About the Cover

Two red-eyed tree frogs (*Agalychnis callidryas*) peer over a leaf. Native to Central and South America, these brightly colored frogs inhabit lowland tropical rain forests near water. They are nocturnal animals and sleep attached to leaves during the day. They blend into the foliage quite well, because they cover the colorful parts of their bodies when sleeping. The bulging red eyes, red feet, and blue and yellow stripes along the sides of their bodies are thought to startle potential predators who come upon them during the day when they are sleeping. The little frogs open their eyes and leap, exposing all their colors and for a brief moment confusing the would-be predator. When red-eyed tree frogs mate, the female deposits her eggs on a leaf that overhangs the water. When the eggs hatch, the tadpoles drop into the water, where they live and continue to develop.

ABOUT THE AUTHORS

ELDRA P. SOLOMON has written several leading college-level textbooks in biology and in human anatomy and physiology. Her books have been translated into more than 10 languages. Dr. Solomon earned an M.S. from the University of Florida and an M.A. and Ph.D. from the University of South Florida. She is an adjunct professor and member of the Graduate Faculty at the University of South Florida. Dr. Solomon taught biology and nursing students for more than 20 years.

Dr. Solomon is a biopsychologist as well as a biologist with a special interest in the neurophysiology of traumatic experience. Her research has focused on the relationships among stress, emotions, and health. In her clinical work, she specializes in health psychology and Post-traumatic Stress Disorder. Dr. Solomon has served as Clinical Director of the Center for Mental Health Education, Assessment, and Therapy since 1992.

Dr. Solomon has been recognized nationally and internationally. She was an Invited Scientist to the XVth Congress of Scientific Investigation, sponsored by Interamerican University of Puerto Rico, where she presented the Plenary Session, "Mind-Body Connections—An Introduction to Psychoneuroimmunology." She has been profiled more than 20 times in leading publications, including *Who's Who in America, Who's Who in Science and Engineering, Who's Who in Medicine and Healthcare, Who's Who in American Education, Who's Who of American Women,* and *Who's Who in the World.*

LINDA R. BERG is an award-winning teacher and textbook author. She received a B.S. in science education, an M.S. in botany, and a Ph.D. in plant physiology from the University of Maryland. Her research focused on the evolutionary implications of steroid biosynthetic pathways in various organisms.

Dr. Berg taught at the University of Maryland at College Park for 17 years and is presently an Adjunct Professor at St. Petersburg College in Florida. During her career, she has taught introductory courses in biology, botany, and environmental science to thousands of students. At the University of Maryland, she received numerous teaching and service awards. Dr. Berg is also the recipient of many national and regional awards, including the National Science Teachers Association Award for Innovations in College Science Teaching, the Nation's Capital Area Disabled Student Services Award, and the Washington Academy of Sciences Award in University Science Teaching.

During her career as a professional science writer, Dr. Berg has authored or co-authored several leading college science textbooks. Her writing reflects her teaching style and love of science.

DIANA W. MARTIN is the Director of General Biology, Division of Life Sciences, at Rutgers University, New Brunswick Campus. She received an M.S. at Florida State University, where she studied the chromosomes of related plant species to understand their evolutionary relationships. She earned a Ph.D. at the University of Texas at Austin, where she studied the genetics of the fruit fly, *Drosophila melanogaster,* and then conducted postdoctoral research at Princeton University. She has taught general biology and other courses at Rutgers for more than 20 years and has been involved in writing textbooks since 1988. She is immensely grateful that her decision to study biology in college has led to a career that allows her many ways to share her excitement about all aspects of biology.

Preface

Biology is an exciting and dynamic science that affects every aspect of our lives from our health and behavior to the challenging environmental issues that confront us. Recent discoveries in the biological sciences have increased our understanding of both the unity and diversity of life's processes and adaptations. With this understanding, we have become more aware of our interdependence with the vast diversity of organisms with which we share planet Earth.

BIOLOGY IS A BOOK FOR STUDENTS

One of our principal goals in developing *Biology* has been to share with beginning biology students our sense of excitement about biology. We seek to help students better appreciate Earth's diverse organisms, their remarkable adaptations to the environment, and their evolutionary and ecological relationships. We want students to understand the dynamic way that science works and to appreciate the contributions of scientists whose discoveries not only expand our knowledge of biology but also help shape and protect the future of our planet.

Since the earliest edition of *Biology,* we have focused on presenting the principles of biology in a way that is accurate, interesting and accessible to the student. In this seventh edition of *Biology,* we continue this tradition. We have worked hard to write in a student-friendly style. Throughout the text, we spark interest by relating concepts to experience within the student's frame of reference. By helping students make such connections, we facilitate the integration of concepts. In addition, we use *Focus On boxes* to explore issues of special relevance to students (such as the effects of smoking or alcohol abuse). These boxes also provide a forum for discussing certain topics of current interest in more detail, such as Alzheimer's disease and seed banks. We include numerous tables, many illustrated, to help the student organize and summarize material presented in the text. We hope the combined effect of an engaging writing style and interesting features will fascinate students and encourage them to continue their study of biology.

INTRODUCING OUR LEARNING SYSTEM

We have developed a text that is enjoyable to read, with a well-developed art program, and in the seventh edition we introduce our new Learning System, which focuses on learning outcomes. Learning the principles of biology is challenging. To help students master this complex subject, we provide Learning Objectives both for the course and for each major section of every chapter. At the end of each section, we provide Review questions based on the learning objectives so students can assess their mastery of the material presented in the section. Throughout the book, students are directed to BiologyNow, a powerful diagnostic tool on the free CD-ROM, which helps students assess their study needs and master the chapter objectives. After taking a pretest on BiologyNow, students receive feedback based on their answers, and links to animations and other resources keyed to their specific learning needs. Select illustrations in the text are also keyed to Active Figures on the BiologyNow CD-ROM.

Course Learning Objectives

The student can demonstrate mastery of the principles of biology by responding accurately to the following Course Learning Objectives:

- Design an experiment to test a given hypothesis, using the procedure and terminology of the scientific method.
- Cite the cell theory, and relate structure to function in both prokaryotic and eukaryotic cells.
- Describe the theory of evolution, explain why it is the principal unifying concept in biology, and discuss natural selection as the primary agent of evolutionary change.
- Explain the role of genetic information in all species, and discuss applications of genetics that affect society.
- Describe several mechanisms by which cells and organisms transfer information, including the use of nucleic acids, chemical signals (such as hormones and pheromones), electrical signals (for example, neural transmission), signal transduction, sounds, and visual displays.

- Argue for or against the classification of organisms in three domains and six kingdoms, characterizing each of these clades; based on your knowledge of genetics and evolution, give specific examples of the unity and diversity of these organisms.
- Compare the structural adaptations, life processes, and life cycles of a prokaryote, protist, fungus, plant, and animal.
- Define *homeostasis,* and give examples of regulatory mechanisms, including feedback systems.
- Trace the flow of matter and energy through a photosynthetic cell and a nonphotosynthetic cell, and through the biosphere, comparing the roles of producers, consumers, and decomposers.
- Describe the study of ecology at the levels of an individual organism, a population, a community, and an ecosystem.

Learning System Strategies

We use numerous learning strategies to increase the student's success:

- ***Learning Objectives*** at the beginning of each major section in the chapter indicate, in behavioral terms, what the student must do to demonstrate mastery of the material in that section.
- Each major section of the chapter is followed by a series of ***Review*** **questions** that assess comprehension by asking the student to describe, explain, compare, contrast, or illustrate important concepts. The review questions are based on the section Learning Objectives.
- A list of the major section headings at the beginning of each chapter provides a ***Chapter Overview***. Chapter outlines, including heads and subheads, are posted on our Web site at **http://biology.brookscole.com/solomon7**.
- ***Concept Statement Subheads*** introduce sections, previewing and summarizing the key idea or ideas to be discussed in that section.
- ***Sequence Summaries*** within the text simplify and summarize information presented in paragraph form. For example, paragraphs describing blood circulation through the body or the steps by which cells take in certain materials are followed by a Sequence Summary listing the structures or steps.
- A ***Summary with Key Terms*** at the end of each chapter is organized around the chapter Learning Objectives. This summary provides a review of the material, and because selected key terms are boldfaced in the summary, students are provided with the opportunity to study vocabulary words within the context of related concepts.
- **End-of-chapter questions** provide students with the opportunity to evaluate their understanding of the material in the chapter. The ***Post-Test*** consists of multiple-choice questions, some of which are based on the recall of important terms, whereas others challenge students to integrate their knowledge. Answers to the Post-Test questions are provided at the end of the chapter. A series of ***Critical Thinking*** **questions** encourages the student to make connections among important concepts. To answer these questions, the student must apply the concepts just learned to new situations or relate concepts learned in previous chapters to concepts in the current chapter.
- The ***Glossary*** at the end of the book, the most comprehensive glossary found in any biology text, provides precise definitions of terms. The Glossary is especially useful because it is extensively cross-referenced and includes pronunciations. The vertical purple bar along the margin facilitates rapid access to the Glossary. The companion Web Site also includes glossary flash cards with audio pronunciations.
- An ***art program that is fully integrated with the text*** brings to life, reinforces, and expands concepts discussed in the text. New in this edition are figures featured to illustrate key concepts. Many figures have numbered, multiple parts that show sequences of events in important processes or life cycles. Numerous photographs, both alone and combined with line art, help students understand concepts by connecting the "real" to the "ideal." The line art uses devices such as ***orientation icons*** to help the student put the detailed figures into the broad context. We use symbols and colors consistently throughout the book, to help students connect concepts. For example, the same four colors and shapes are used throughout the book to identify guanine, cytosine, adenine, and thymine.

