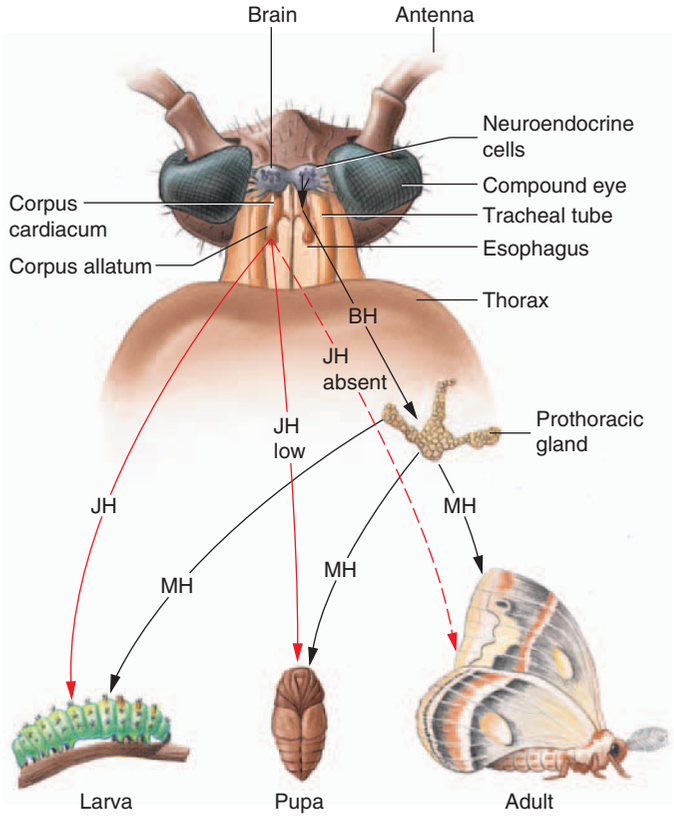

FIGURE **47-8** **Regulation of growth and molting in insects.**

The dissection of an insect head shows the brain, paired corpora allata, and corpora cardiaca. Neuroendocrine cells secrete brain hormone (BH), which is stored in the corpora cardiaca. When released, BH stimulates the prothoracic glands to secrete molting hormone (MH), which stimulates growth and molting. In the immature insect, the corpora allata secrete juvenile hormone (JH), which suppresses metamorphosis at each larval molt. Metamorphosis to the adult form occurs when molting hormone acts in the absence of juvenile hormone.

In the immature insect, paired endocrine glands called **corpora allata** (sing., *corpus allatum*) secrete **juvenile hormone (JH).** This hormone suppresses metamorphosis at each larval molt so that the insect increases in size while remaining in its immature state; after the molt, the insect is still in a larval stage. When the concentration of JH decreases, metamorphosis occurs, and the insect is transformed into a pupa (see Chapter 29). In the absence of JH, the pupa molts and becomes an adult. The nervous system regulates the secretory activity of the corpora allata, and the amount of JH decreases with successive molts.

THE VERTEBRATE ENDOCRINE SYSTEM

Learning Objectives

6 Identify the principal vertebrate endocrine glands, and describe the actions of their hormones.

7 Describe the mechanisms by which the hypothalamus and pituitary gland integrate many regulatory functions; describe the actions of the hypothalamic and pituitary hormones.

8 Describe the actions of the thyroid and parathyroid hormones, their regulation, and the effects of malfunction.

9 Contrast the actions of insulin and glucagon, and describe the disorders associated with impaired function of these hormones or their receptors.

10 Describe the actions of the adrenal hormones, including their role in helping the body cope with stress.

Vertebrate hormones regulate such diverse activities as growth, development, reproduction, metabolic rate, fluid balance, blood homeostasis, and coping with stress. Most vertebrates have similar endocrine glands, although the actions of some hormones may be different in various groups. Table 47-1 gives the sources, target tissues, and principal physiological actions of some of the major vertebrate hormones. Many of these hormones are regulated by the hypothalamus and pituitary gland. The principal human endocrine glands are illustrated in Figure 47-9.