Emphasis on the Process of Science

Understanding how scientific knowledge is derived is crucial for scientists and nonscientists alike. *Biology* provides insight into what science is, how scientists work, the roles of the many scientists who have contributed to our current understanding of biology, and how scientific knowledge affects daily life. Two features clearly reflect this emphasis:

- A ***"Process of Science"*** **icon**, embedded at relevant points in the text, highlights discussions about the work that scientists do and helps students to understand that the process of scientific discovery is ongoing and indefinite. In addition to the discussion on the process and method of science in Chapter 1, we give many examples of this dynamic process within the context of each particular subject discussed.
- ***On the Cutting Edge*** **boxes** present exciting research areas, such as how some plant-eating insects "eavesdrop" on plant defensive signals and respond by activating their own defenses (see Chapter 36). The abstract for the Cutting Edge box is formatted like a much-abbreviated science report, which further reinforces the student's understanding of the scientific process being reported.

AN OVERVIEW OF *BIOLOGY*, SEVENTH EDITION

Three themes provide the structural foundation for *Biology:* the evolution of life, the transmission of biological information, and the flow of energy through living systems. As we introduce the concepts of modern biology, we explain how these themes are connected and how life depends on them.

Educators present the major topics of an introductory biology course in a variety of orders. For this reason, we carefully designed the eight parts of this book so that they do not depend heavily on preceding chapters and parts. The instructor can present the eight parts and their 55 chapters in any number of sequences with pedagogical success. Chapter 1, which introduces the student to the major principles of biology, provides a good springboard for future discussions, whether the professor prefers to start with the "big picture" and work down, or vice versa.

In this edition, as in previous editions, we examined every line of every chapter for accuracy and currency, and we made a serious attempt to update every topic and verify all new material. The following brief survey provides a general overview of the eight parts of *Biology* and some changes made to the seventh edition.

Part 1: The organization of life

The five chapters that make up Part 1 give the student basic background knowledge. We begin Chapter 1 by discussing the Human Genome Project and then introduce the main themes of the book—evolution, energy transfer, and information transfer. Chapter 1 examines several fundamental concepts: the characteristics and similarities of living things; the organization of life on individual and ecological levels; information transfer; evolution as the main unifying concept in biology; the diversity of life and how biologists classify organisms; energy transfer; and how science works. Chapters 2 and 3, which focus on the molecular level of organization, establish the foundations in chemistry necessary for understanding biological processes. Chapters 4 and 5 focus on the cell level of organization. Research on receptors and signal transduction is shedding light on many life processes on a cell level. We introduce these concepts in Chapter 5. However, we are convinced that this information is best delivered within a context, so we integrate many research findings on receptors and signal transduction in relevant chapters throughout the book.

Part 2: Energy transfer through living systems

Because all living cells need energy for life processes, the flow of energy through living systems—that is, capturing energy and converting it to usable forms—is a basic theme of *Biology.* Chapter 6 examines how cells capture, transfer, store, and use energy. Chapters 7 and 8, which can be taught in either order, discuss the metabolic adaptations by which organisms obtain and use energy through cellular respiration and photosynthesis.

Part 3: The continuity of life: genetics

We have completely revised and updated the eight chapters of Part 3 for the seventh edition. There are many new illustrations, seven new ones in Chapter 10 alone. In these chapters we explore the science of genetics, giving students the tools they need to grasp the important new findings reported almost daily. We begin this unit by discussing mitosis and meiosis (Chapter 9), thus providing a foundation for considering Mendelian genetics and related patterns of inheritance in Chapter 10. We then turn our attention to the flow of information in cells, beginning with the structure and replication of DNA (in Chapter 11), followed by a discussion of RNA and protein synthesis (Chapter 12). Gene regulation is discussed in Chapter 13, and in Chapter 14, we focus on genetic engineering. These chapters build the necessary foundation for exploring the human genome in Chapter 15. In Chapter 16, we introduce the role of genes in development, emphasizing studies on specific model organisms that have led to spectacular advances in this field. Changes in these chapters include new material on how genes interact with the environment to determine phenotype, latest findings on telomeres and telomerase, new material on mammalian cloning, and a new Cutting Edge box on studying aging in mice. New tables show a timeline of selected historical DNA discoveries, present color-coded data that support Chargaff's rules, and summarize the enzymes involved in DNA replication.

Part 4: The continuity of life: evolution

Although we explore evolution as the cornerstone of biology throughout the book, Part 4 delves into the subject in depth. We provide the history behind the discovery of the theory of evolution, the mechanism by which it occurs, and the methods by which it is studied and tested. Chapter 17 introduces the Darwinian concept of evolution and presents several kinds of evidence that support the theory of evolution. In Chapter 18, we examine evolution at the population level. Chapter 19 describes the evolution of new species and discusses aspects of macroevolution. Chapter 20 summarizes the evolutionary history of life on Earth. In Chapter 21 we recount the evolution of the primates, including humans. Many topics and examples have been added to the seventh edition, including new material on molecular clocks, the evolutionary species concept, sexual selection, recent fossil discoveries of human ancestors, and a new Cutting Edge box on the origin of flight in birds.

Part 5: The diversity of life

In this edition of *Biology,* we emphasize the cladistic approach. Based on recent developments and on reviewer input, we have replaced the phylogenetic trees of past editions with cladograms. We use an evolutionary framework to discuss each group of organisms, presenting current hypotheses of how groups of organisms are related. By focusing on evolutionary relationships and the structural and functional adaptations of each group of organisms, we avoid the traditional parade through the phyla that is characteristic of many biology textbooks.

In Chapter 22, we discuss *why* organisms are classified and provide insight into the scientific process of deciding *how* they are classified. Chapter 23, focuses on the viruses and prokarotes, compares the three domains, and discusses viroids, prions, and emerging diseases. We have revised Chapter 24 to reflect the developing consensus on protist diversity. We summarize the eight major eukaryote groups, and include a new table and new figure showing evolutionary relationships among the groups. Chapter 25 describes the fungi. Chapters 26 and 27 present the members of the plant kingdom. In Chapters 28 through 30, which cover the diversity of animals, we present the most recent classification of animal phyla, including division into Lophotrochozoa, Ecdysozoa, and Deuterostomia clades.

Part 6: Structure and life processes in plants

Part 6 introduces students to the fascinating plant world. It stresses relationships between structure and function in plant cells, tissues, organs, and individual organisms. In Chapter 31, we introduce plant structure, growth, and differentiation. Chapters 32 through 34 discuss the structural and physiological adaptations of leaves, stems, and roots. Chapter 35 describes reproduction in flowering plants, including asexual reproduction, flowers, fruits, and seeds. Chapter 36 focuses on growth responses and regulation of growth. In the seventh edition, we present the latest findings generated by the continuing explosion of knowledge in plant biology, particularly at the molecular level. Some of the new topics include an updated section on stomatal opening and closing, new information on floral meristem identity genes, updated research on self-incompatibility in plant reproduction, and new data on nastic movements and tropisms.

Part 7: Structure and life processes in animals

In Part 7, we emphasize the structural, functional, and behavioral adaptations that help animals meet environmental challenges. We use a comparative approach to examine how various animal groups have solved similar and diverse problems. In Chapter 37, we discuss the basic tissues and organ systems of the animal body, homeostasis, and how animals regulate their body temperature. Chapter 38 focuses on body coverings, skeletons, and muscles. In Chapters 39 through 41, we discuss neural signaling, neural regulation, and sensory reception. In Chapters 42 through 49, we compare how different animal groups carry on specific life processes, such as internal transport, internal defense, gas exchange, digestion, reproduction, and development. Each chapter in this part considers the human adaptations for the life processes being discussed. The unit ends with a discussion of behavioral adaptations in Chapter 50, which includes a reorganized and updated sections on sexual selection and on helping behavior.

Reflecting recent research findings, we have added material on glial cells, new findings on a neurotrophin that opens certain sodium channels, and a Cutting Edge box on the neurophysiology of traumatic experience. In the immunology chapter, we have added a discussion of the danger hypothesis and have included new findings on Toll signaling receptors and pathogen-associated molecular patterns. We introduce new findings on mechanisms of hormone action and have added a brief section on enzyme-linked receptors.

Part 8: The interactions of life: ecology

Part 8 focuses on the dynamics of populations, communities, and ecosystems and on the application of ecological principles to disciplines such as conservation biology. Chapters 51 through 54 give the student an understanding of the ecology of populations, communities, ecosystems, and the biosphere, whereas the final chapter (55) focuses on environmental problems humans have caused. We continue to interweave ecological theory and the scientific process by giving clear, concrete examples of ecological studies to illustrate conceptual points. Among the many changes in this unit, the authors have updated Vitousek's work on human appropriation of global NPP, expanded the definition of biological diversity, and added a new section on dominant species.

A COMPREHENSIVE PACKAGE FOR LEARNING AND TEACHING

To further facilitate learning, a carefully designed supplement package is available. In addition to the usual print resources, we are pleased to present student multimedia tools that have been developed in conjunction with the text.

Resources for Students

Study Guide to Accompany *Biology,* Seventh Edition, by Ronald S. Daniel of California State Polytechnic University, Pomona; Sharon C. Daniel of Orange Coast College; and Ronald L. Taylor. Extensively updated for this edition, the study guide provides the student with many opportunities to review chapter concepts. Multiple-choice study questions, coloring book exercises, vocabulary-building exercises, and many other types of active-learning tools are provided to suit different cognitive learning styles.

A Problem-Based Guide to Basic Genetics by Donald Cronkite of Hope College. This brief guide provides students with a systematic approach to solving genetics problems, along with numerous solved problems and practice problems.

Web Site. The content-rich companion Web site that accompanies *Biology*, seventh edition, gives students access to a wealth of high-quality resources, including focused quizzing, a Glossary complete with pronunciations, *InfoTrac College Edition* (with questions), Internet Activities (with questions), Chapter Summaries, Learning Objectives, further readings for each chapter, and annotated Web links. The site also includes an all-new genetics resource, including specialized genetics problems. Finally, Career Visions interviews on the Web site help students become aware of the many doors that a biology degree can open by shar-

ing the experiences of young people who have found fulfilling careers in which they use their knowledge of biology.

Additional Resources for Instructors

The instructors' Examination Copy for this edition lists a comprehensive package of print and multimedia supplements, including online resources, that are available to qualified adopters. Please ask your local sales representative for details.

ACKNOWLEDGMENTS

The development and production of the seventh edition of *Biology* required extensive interaction and cooperation among the authors and many individuals in our home and professional environments. We thank our editors, colleagues, students, family, and friends for their help and support.

Preparing a book of this complexity is challenging and requires a cohesive, talented, and hardworking professional team whose members believe in the project. We were fortunate to have just such a team, and appreciate the contributions of everyone on the editorial and production staff at Brooks/Cole/Thomson Learning who worked on this seventh edition of *Biology*. We thank Michelle Julet, Vice President and Editor-in-Chief, and Executive Editor, Nedah Rose, for their commitment to this book and for their support in making the seventh edition happen. We appreciate Ann Caven, our Marketing Manager, whose expertise ensured that you would know about our new edition.

We appreciate the hard work of our dedicated Developmental Editor, Shelley Parlante, who provided us with valuable input as she guided the seventh edition through its many phases. Developmental Editor Betsy Dilernia carefully reviewed selected chapters and gave us many helpful suggestions for improving the manuscript. We appreciate the help of Teri Hyde, Senior Production Project Manager, and Project Editor Tom Dorsaneo, who expertly shepherded the project. We thank Editorial Assistant Jennifer Keever for quickly providing us with resources whenever we needed them. We also appreciate the help of editorial assistant Sarah Lowe.

We thank Elizabeth Morales for sharing her artistic talent and for her great ideas for visual presentations. We appreciate the efforts of photo editors Don Murie and Joan Murie. We thank Art Director Rob Hugel, Text Designer John Walker, and Cover Designer Larry Didona. We also thank Joy Westberg for developing the Instructor's Preface.

We are grateful to Travis Metz, Technology Project Manager, who coordinated the many high-tech components of the computerized aspects of our Learning System. We thank Assistant Editor Kari Hopperstead for coordinating the print supplements.

These dedicated professionals and many others at Brooks/Cole provided the skill, attention, and good humor needed to produce *Biology*, Seventh Edition. We thank them for their help and support throughout this project.

We greatly appreciate the expert assistance of Mary Kay Hartung of Florida Gulf Coast University, who came to our rescue whenever we had difficulty finding information. Whenever asked, she quickly helped us find needed research studies from the Internet. We thank doctoral student Lois Ball of the University of South Florida, Department of Biology, who reviewed several chapters and offered helpful suggestions.

We thank our families and friends for their understanding, support, and encouragement as we struggled through many revisions and deadlines. We especially thank Dr. Amy Solomon, Dr. Kathleen M. Heide, Mical Solomon, Alan Berg and Jennifer Brookhouzen, and Dr. Charles Martin and Margaret Martin for their support and input.

Our colleagues and students who have used our book have provided valuable input by sharing their responses to past editions of *Biology*. We thank them and ask again for their comments and suggestions as they use this new edition. We can be reached through the Internet at our Web site **http://biology.brookscole.com/solomon7** or through our editors at Brooks/Cole, a division of Thomson Learning.

We express our thanks to the many biologists who have read the manuscript during various stages of its development and provided us with valuable suggestions for improving it. Seventh-edition reviewers include the following:

Hema Bandaranayake, Xavier University of Louisiana; Gayle Birchfield, University of Missouri; Judy Bluemer, Morton College; Paul Bottino, University of Maryland; Nancy Boury, Iowa State University; Robert Boyd, Auburn University; Jeff Carmichael, University of North Dakota; Linda Collins, University of Tennessee Chattanooga; Elizabeth Cowles, Eastern Connecticut State University; Andrew Crain, Maryville College; Karen Dalton, Community College of Baltimore County; Robert Evans, Rutgers University; Daniel Fairbanks, Brigham Young University; Christopher Harendza, Montgomery County Community College; Harriette Howard-Lee Block, Prairie View A&M University; Joan Hudson, Sam Houston State University; John B. Jenkins, Swarthmore College; Craig Martin, University of Kansas; Allan Nelson, Tarleton State University; Nancy L. Pencoe, State University of West Georgia; Chris E. Petersen, College of DuPage; Sylvia Christie Saunders, Borough of Manhattan Community College and City University of New York; Gerald Shields, Carroll College; Rob Snetsinger, Queen's University; Louisa Stark, University of Utah Genetic Science; Mary White, Southeastern Louisiana University; Heather Weber, Los Angeles City College.

We would also like to thank the Introductory Biology Students at Ohio University and Montgomery County Community College.

To the Student

Biology is a challenging subject. The thousands of students we have taught have differed in their life goals and learning styles. Some have had excellent backgrounds in science, others poor ones. Regardless of their backgrounds, it is common for students taking their first college biology course to find that they must work harder than they expected. You can make the task easier by using approaches to learning that have been successful for a broad range of our students over the years. Be sure to use the Learning System we use in this book. It is described in the Preface.

Make a Study Schedule

Many college professors suggest that students study three hours for every hour spent in class. This major investment in study time is one of the main differences between high school and college. To succeed academically, college students must learn to manage their time effectively. The actual number of hours you spend studying biology will vary depending on how quickly you learn the material, as well as on your course load and personal responsibilities, such as work schedules and family commitments.

The most successful students are often those who are best organized. At the beginning of the semester, make a detailed daily calendar. Mark off the hours you are in each class, along with travel time to and from class if you are a commuter. After you get your course syllabi, add to your calendar the dates of all exams, quizzes, papers, and reports. As a reminder, it also helps to add an entry for each major exam or assignment one week before the test or due date. Now add your work schedule and other personal commitments to your calendar. Using a calendar helps you find convenient study times.

Many of our successful biology students set aside 2 hours a day to study biology, rather than depending on a weekly marathon session for 8 or 10 hours during the weekend (when that kind of session rarely happens). Put your study hours into your daily calendar, and stick to your schedule.

Determine Whether the Professor Emphasizes Text Material or Lecture Notes

Some professors test almost exclusively on material covered in lecture. Others rely on their students' learning most, or even all, of the content in assigned chapters. Find out what your professor's requirements are, because the way you study will vary accordingly.

How to study when professors test lecture material

If lectures are the main source of examination questions, make your lecture notes as complete and organized as possible. Before going to class, skim over the chapter, identifying key terms and examining the main figures, so that you can take effective lecture notes. Spend no more than one hour on this.

Within 24 hours after class, rewrite (or type) your notes. Before rewriting, however, read the notes and make marginal notes about anything that is not clear. Then read the corresponding material in your text. Highlight or underline any sections that clarify questions you had in your notes. Read the *entire* chapter, including parts that are not covered in lecture. This extra information will give you breadth of understanding and will help you grasp key concepts.

After reading the text, you are ready to rewrite your notes, incorporating relevant material from the text. It also helps to use the Glossary to help define unfamiliar terms. Many students develop a set of flash cards of key terms and concepts as a way to study. Flash cards are a useful tool to help you learn scientific terminology. They are portable and can be used at times when other studying is not possible, for example, when riding a bus.

Flash cards are not effective when the student tries to second-guess the professor. ("She won't ask this, so I won't make a flash card of it.") Flash cards are also a hindrance when students rely on them exclusively. Studying flash cards instead of reading the text is a bit like reading the first page of each chapter in a mystery novel: It's hard to fill in the missing parts, because you are learning the facts in a disconnected way.

How to study when professors test material in the book

If the assigned readings in the text are going to be tested, you must use your text intensively. After reading the chapter introduction, read the list of Learning Objectives for the first section. These objectives are written in behavioral terms; that is, they ask you to "do" something in order to demonstrate mastery. The objectives give you a concrete set of goals for each section of the

chapter. At the end of each section, you will find Review questions keyed to the Learning Objectives. Test yourself, going back over the material to check your responses.

Read each chapter section *actively.* Many students read and study passively. An active learner always has questions in mind and is constantly making connections. For example, there are many processes that must be understood in biology. Don't try to blindly memorize these; instead, think about causes and effects, so that every process becomes a story. Eventually you'll see that many processes are connected by common elements.