Homeostasis depends on normal concentrations of hormones

When a disorder or disease process affects an endocrine gland, the rate of secretion may become abnormal. If **hyposecretion** (abnormally reduced output) occurs, target cells are deprived of needed stimulation. If **hypersecretion** (abnormally increased output) occurs, the target cells may be overstimulated. In some endocrine disorders, an appropriate amount of hormone is secreted, but the target cell receptors do not function properly. As a result, the target cells cannot respond to the hormone. Any of these abnormalities leads to loss of homeostasis, resulting in predictable metabolic malfunctions and clinical symptoms (Table 47-2).

The hypothalamus regulates the pituitary gland

Most endocrine activity is controlled directly or indirectly by the **hypothalamus,** which links the nervous and endocrine systems both anatomically and physiologically. The **pituitary gland** is connected to the hypothalamus by the pituitary stalk. In response to input from other areas of the brain and from hormones in the blood, neurons of the hypothalamus secrete neurohormones that regulate specific physiological processes.

Because its secretions control the activities of several other endocrine glands, biologists consider the pituitary gland to be the master gland of the body. Although it is only the size of a large pea and weighs only about 0.5 g (0.02 oz), the pituitary gland produces and secretes at least seven peptide hormones that exert far-reaching influence over body activities. The human pituitary gland consists of two main parts: the **anterior lobe** and the **posterior lobe.** In some vertebrates, an intermediate lobe is present.

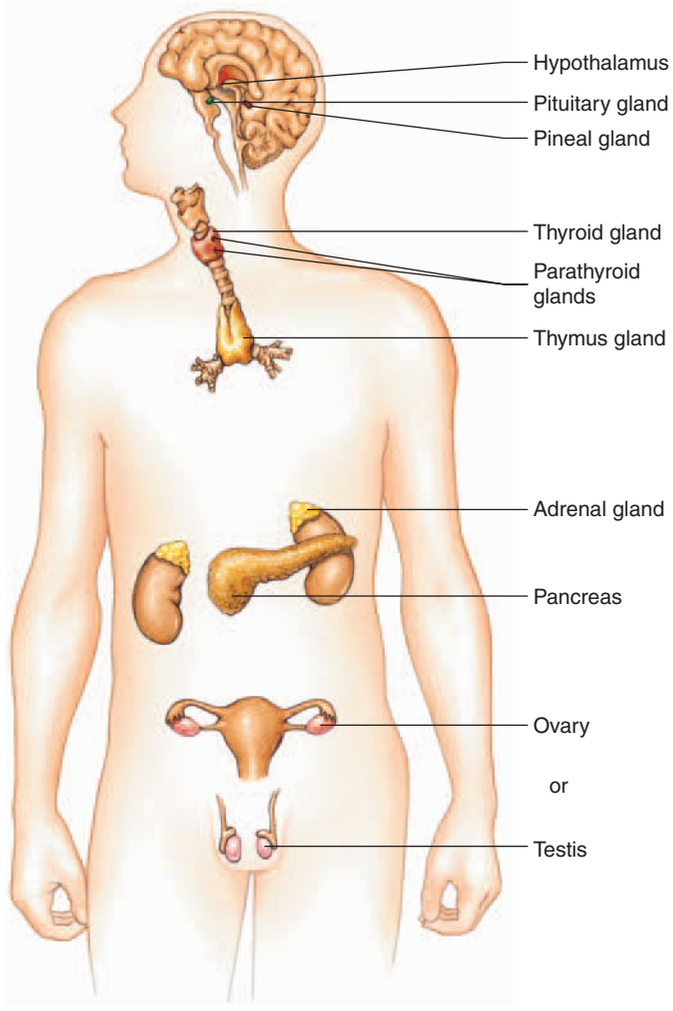

FIGURE **47-9** **The classical human endocrine glands.**
The hormones produced by these glands and their actions are discussed in this chapter.