You will probably have to read each chapter two or three times before mastering the material. The second and third times through will be much easier than the first, because you'll be reinforcing concepts that you have already partially learned.

After reading the chapter, write a four- to six-page chapter outline by using the subheads as the body of the outline (first-level heads are boldface, in color, and all caps; second-level heads are in color and not all caps). Flesh out your outline by adding important concepts and boldface terms with definitions. Use this outline when preparing for the exam.

Now it is time to test yourself. Answer the Post-Test questions, and check your answers. Write answers to each of the Critical Thinking questions. Finally, review the Learning Objectives in the Chapter Summary and try to answer them before reading the summary provided. If your professor has told you that some or all of the exam will be short-answer or essay format, write out the answer for each Learning Objective. Remember, this is a self-test. If you do not know an answer to a question, find it in the text. If you can't find the answer, use the Index.

Learn the Vocabulary

One stumbling block for many students is learning the many terms that make up the language of biology. In fact, it would be much more difficult to learn and communicate if we did not have this terminology, because words are really tools for thinking. Learning terminology generally becomes easier if you realize that most biological terms are modular. They consist of mostly Latin and Greek roots; once you learn many of these, you will have a good idea of the meaning of a new word even before it is defined. For this reason, we have included an Appendix on Understanding Biological Terms. To be sure you understand the precise definition of a term, use the Index and Glossary. The more you use biological terms in speech and writing, the more comfortable you will be.

Form a Study Group

Active learning is facilitated if you do some of your studying in a small group. In a study group, the roles of teacher and learner can be interchanged: A good way to learn material is to teach. A study group lets you meet challenges in a nonthreatening environment and can provide some emotional support. Study groups are effective learning tools when combined with individual study of text and lecture notes. If, however, you and other members of your study group have not prepared for your meetings by studying individually in advance, the study session can be a waste of time.

Prepare for the Exam

Your calendar tells you it is now one week before your first biology exam. If you have been following these suggestions, you are well prepared and will need only some last-minute reviewing. No all-nighters will be required.

During the week prior to the exam, spend two hours each day actively studying your lecture notes or chapter outlines. It helps many students to read these notes out loud (most people listen to what they say!). Begin with the first lecture/chapter covered on the exam, and continue in the order on the lecture syllabus. Stop when you have reached the end of your two-hour study period. The following day, begin where you stopped the previous day. When you reach the end of your notes, start at the beginning and study them a second time. The material should be very familiar to you by the second or third time around. At this stage, use your textbook only to answer questions or clarify important points.

The night before the exam, do a little light studying, eat a nutritious dinner, and get a full night's sleep. That way, you'll arrive in class on exam day with a well-rested body (and brain) and the self-confidence that goes with being well prepared.

Contents

Part 1 THE ORGANIZATION OF LIFE

1 A VIEW OF LIFE 1

Characteristics of Life 2
- *Organisms are composed of cells 2*
- *Organisms grow and develop 3*
- *Organisms regulate their metabolic processes 3*
- *Organisms respond to stimuli 3*
- *Organisms reproduce 4*
- *Populations evolve and become adapted to the environment 5*

Biological Organization 5
- *Organisms have several levels of organization 7*
- *Several levels of ecological organization can be identified 7*

Information Transfer 7
- *DNA transmits information from one generation to the next 7*
- *Information is transmitted by chemical and electrical signals 7*

Evolution: The Basic Unifying Concept of Biology 8
- *Biologists use a binomial system for naming organisms 9*
- *Taxonomic classification is hierarchical 9*
- *Organisms can be assigned to three domains and six kingdoms 10*
- *Species adapt in response to changes in their environment 10*
- *Natural selection is an important mechanism by which evolution proceeds 10*
- *Populations evolve as a result of selective pressures from changes in the environment 12*

The Energy of Life 12
- *Energy flows through cells and organisms 13*
- *Energy flows through ecosystems 13*

The Process and Method of Science 14
- *Science requires systematic thought processes 15*
- *Scientists make careful observations and ask critical questions 15*
- *A hypothesis is a testable statement 16*
- *Predictions can be tested by experiment 17*
- *Scientists interpret the results of experiments and make conclusions 17*
- *A well-supported hypothesis my lead to a theory 18*
- *Science has ethical dimensions 19*

ON THE CUTTING EDGE New Possibilities for Environmentally Friendly Pest-Control Strategies 16

2 ATOMS AND MOLECULES: THE CHEMICAL BASIS OF LIFE 22

Elements And Atoms 23
- *An atom is uniquely identified by its number of protons 23*
- *Protons plus neutrons determine atomic mass 23*
- *Isotopes of an element differ in number of neutrons 25*
- *Electrons move in orbitals corresponding to energy levels 25*

Chemical Reactions 26
- *Atoms form compounds and molecules 27*
- *Simplest, molecular, and structural chemical formulas give different information 27*
- *One mole of any substance contains the same number of units 27*
- *Chemical equations describe chemical reactions 27*

Chemical Bonds 28
- *In covalent bonds electrons are shared 28*
- *Ionic bonds form between cations and anions 30*
- *Hydrogen bonds are weak attractions 32*

Redox Reactions 32

Water 32
- *Water helps maintain a stable temperature 33*

Acids, Bases, and Salts 36
- *pH is a convenient measure of acidity 36*
- *Buffers minimize pH change 37*
- *An acid and a base react to form a salt 37*

3 THE CHEMISTRY OF LIFE: ORGANIC COMPOUNDS 41

Carbon Atoms and Molecules 42
- *Isomers have the same molecular formula, but different structures 43*
- *Functional groups change the properties of organic molecules 44*
- *Many biological molecules are polymers 45*

Carbohydrates 46
- *Monosaccharides are simple sugars 46*
- *Disaccharides consist of two monosaccharide units 47*
- *Polysaccharides can store energy or provide structure 48*
- *Some modified and complex carbohydrates have special roles 50*

Lipids 51
- *Triacylglycerol is formed from glycerol and three fatty acids 51*
- *Saturated and unsaturated fatty acids differ in physical properties 52*
- *Phospholipids are components of cell membranes 53*
- *Carotenoids and many other pigments are derived from isoprene units 53*
- *Steroids contain four rings of carbon atoms 53*
- *Some chemical mediators are lipids 54*

Proteins 54
- *Amino acids are the subunits of proteins 54*
- *Proteins have four levels of organization 55*
- *The amino acid sequence of a protein determines its conformation 60*

Nucleic Acids 61
- *Some nucleotides are important in energy transfers and other cell functions 62*

Identifying Biological Molecules 63

4 ORGANIZATION OF THE CELL 66

Cell Organization and Size 67
- *The organization of all cells is basically similar 67*
- *Cell size is limited 67*
- *Cell size and shape are related to function 69*

Methods for Studying Cells 69
- *Light microscopes are used to study stained or living cells 69*
- *Electron microscopes provide a high-resolution image that can be greatly magnified 70*
- *Cell fractionation enables the study of cell components 71*

Prokaryotic and Eukaryotic Cells 72

Cell Membranes 73

The Cell Nucleus 76

Organelles in the Cytoplasm 80
- *The endoplasmic reticulum and ribosomes manufacture proteins 80*
- *The Golgi complex processes, sorts, and modifies proteins 82*
- *Lysosomes are compartments for digestion 83*
- *Peroxisomes metabolize small organic compounds 83*
- *Vacuoles are large, fluid-filled sacs with a variety of functions 84*
- *Mitochondria and chloroplasts are energy-converting organelles 84*

The Cytoskeleton 87
- *Microtubules are hollow cylinders 87*
- *Cilia and flagella are composed of microtubules 88*
- *Microfilaments consist of intertwined strings of actin 89*
- *Intermediate filaments help stabilize cell shapes 90*

Cell Coverings 90

FOCUS ON *Acetabularia* and the Control of Cell Activities 78

5 BIOLOGICAL MEMBRANES 95

The Structure of Biological Membranes 96
- *Phospholipids form bilayers in water 96*
- *Current data support a fluid mosaic model of membrane structure 96*
- *Biological membranes are two-dimensional fluids 98*
- *Biological membranes fuse and form closed vesicles 99*
- *Membrane proteins include integral and peripheral proteins 99*
- *Proteins are oriented asymmetrically across the bilayer 100*
- *Membrane proteins function in transport, information transfer, and as enzymes 101*

Passage of Materials Through Cell Membranes 102
- *Random motion of particles leads to diffusion 103*
- *Osmosis is diffusion of water (solvent) across a selectively permeable membrane 103*
- *Two solutions may be isotonic, or one may be hypertonic and the other hypotonic 104*
- *Turgor pressure is the internal hydrostatic pressure usually present in walled cells 104*
- *Channel proteins and carrier proteins affect membrane permeability 105*
- *Facilitated diffusion occurs down a concentration gradient 105*
- *Some carrier-mediated active transport systems "pump" substances against their concentration gradients 107*
- *Linked cotransport systems indirectly provide energy for active transport 107*

Facilitated diffusion is powered by a concentration gradient; active transport requires another energy source 109
The patch clamp technique has revolutionized the study of ion channels 109
In exocytosis and endocytosis, vesicles or vacuoles transport large particles 110

Cell Signaling 112

Cell Junctions 114
Anchoring junctions connect cells of an epithelial sheet 114
Tight junctions seal off intercellular spaces between some animal cells 115
Gap junctions permit transfer of small molecules and ions 115
Plasmodesmata allow certain molecules and ions to move between plant cells 115

Part 2 ENERGY TRANSFER THROUGH LIVING SYSTEMS

6 ENERGY AND METABOLISM 120

Biological Work 121
Organisms carry out conversions between potential energy and kinetic energy 121

The Laws of Thermodynamics 121
The total energy in the universe does not change 121
The entropy of the universe is increasing 122

Energy and Metabolism 122
Enthalpy is the total potential energy of a system 123
Free energy is available to do cell work 123
Chemical reactions involve changes in free energy 123
Free energy decreases during an exergonic reaction 123
Free energy increases during an endergonic reaction 124
Diffusion is an exergonic process 124
Free energy changes depend on the concentrations of reactants and products 124
Cells drive endergonic reactions by coupling them to exergonic reactions 125

ATP, the Energy Currency of the Cell 125
ATP donates energy through the transfer of a phosphate group 125
ATP links exergonic and endergonic reactions 126
The cell maintains a very high ratio of ATP to ADP 126

Energy Transfer in Redox Reactions 127
Most electron carriers transfer hydrogen atoms 127

Enzymes 128
All reactions have a required energy of activation 129
An enzyme lowers a reaction's activation energy 129
An enzyme works by forming an enzyme-substrate complex 129
Enzymes are specific 130
Many enzymes require cofactors 130
Enzymes are most effective at optimal conditions 131
Enzymes are organized into teams in metabolic pathways 132
The cell regulates enzymatic activity 132
Enzymes are inhibited by certain chemical agents 133
Some drugs are enzyme inhibitors 134

7 HOW CELLS MAKE ATP: ENERGY-RELEASING PATHWAYS 137

Redox Reactions 138

The Four Stages of Aerobic Respiration 138
In glycolysis, glucose yields two pyruvates 140
Pyruvate is converted to acetyl CoA 141
The citric acid cycle oxidizes acetyl CoA 141
The electron transport chain is coupled to ATP synthesis 144
Aerobic respiration of one glucose yields a maximum of 36—38 ATPs 148

Energy Yield of Nutrients Other Than Glucose 151

Anaerobic Respiration and Fermentation 151
Alcohol fermentation and lactate fermentation are inefficient 152

FOCUS ON Electron Transport and Heat 147

8 PHOTOSYNTHESIS: CAPTURING ENERGY 156

Light 157

Chloroplasts 158
Chlorophyll is found in the thylakoid membrane 158
Chlorophyll is the main photosynthetic pigment 160

Overview of Photosynthesis 161
ATP and NADPH are the products of the light-dependent reactions: An overview 162
Carbohydrates are produced during the carbon fixation reactions: An overview 162

The Light-Dependent Reactions 163
Photosystems I and II each consist of a reaction center and multiple antenna complexes 163
Noncyclic electron transport produces ATP and NADPH 163
Cyclic electron transport produces ATP but no NADPH 165
ATP synthesis occurs by chemiosmosis 165

The Carbon Fixation Reactions 167
Most plants use the Calvin cycle to fix carbon 167
Photorespiration reduces photosynthetic efficiency 169
The initial carbon fixation step differs in C_4 plants and in CAM plants 169

Part 3 THE CONTINUITY OF LIFE: GENETICS

9 CHROMOSOMES, MITOSIS, AND MEIOSIS 174

Eukaryotic Chromosomes 175
DNA is organized into informational units called genes 175
DNA is packaged in a highly organized way in chromosomes 175
Chromosome number and informational content differ among species 176

The Cell Cycle and Mitosis 177
Chromosomes duplicate during interphase 177
During prophase, duplicated chromosomes become visible with the microscope 178
Duplicated chromosomes line up on the midplane during metaphase 181
During anaphase, chromosomes move toward the poles 181
During telophase, two separate nuclei form 181
Cytokinesis forms two separate daughter cells 181
Mitosis produces two cells genetically identical to the parent cell 181
An internal genetic program interacting with external signals regulates the cell cycle 182

Sexual Reproduction and Meiosis 184
Meiosis produces haploid cells with unique gene combinations 184
Prophase I includes synapsis and crossing-over 185
During meiosis I, homologous chromosomes separate 187
Chromatids separate in meiosis II 188
Mitosis and meiosis lead to contrasting outcomes 188
The timing of meiosis in the life cycle varies among species 188

10 THE BASIC PRINCIPLES OF HEREDITY 193

Mendel's Principles of Inheritance 194
Alleles separate before gametes are formed 195
Alleles occupy corresponding loci on homologous chromosomes 196
A monohybrid cross involves individuals with different alleles of a given locus 197
A dihybrid cross involves individuals that have different alleles at two loci 199
Alleles on nonhomologous chromosomes are randomly distributed into gametes 199
The rules of probability are useful in predicting Mendelian inheritance 200
The rules of probability can be applied to a variety of calculations 201

Mendelian Inheritance and Chromosomes 202
Linked genes do not assort independently 203
Calculating the frequency of crossing-over reveals the linear order of linked genes on a chromosome 204
Sex is generally determined by sex chromosomes 205

Extensions of Mendelian Genetics 209
Dominance is not always complete 209
Multiple alleles for a locus may exist in a population 210
A single gene may affect multiple aspects of the phenotype 211
Alleles of different loci may interact to produce a phenotype 211
Polygenes act additively to produce a phenotype 212
Genes interact with the environment to shape phenotype 212

FOCUS ON Solving Genetics Problems 206

11 DNA: THE CARRIER OF GENETIC INFORMATION 218

Evidence of DNA As the Hereditary Material 219
DNA is the transforming principle in bacteria 219
DNA is the genetic material in certain viruses 220

The Structure of DNA 221
DNA is made of two polynucleotide chains intertwined to form a double helix 222
In double-stranded DNA, hydrogen bonds form between A and T and between G and C 223

DNA Replication 225
Meselson and Stahl verfied the mechanism of semiconservative replication 225
Semiconservative replication explains the perpetuation of mutations 225
DNA replication is complex process that requires protein "machinery" 227
Telomeres cap eukaryotic chromosome ends 230

12 GENE EXPRESSION 234

Discovery of the Gene-Protein Relationship 235

Beadle and Tatum proposed the one-gene, one-enzyme hypothesis 235

Information Flow from DNA to Protein: An Overview 236

DNA is transcribed to form RNA 237

RNA is translated to form a polypeptide 237

Biologists cracked the genetic code in the 1960s 238

Transcription 239

The synthesis of mRNA includes initiation, elongation, and termination 240

Messenger RNA contains base sequences that do not directly code for protein 241

Translation 241

An amino acid is attached to tRNA before incorporation into a polypeptide 242

The components of the translational machinery come together at the ribosomes 242

During elongation amino acids are added to the growing polypeptide chain 244

A polyribosome is a complex of one mRNA and many ribosomes 246

Variations in Protein Synthesis in Different Organisms 247

Both noncoding and coding sequences are transcribed from eukaryotic genes 247

The evolution of eukaryotic gene structure is not completely understood 248

The usual direction of information flow has exceptions 249

Mutations and Genes 250

Base substitution mutations result from the exchange of one base pair for another 250

Frameshift mutations result from the insertion or deletion of base pairs 250

Some mutations involve larger DNA segments 250

Mutations have various causes 252

A gene is a functional unit 252

13 GENE REGULATION 255

Gene Regulation in Bacteria and Eukaryotes: An Overview 256

Gene Regulation in Bacteria 256

Operons in bacteria facilitate the coordinated control of functionally related genes 256

Some posttranscriptional regulation occurs in bacteria 263

Gene Regulation in Eukaryotic Cells 263

Eukaryotic transcription is controlled at many sites and by many different regulatory molecules 264

The mRNAs of eukaryotes have many tupes of posttranscriptional control 267

Posttranslational chemical modifications may alter the activity of eukaryotic proteins 268

14 DNA TECHNOLOGIES 272

Recombinant DNA Methods 273

Restriction enzymes are "molecular scissors" 273

Recombinant DNA forms when DNA is spliced into a vector 273

DNA can be cloned inside cells 275

The polymerase chain reaction is a technique for amplifying DNA in vitro 278

Gel electrophoresis is used for separating macromolecules 279

One way to characterize DNA is to determine its sequence of nucleotides 280

Applications of DNA Technologies 282

DNA technology has revolutionized medicine and pharmacology 282

DNA typing has applications ranging from forensics to analyzing ancient DNA 283

Transgenic organisms have incorporated foreign DNA into their cells 284

Safety Guidelines for DNA Technology 287

15 THE HUMAN GENOME 290

Studying Human Genetics 291

Human chromosomes are studied by karyotyping 291

Family pedigrees help identify some inherited conditions 292

The Human Genome Project sequenced the DNA on all human chromosomes 291

Researchers use mouse models to study human genetic diseases 296

Abnormalities in Chromosome Number and Structure 297

Down syndrome is caused by trisomy 21 297

Most sex chromosome aneuploidies are less severe than autosomal aneuploidies 299

Aneuploidies usually result in prenatal death 300

Abnormalities in chromosome structure cause certain disorders 300

Genetic Diseases Caused by Single-Gene Mutations 301

Most genetic diseases are inherited as autosomal recessive traits 301

Some genetic diseases are interited as X-linked recessive traits 304

Gene Therapy 305
Gene therapy programs are carefully scrutinized 305
Genetic Testing and Counseling 305
Prenatal diagnosis detects chromosome abnormalities and gene defects 305
Genetic screening searches for genotypes or karyotypes 306
Genetic counselors educate people about genetic diseases 307
Human Genetics, Society, and Ethics 308
Genetic discrimination provokes heated debate 308
Many ethical issues related to human genetics must be addressed 308