The posterior lobe of the pituitary gland releases hormones produced by the hypothalamus

The **posterior lobe** of the pituitary gland develops from brain tissue. This neuroendocrine organ *secretes* two peptide hormones, **oxytocin** and **antidiuretic hormone,** or **ADH** (also known as *vasopressin*). (The function of ADH in regulating water reabsorption in the kidneys was discussed in Chapter 46.) These

TABLE 47-1 **Some Endocrine Glands and Their Hormones***

Gland	Hormone	Target Tissue	Principal Actions
Hypothalamus	Releasing and inhibiting hormones	Anterior lobe of pituitary	Regulate secretion of hormones by the anterior pituitary
Posterior pituitary (storage and release of hormones produced by hypothalamus)	Oxytocin	Uterus Mammary glands	Stimulates contraction Stimulates ejection of milk into ducts
	Antidiuretic hormone (ADH)	Kidneys (collecting ducts)	Stimulates reabsorption of water
Anterior pituitary	Growth hormone (GH)	General	Stimulates growth of skeleton and muscle
	Prolactin	Mammary glands	Stimulates milk production
	Thyroid-stimulating hormone (TSH)	Thyroid gland	Stimulates secretion of thyroid hormones
	Adrenocorticotropic hormone (ACTH)	Adrenal cortex	Stimulates secretion of adrenal cortical hormones
	Gonadotropic hormones* (follicle-stimulating hormone [FSH]; luteinizing hormone [LH])	Gonads	Stimulate gonad function and growth
Thyroid gland	Thyroxine (T_4) and triiodothyronine (T_3)	General	Stimulate metabolic rate; regulate energy metabolism
	Calcitonin	Bone	Lowers blood-calcium level
Parathyroid glands	Parathyroid hormone	Bone, kidneys digestive tract	Regulates blood-calcium level
Pancreas	Insulin	General	Lowers blood glucose concentration
	Glucagon	Liver, adipose tissue	Raises blood glucose concentration
Adrenal Medulla	Epinephrine and norepinephrine	Muscle; blood vessels; liver; adipose tissue	Help body cope with stress; increase metabolic rate; raise blood glucose level; increase heart rate and blood pressure
Adrenal Cortex	Mineralocorticoids	Kidney tubules	Maintain sodium and potassium balance
	Glucocorticoids	General	Help body cope with long-term stress; raise blood-glucose level
Pineal gland	Melatonin	Hypothalamus	Important in biological rhythms
Ovary†	Estrogens	General; uterus	Develop and maintain sex characteristics in female; stimulate growth of uterine lining
	Progesterone	Uterus; breast	Stimulates development of uterine lining
Testis†	Testosterone	General; reproductive structures	Develops and maintains sex characteristics in males; promotes spermatogenesis

*Discussed in Chapter 48.

†For more detailed description see Tables 48-1 and 48-2.

TABLE 47-2 **Consequences of Endocrine Malfunction**

Hormone	Hyposecretion	Hypersecretion
Growth hormone	Pituitary dwarfism	Gigantism if malfunction occurs in childhood; acromegaly in adult
Thyroid hormones	Cretinism (in children); myxedema, a condition of prounounced adult hypothyroidism; dietary iodine deficiency leads to hyposecretion and goiter	Hyperthyroidism; increased metabolic rate, nervousness, irritability; goiter, can be caused by Grave's disease
Parathyroid hormone	Spontaneous discharge of nerves; spasms; tetany; death	Weak, brittle bones; kidney stones
Insulin	Diabetes mellitus	Hypoglycemia
Hormones of adrenal cortex	Addison's disease	Cushing's disease

hormones are actually *produced* by neuroendocrine cells in two distinct areas of the hypothalamus. Enclosed within vesicles, oxytocin and ADH are transported down the axons of these neuroendocrine cells into the posterior lobe of the pituitary gland (Fig. 47-10). The vesicles are stored in the axon terminals until the neuron is stimulated. Then the hormones are released and diffuse into surrounding capillaries.

Oxytocin concentration in the blood rises toward the end of pregnancy, stimulating the strong contractions of the uterus needed to expel a baby. Oxytocin is sometimes administered clinically to initiate or speed labor. After birth, when an infant sucks at its mother's breast, sensory neurons signal the pituitary to release oxytocin. The hormone stimulates contraction of smooth muscle cells surrounding the milk glands so that milk is let down into the ducts, from which it can be sucked by the infant. Because oxytocin also stimulates the uterus to contract, breast-feeding promotes recovery of the uterus to nonpregnant size.