16 GENES AND DEVELOPMENT 312

Cell Differentiation and Nuclear Equivalence 313
A totipotent nucleus contains all the instructions for development 313
The first cloned mammal was a sheep 315
Stem cells divide and give rise to differentiated cells 317
Most cell differences are due to differential gene expression 317
Some exceptions to the principle of nuclear equivalence have been found 318
The Genetic Control of Development 318
The maternal genome controls early development in Drosophila melanogaster *319*
Developmental studies of C. elegans *elucidated apoptosis 323*
The mouse is a model for mammalian development 326
Arabidopsis *is a model for studying plant development, including transcription factors 327*
Cancer and Cell Development 329
ON THE CUTTING EDGE Studying Aging in Mice 328

Part 4 THE CONTINUITY OF LIFE: EVOLUTION

17 INTRODUCTION TO DARWINIAN EVOLUTION 333

Pre-Darwinian Ideas about Evolution 334
Darwin and Evolution 335
Darwin proposed that evolution occurs by natural selection 336
The modern synthesis combines Darwin's theory with genetics 337
Biologists study the effect of chance on evolution 338
Evidence for Evolution 339
The fossil record provides strong evidence for evolution 339
Comparative anatomy of related species demonstrates similarities in their structures 342
The distribution of plants and animals supports evolution 344
Developmental biology helps unravel evolutionary patterns 346
Molecular comparisons among organisms provide evidence for evolution 347
Evolutionary hypotheses are tested experimentally 349

18 EVOLUTIONARY CHANGE IN POPULATIONS 353

Genotype, Phenotype, and Allele Frequencies 354
The Hardy-Weinberg Principle 354
Genetic equilibrium occurs if certain conditions are met 355
Human MN blood groups are a valuable illustration of the Hardy-Weinberg principle 356
Microevolution 356
Nonrandom mating changes genotype frequencies 357
Mutation increases variation within a population 357
In genetic drift, random events change allele frequencies 358
Gene flow generally increases variation within a population 359
Natural selection changes allele frequencies in a way that increases adaptation 359
Genetic Variation in Populations 361
Genetic polymorphism exists among alleles and the proteins for which they code 361
Balanced polymorphisms exists for long periods 362
Neutral variation may give no selective advantage or disadvantage 364
Populations in different geographic areas often exhibit genetic adaptations to local environments 364

19 SPECIATION AND MACROEVOLUTION 367

Reproductive Isolation 368
Prezygotic barriers interfere with fertilization 368
Postzygotic barriers prevent gene flow when fertilization occurs 370
Biologists are discovering the genetic basis of isolating mechanisms 370
Speciation 371
Long physical isolation and different selective pressures result in allopatric speciation 371
Two populations diverge in the same physical location by sympatric speciation 373

Reproductive isolation breaks down in hybrid zones 375

The Rate of Evolutionary Change 376

Macroevolution 377

Evolutionary novelties originate through modifications of pre-existing structures 377

Adaptive radiation is the diversification of an ancestral species into many species 378

Extinction is an important aspect of evolution 380

Is microevolution related to speciation and macroevolution? 382

20 THE ORIGIN AND EVOLUTIONARY HISTORY OF LIFE 385

Chemical Evolution on Early Earth 386

Organic molecules formed on primitive earth 387

The First Cells 388

Molecular reproduction was a crucial step in the origin of cells 388

Biological evolution began with the first cells 389

The first cells were probably heterotrophic 390

Aerobes appeared after oxygen increased in the atmosphere 390

Eukaryotic cells descended from prokaryotic cells 391

The History of Life 392

Precambrian deposits contain fossils of cells and simple animals 393

A diversity of organisms evolved during the Paleozoic era 393

Dinosaurs and other reptiles dominated the Mesozoic era 396

The Cenozoic era is the Age of Mammals 399

ON THE CUTTING EDGE The Origin of Flight in Birds 400

21 THE EVOLUTION OF PRIMATES 404

Primate Adaptations 405

Primate Classification 406

Suborder Anthropoidea includes monkeys, apes, and humans 406

Many classification schemes place apes and humans in three families 408

Hominid Evolution 409

The earliest hominid may belong to the genus Sahelanthropus 410

Australopithecines *are immediate ancestors of the genus* Homo 411

Homo habilis *is the oldest member of the genus* Homo 412

Homo erectus *apparently evolved from* Homo habilis 412

Archaic Homo sapiens *appeared about 800,000 years ago* 413

Neandertals appeared approximately 230,000 years ago 413

Biologists debate the origin of modern Homo sapiens 414

Cultural Evolution 415

Development of agriculture resulted in a more dependable food supply 416

Cultural evolution has had a profound impact on the biosphere 416

Part 5 THE DIVERSITY OF LIFE

22 UNDERSTANDING DIVERSITY: SYSTEMATICS 419

Binomial Nomenclature 420

Taxonomic Categories 421

Kingdoms or Domains? 421

Reconstructing Phylogeny 424

Homologous structures are important in determining evolutionary relationships 425

Shared derived characters provide clues about phylogeny 425

Biologists carefully choose taxonomic criteria 426

Molecular biology provides additional characters 426

Taxa should reflect evolutionary relationships 427

Two Major Approaches to Systematics 428

Evolutionary systematics allows paraphyletic groups 428

Cladistics emphasizes phylogeny 429

In a cladogram each branch point represents a major evolutionary step 432

23 VIRUSES AND PROKARYOTES 435

Viruses 436

A virus particle consists of nucleic acid surrounded by a protein coat 436

The International Committee on Taxonomy of Viruses classifies viruses 436

Viruses may have "escaped" from cells 436

Bacteriophages are viruses that attack bacteria 437

Lytic reproductive cycles destroy the host cell 437

Temperate viruses integrate their DNA into the host DNA 438

Some viruses infect animal cells 439

Some viruses infect plant cells 439

Viroids and Prions 443

Prokaryotes 444
Prokaryotes have several common shapes 444
Prokaryotic cells lack membrane-enclosed organelles 444
A cell wall typically covers the cell surface 445
Many types of prokaryotes are motile 446
Prokaryotes have a circular DNA molecule 446
Most prokaryotes reproduce by binary fission 446
Some bacteria form endospores 447
Metabolic diversity is evident among prokaryotes 448

The Two Prokaryote Domains 449
Members of the Archaea survive in harsh environments 450
Eubacteria are the most familiar prokaryotes 451

Effects of Prokaryotes on the Environment 451
Prokaryotes are of great ecological importance 451
Some prokaryotes cause disease 453
Prokaryotes are used in many commercial processes 454

ON THE CUTTING EDGE Emerging and Re-emerging Diseases 443

24 PROTISTS 458

Introduction to the Protists 459

Evolution of the Eukaryotes 459
Mitochondria and chloroplasts probably originated from endosymbionts 460
A consensus is slowly emerging in eukaryote classification 460

Representative Protists 461
Excavates are anaerobic zooflagellates 462
Discicristates include euglenoids and trypanosomes 464
Alveolates have flattened vesicles under the plasma membrane 465
Motile cells of heterokonts are biflagellate 468
Cercozoa are amoeboid cells enclosed in shells 471
Red algae, green algae, and land plants are collectively classified as plants 473
Amoebozoa have lobose pseudopodia 475
Opisthokonts include choanoflagellates, fungi, and animals 477

25 KINGDOM FUNGI 481

Characteristics of Fungi 482
Most fungi have a filamentous body plan 482
Fungi reproduce by spores 482

Fungal Diversity 483
Chytridiomycetes are the most primitive fungi 483
Zygomycetes reproduce sexually by forming zygospores 485
Ascomycetes reproduce sexually by forming ascospores 487
Basidiomycetes reproduce sexually by forming basidiospores 489
Imperfect fungi have no known sexual stage 489

Lichens 491

Ecological Importance of Fungi 493

Economic and Medical Importance of Fungi 494
Fungi provide beverages and food 494
Fungi produce useful drugs and chemicals 495
Fungi cause many important plant diseases 495
Fungi cause certain animal diseases 496

26 THE PLANT KINGDOM: SEEDLESS PLANTS 499

Adaptations of Plants 500
The plant life cycle alternates haploid and diploid generations 500
Four major groups of plants evolved 501

Bryophytes 502
Moss gametophytes are differentiated into "leaves" and "stems" 502
Liverwort gametophytes are either thalloid or leafy 505
Hornwort gametophytes are inconspicuous thalloid plants 505
Bryophytes are used for experimental studies 505
Bryophyte evolution is based on fossils and on structural and molecular evidence 506

Seedless Vascular Plants 507
Ferns have a dominant sporophyte generation 508
Whisk ferns are the simplest vascular plants 510
Horsetails have hollow, jointed stems 510
Club mosses are small plants with rhizomes and short, erect branches 512
Some ferns and club mosses are heterosporous 512
Seedless vascular plants are used for experimental studies 513
Seedless vascular plants arose more than 420 mya 514

FOCUS ON Ancient Plants and Coal Formation 510

27 THE PLANT KINGDOM: SEED PLANTS 517

Seed Plants 518

Gymnosperms 518
Conifers are woody plants that produce seeds in cones 518
Cycads have seed cones and compound leaves 521

Ginkgo biloba *is the only living species in its phylum* 522
Gnetophytes include three unusual genera 523

Flowering Plants 524
Monocots and dicots are the two classes of flowering plants 524
Flowers are involved in sexual reproduction 525
The life cycle of flowering plants includes double fertilization 527
Seeds and fruits develop after fertilization 528
Flowering plants have many adaptations that account for their success 528
Studying how flowers evolved provides insights into the evolutionary process 529

The Evolution of Seed Plants 529

28 THE ANIMAL KINGDOM: AN INTRODUCTION TO ANIMAL DIVERSITY 534

Animal Characteristics 535

Animal Habitats 535

Reconstructing Phylogeny 536
Biologists classify animals according to body symmetry 536
Biologists group animals according to type of body cavity 537
Coelomate animals form two main groups based on differences in development 538
Biologists are using molecular data to rethink animal relationships 539

The Parazoa 541
Collar cells characterize sponges 541

The Radiata 543
Cnidarians have unique stinging cells 543
Class Hydrozoa includes solitary and colonial forms 545
The medusa stage is dominant among the jellyfish 546
Anthozoans occur only as polyps 546
Comb jellies have adhesive glue cells that trap prey 547

29 THE ANIMAL KINGDOM: THE PROTOSOMES 550

The Lophotrochozoa 551
Flatworms are bilateral acoelomates 551
Phylum Nemertea is characterized by the proboscis 554
Mollusks have a muscular foot, visceral mass, and mantle 554
Annelids are segmented worms 559
The lophophorate phyla are distinguished by a ciliated ring of tentacles 561
Rotifers have a crown of cilia 562

The Ecdysozoa 563
Roundworms are of great ecological importance 563
Arthropods are characterized by jointed appendages and an exoskeleton of chitin 564

30 THE ANIMAL KINGDOM: THE DEUTEROSTOMES 575

Echinoderms 577
Members of class Crinoidea are suspension feeders 578
Many members of class Asteroidea capture prey 578
Class Ophiuroidea is the largest class of echinoderms 578
Members of class Echinoidea have moveable spines 578
Members of class Holothuroidea are elongated, sluggish animals 578
Members of class Concentricycloidea have a unique water vascular system 579

Chordate Characters 579

Invertebrate Chordates 580
Tunicates are common marine animals 580
Lancelets may be closely related to vertebrates 580
Chordate phylogeny is controversial 580

Introducing the Vertebrates 582
The vertebral column is a key vertebrate character 582
Certain aspects of vertebrate phylogeny are still unclear 582

Jawless Fishes 584

Fishes and Amphibians 584
Members of class Chondrichthyes are cartilaginous fishes 585
The ray-finned fishes gave rise to modern bony fishes 587
Did descendants of the lobe-finned fishes or lungfishes move onto the land? 587
Amphibians were the first successful land vertebrates 589

Amniotes 590
Our understanding of amniote phylogeny is changing 590
Reptiles have many terrestrial adaptations 591
Are birds really dinosaurs? 592
Modern birds are adapted for flight 593
Mammals are characterized by hair and mammary glands 594

Part 6 STRUCTURE AND LIFE PROCESSES IN PLANTS

31 PLANT STRUCTURE, GROWTH, AND DIFFERENTIATION 601

Plants Structure and Lifespan 602
Plants have different life history strategies 603

The Plant Body 603
The plant body consists of cells and tissues 603
The ground tissue system is composed of three simple tissues 604
The vascular tissue system consists of two complex tissues 608
The dermal tissue system consists of two complex tissues 611

Plant Meristems 612
Primary growth takes place at apical meristems 613
Secondary growth takes place at lateral meristems 613

32 LEAF STRUCTURE AND FUNCTION 617

Leaf Form and Structure 618
Leaf structure consists of an epidermis, photosynthetic ground tissue, and vascular tissue 618
Leaf structure is related to function 622

Stomatal Opening and Closing 624
Blue light triggers stomatal opening 625
Other factors also affect stomatal opening and closing 626

Transpiration and Guttation 626
Some plants exude liquid water 627

Leaf Abscission 627
In many leaves, abscission occurs at an abscission zone near the base of the petiole 628

Modified Leaves 628
Modified leaves of insectivorous plants capture insects 630

FOCUS ON Air Pollution and Leaves 624

33 STEMS AND PLANT TRANSPORT 633

External Stem Structure in Woody Twigs 634

Stem Growth and Structure 634
Herbaceous dicot and monocot stems differ in internal structure 635
Woody plants have stems with secondary growth 636

Transport in the Plant Body 641
Water and minerals are transported in xylem 642
Sugar in solution is translocated in phloem 645

FOCUS ON Tree Ring Analysis and Climate Change 642

34 ROOTS AND MINERAL NUTRITION 650

Root Structure and Function 651
Roots have root caps and root hairs 651
The arrangement of vascular tissues distinguishes the roots of herbaceous dicots and monocots 652
Woody plants have roots with secondary growth 655
Some roots are specialized for unusual functions 656

Root Associations with Other Organisms 658

The Soil Environment 658
Soil is composed of inorganic minerals, organic matter, air, and water 659
The organisms living in the soil form a complex ecosystem 661
Soil pH affects soil characteristics and plant growth 661
Soil provides most of the minerals found in plants 662
Soil can be damaged by human mismanagement 663

35 REPRODUCTION IN FLOWERING PLANTS 668

The Flowering Plant Life Cycle 669
Flowers are involved in sexual reproduction 669
Female gametophytes are produced in the ovary, male gametophytes in the anther 670

Pollination 671
Many plant species have mechanisms to prevent self-pollination 671
Flowering plants and their animal pollinators have coevolved 672
Some flowering plants depend on wind to disperse pollen 673

Fertilization and Seed/Fruit Development 674
A unique double-fertilization process occurs in flowering plants 674
Embryonic development in seeds is orderly and predictable 674
The mature seed contains an embryonic plant and storage materials 674
Fruits are mature, ripened ovaries 676
Seed dispersal is highly varied 679

Asexual Reproduction in Flowering Plants 682
Apomixis is the production of seeds without the sexual process 683

A Comparison of Sexual and Asexual Reproduction 684
Sexual reproduction has some disadvantages 684

FOCUS ON Seed Banks 676

36 PLANT GROWTH AND DEVELOPMENT 687

Germination and Early Growth 688
Seed germination requires favorable environmental conditions 688
Dicots and monocots exhibit characteristic patterns of early growth 689

Light Signals and Plant Development 689
Phytochrome detects day length 690
Competition for sunlight among shade-avoiding plants involves phytochrome 691
Phytochrome is involved in other responses to light, including germination 691
Phytochrome acts by signal transduction 692
Light influences circadian rhythms 692

Nastic Movements and Tropisms 694
Changes in turgor induce nastic movements 694
A tropism is directional growth in response to an external stimulus 694

Plant Hormones and Development 696
Plant hormones act by signal transduction 696
Auxins promote cell elongation 698
Gibberellins promote stem elongation 700
Cytokinins promote cell division 700
Ethylene promotes abscission and fruit ripening 702
Abscisic acid promotes seed dormancy 703
Additional signaling molecules affect growth and development, including plant defenses 704
Unidentified plant hormones remain to be discovered 704

ON THE CUTTING EDGE Herbivore Defense Against Plant-Produced Signaling Molecules 705

FOCUS ON Cell and Tissue Culture 702

Part 7 STRUCTURE AND LIFE PROCESSES IN ANIMALS

37 THE ANIMAL BODY: INTRODUCTION TO STRUCTURE AND FUNCTION 709

Tissues 710
Epithelial tissues cover the body and line its cavities 710
Connective tissues support other body structures 711
Muscle tissue is specialized to contract 717
Nervous tissue controls muscles and glands 717

Organs and Organ Systems 719
The body maintains homeostasis 719

Regulating Body Temperature 722
Ectotherms absorb heat from their surroundings 723
Endotherms derive heat from metabolic processes 723
Many animals respond physiologically to changes in environmental temperature 725

FOCUS ON Unwelcome Tissues: Cancers 718

38 PROTECTION, SUPPORT, AND MOVEMENT 728

Epithelial Coverings 729
Invertebrate epithelium may function in secretion or gas exchange 729
Vertebrate skin functions in protection and temperature regulation 729

Skeletal Systems 730
In hydrostatic skeletons, body fluids transmit force 730
Mollusks and arthropods have nonliving exoskeletons 731
Internal skeletons are capable of growth 731
The vertebrate skeleton has two main divisions 732

Muscle Contraction 734
Invertebrate muscle varies among groups 734
A vertebrate muscle may consist of thousands of muscle fibers 735
Contraction occurs when actin and myosin filaments slide past each other 735
ATP powers muscle contraction 739

Skeletal muscle action depends on muscle pairs that work antagonistically 739
Muscle fibers may be specialized for slow or quick responses 739
Smooth, cardiac, and skeletal muscle respond in specific ways 740

39 NEURAL SIGNALING 744

Information Flow Through the Nervous System 745

Neurons and Glial Cells 746
Glial cells provide metabolic and structural support 746
A typical neuron consists of a cell body, dendrites, and an axon 746

Transmitting Information Along the Neuron 747
The neuron membrane has a resting potential 747
Graded local signals vary in magnitude 749
An action potential is generated by an influx of Na^+ and an efflux of K^+ 749