The anterior lobe of the pituitary gland regulates growth and other endocrine glands

The **anterior lobe** of the pituitary develops from epithelial cells rather than neural cells. The anterior lobe functions like a classical endocrine gland: it receives signals by way of the blood and releases its hormones into the blood. The hypothalamus produces several **releasing hormones** and **inhibiting hormones** that regulate the production and secretion of specific hormones by the anterior pituitary gland. These neurohormones enter capillaries and pass through special portal veins that connect the hypothalamus with the anterior lobe of the pituitary. (These portal veins, like the hepatic portal vein, do not deliver blood to a larger vein directly but connect two sets of capillaries.) Within the anterior lobe of the pituitary, the portal veins divide into a second set of capillaries. The releasing and inhibiting hormones pass through the walls of these capillaries into the tissue of the anterior lobe.

The anterior lobe secretes prolactin, growth hormone, and several **tropic hormones** that stimulate other endocrine glands (Fig. 47-11). **Prolactin** stimulates the cells of the mammary glands to produce milk in a nursing mother.

Growth hormone stimulates protein synthesis

Small children measure themselves periodically against their parents, eagerly awaiting that time when they, too, will be "big."

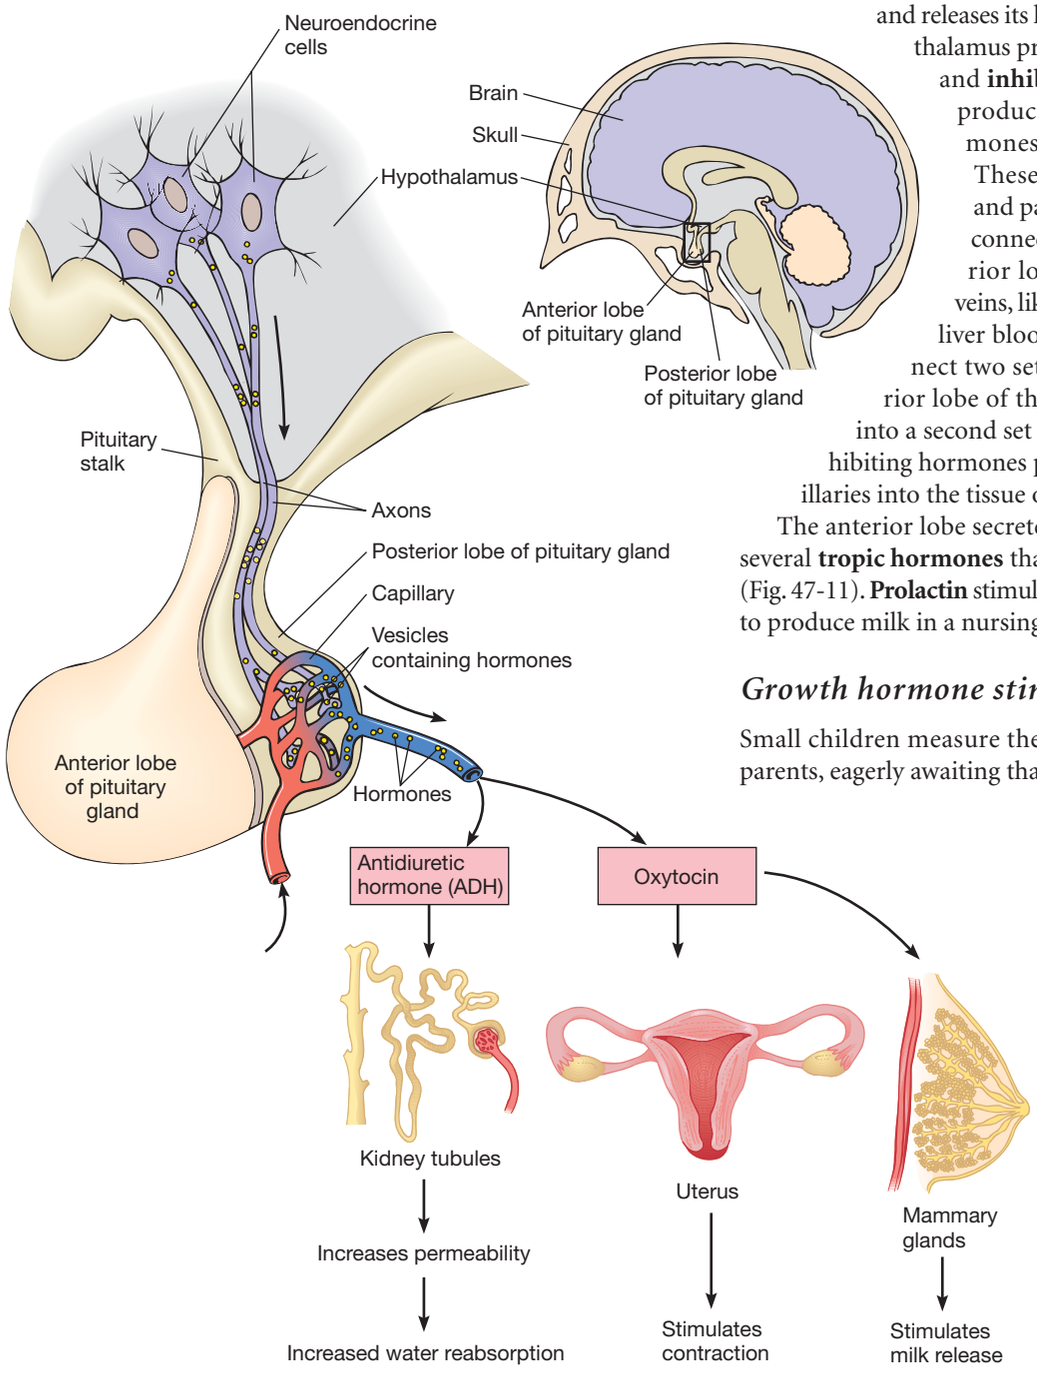

FIGURE **47-10**

The relationship between the hypothalamus and posterior lobe of the pituitary gland.

Neuroendocrine cells of the hypothalamus manufacture hormones that are secreted by the posterior lobe of the pituitary. The axons of these neurons extend down into the posterior lobe of the pituitary. Their hormones are packaged in vesicles that are transported through the axons and stored in their ends. When needed, the hormones are secreted, enter the blood, and are transported by the circulatory system.

Whether someone is tall or short depends on many factors, including genes, diet, and hormonal balance. **Growth hormone** (**GH;** also called *somatotropin*) is referred to as an **anabolic hormone** because it promotes tissue growth. Many of the effects of GH on skeletal growth are indirect. GH stimulates liver cells (and cells of many other tissues) to produce peptides called **insulin-like growth factors (IGFs).** These growth factors (1) promote the linear growth of the skeleton by stimulating cartilage formation in growth areas of bones, and (2) stimulate general tissue growth and increase in organ size by promoting protein synthesis and other anabolic processes.

In adults as well as in growing children, GH is secreted in pulses throughout the day. The hypothalamus regulates GH secretion by secreting a **growth hormone–releasing hormone** (**GHRH**) and a **growth hormone–inhibiting hormone** (**GHIH;** also called somatostatin). A high level of GH in the blood signals the hypothalamus to secrete GHIH and the pituitary slows its release of GH. A low level of GH in the blood stimulates the hypothalamus to secrete GHRH, which stimulates the pituitary gland to release more GH. Many other factors, including blood sugar level, amino acid concentration, and stress, influence GH secretion.

Research supports the age-old notions that to grow, children need plenty of sleep, a proper diet, and regular exercise. Secretion of GH increases during exercise, probably because rapid metabolism by muscle cells lowers the blood glucose level. GH is secreted about 1 hour after the onset of deep sleep and in a series of pulses 2 to 4 hours after a meal.

Emotional support is also necessary for proper growth. Growth is retarded in children who are deprived of cuddling, playing, and other forms of nurture, even when their needs for food and shelter are met. In extreme cases, childhood stress can produce a form of retarded development known as *psychosocial dwarfism.* Some emotionally deprived children exhibit abnormal sleep patterns, which may be the basis for decreased secretion of GH.

Other hormones also influence growth. Thyroid hormones appear necessary for normal GH secretion and function and for normal tissue response to IGFs. Sex hormones must be present for the adolescent growth spurt to occur. However, the presence