Neural Signaling Across Synapses 753
Signals across synapses can be electrical or chemical 753
Neurons use neurotransmitters to signal other cells 753
Neurotransmitters bind with receptors on postsynaptic cells 754
Neurotransmitters and their receptors can send excitatory or inhibitory signals 755

Neural Integration 757

Neural Circuits 758

FOCUS ON Alzheimer's Disease 756

40 NEURAL REGULATION 762

Invertebrate Nervous Systems 763

Organization of the Vertebrate Nervous System 765

Evolution of the Vertebrate Brain 765
The hindbrain develops into the medulla, pons, and cerebellum 766
The midbrain is prominent in fishes and amphibians 766
The forebrain gives rise to the thalamus, hypothalamus, and cerebrum 767

The Human Central Nervous System 768
The spinal cord transmits impulses to and from the brain 768
The most prominent part of the human brain is the cerebrum 770
Brain activity cycles in a sleep—wake pattern 773
The limbic system affects emotional aspects of behavior 774
Learning involves the storage of information and its retrieval 774

The Peripheral Nervous System 777
The somatic division helps the body adjust to the external environment 777
The autonomic division regulates the internal environment 777

Effects of Drugs on the Nervous System 779

ON THE CUTTING EDGE The Neurophysiology of Traumatic Experience 775

FOCUS ON Alcohol: The Most Abused of All Drugs 782

41 SENSORY RECEPTION 786

Types of Sensory Receptors 787

How Sensory Receptors Function 788
Sensation depends on transmission of a coded message 788
Sensory receptors adapt to stimuli 789

Mechanoreceptors 789
Touch receptors are located in the skin 789
Proprioceptors help coordinate muscle movement 790
Many invertebrates have gravity receptors called statocysts 791
Hair cells are characterized by stereocilia 791
Lateral line organs supplement vision in fish 792
The vestibular apparatus maintains equilibrium 792
Auditory receptors are located in the cochlea 793

Chemoreceptors 796
Taste buds detect dissolved food molecules 796
The olfactory epithelium is responsible for the sense of smell 797

Photoreceptors 798
Invertebrate photoreceptors include eyespots, simple eyes, and compound eyes 799
Vertebrate eyes form sharp images 799
The retina contains light-sensitive rods and cones 801

42 INTERNAL TRANSPORT 807

Types of Circulatory Systems 808
Many invertebrates have an open circulatory system 808
Some invertebrates have a closed circulatory system 809
All vertebrates have a closed circulatory system 809

Vertebrate Blood 810
Plasma is the fluid component of blood 810
Red blood cells transport oxygen 811
White blood cells defend the body against disease organisms 812
Platelets function in blood clotting 812

Vertebrate Blood Vessels 813

Evolution of the Vertebrate Cardiovascular System 815

The Human Heart 816
Each heartbeat is initiated by a pacemaker 817
The nervous system regulates heart rate 819
Stroke volume depends on venous return 820
Cardiac output varies with the body's need 821

Blood Pressure 821
Blood pressure is highest in arteries 822
Blood pressure is carefully regulated 824

The Pattern of Circulation 824
The pulmonary circulation oxygenates the blood 824
The systemic circulation delivers blood to the tissues 825

The Lymphatic System 826
The lymphatic system consists of lymphatic vessels and lymph tissue 826
The lymphatic system plays an important role in fluid homeostasis 827

FOCUS ON Cardiovascular Disease 822

43 INTERNAL DEFENSE 831

Nonspecific and Specific Immunity: An Overview 832
Invertebrates launch nonspecific immune responses 832
Vertebrates launch nonspecific and specific immune responses 833

Nonspecific Immune Responses 833
Soluble molecules mediate immune responses 833
Phagocytes and natural killer cells destroy pathogens 834
Inflammation is a protective response 835

Specific Immune Responses 836
Many types of cells are involved in specific immune responses 836
The major histocompatibility complex permits recognition of self 838

Cell-Mediated Immunity 839

Antibody-Mediated Immunity 840
A typical antibody consists of four polypeptide chains 842
Antibodies are grouped in five classes 843
Antigen—antibody binding activates other defenses 843
The immune system responds to millions of different antigens 843
Monoclonal antibodies are highly specific 844

Immunological Memory 845
A secondary immune response is more effective than a primary response 845
Immunization induces active immunity 846
Passive immunity is borrowed immunity 847

The Immune System and Disease 847
Cancer cells evade the immune system 847
Immunodeficiency disease can be inherited or acquired 848
HIV is the major cause of acquired immunodeficiency 848

Harmful Immune Responses 851
Graft rejection is an immune response against transplanted tissue 851
Rh incompatibility can result in hypersensitivity 851
Allergic reactions are directed against ordinary environmental antigens 852
In an autoimmune disease, the body attacks its own tissues 853

44 GAS EXCHANGE 857

Adaptations for Gas Exchange in Air or Water 858

Types of Respiratory Surfaces 859
The body surface may be adapted for gas exchange 859
Tracheal tube systems of arthropods deliver air directly to the cells 859
Gills of aquatic animals are respiratory surfaces 859
Terrestrial vertebrates exchange gases through lungs 861

The Mammalian Respiratory System 862
The airway conducts air into the lungs 862
Gas exchange occurs in the alveoli of the lungs 863
Ventilation is accomplished by breathing 863
The quantity of respired air can be measured 865
Gas exchange takes place in the alveoli 865
Gas exchange takes place in the tissues 866
Respiratory pigments increase capacity for oxygen transport 866
Carbon dioxide is transported mainly as bicarbonate ions 867
Breathing is regulated by respiratory centers in the brain 867
Hyperventilation reduces carbon dioxide concentration 869
High flying or deep diving can disrupt homeostasis 869
Some mammals are adapted for diving 869

Breathing Polluted Air 870

FOCUS ON The Effects of Smoking 871

45 PROCESSING FOOD AND NUTRITION 875

Nutritional Styles and Adaptations 876
- *Animals are adapted to their mode of nutrition 876*
- *Some invertebrates have a digestive cavity with a single opening 876*
- *Most animal digestive systems have two openings 878*

The Vertebrate Digestive System 878
- *Food processing begins in the mouth 879*
- *The pharynx and esophagus conduct food to the stomach 880*
- *Food is mechanically and enzymatically digested in the stomach 880*
- *Most enzymatic digestion takes place inside the small intestine 882*
- *The liver secretes bile 883*
- *The pancreas secretes digestive enzymes 883*
- *Nutrients are digested as they move through the digestive tract 883*
- *Nerves and hormones regulate digestion 884*
- *Absorption takes place mainly through the villi of the small intestine 885*
- *The large intestine eliminates waste 885*

Required Nutrients 885
- *Carbohydrates provide energy 886*
- *Lipids provide energy and are used to make biological molecules 886*
- *Proteins serve as enzymes and as structural components of cells 888*
- *Vitamins are organic compounds essential for normal metabolism 888*
- *Minerals are inorganic nutrients 888*
- *Antioxidants protect against oxidants 889*
- *Phytochemicals play important roles in maintaining health 890*

Energy Metabolism 891
- *Undernutrition can cause serious health problems 891*
- *Obesity is a serious nutritional problem 892*

46 OSMOREGULATION AND DISPOSAL OF METABOLIC WASTES 896

Metabolic Waste Products 897

Osmoregulation and Metabolic Waste Disposal in Invertebrates 898
- *Nephridial organs are specialized for osmoregulation and/or excretion 898*
- *Malpighian tubules conserve water 898*

Osmoregulation and Metabolic Waste Disposal in Vertebrates 899
- *Freshwater vertebrates must rid themselves of excess water 899*
- *Marine vertebrates must replace lost fluid 900*
- *Terrestrial vertebrates must conserve water 900*

The Urinary System 901
- *The nephron is the functional unit of the kidney 903*
- *Urine is produced by filtration, reabsorption, and secretion 904*
- *Urine becomes concentrated as it passes through the renal tubule 906*
- *Urine is composed of water, nitrogenous wastes, and salts 907*
- *Kidney function is regulated by hormones 907*

47 ENDOCRINE REGULATION 913

Cell Signaling 914
- *In classical endocrine signaling, hormones are secreted by endocrine glands 914*
- *Neurohormones are transported in the blood 914*
- *Many endocrinologists include some local regulators as hormones 914*
- *Hormones are assigned to four chemical groups 915*

Regulation of Hormone Secretion 917

Mechanisms of Hormone Action 918
- *Some hormones enter target cells and activate genes 918*
- *Many hormones bind to cell-surface receptors 918*
- *G protein-linked receptors signal second messengers 919*
- *Enzyme-linked receptors function directly 920*
- *Hormone signals are amplified 921*

Invertebrate Neuroendocrine Systems 921

The Vertebrate Endocrine System 922
- *Homeostasis depends on normal concentrations of hormones 922*
- *The hypothalamus regulates the pituitary gland 922*
- *The posterior lobe of the pituitary gland releases hormones produced by the hypothalamus 922*
- *The anterior lobe of the pituitary gland regulates growth and other endocrine glands 924*
- *Thyroid hormones increase metabolic rate 926*
- *The parathyroid glands regulate calcium concentration 927*
- *The islets of the pancreas regulate glucose concentration 927*
- *The adrenal glands help the body cope with stress 930*
- *Many other hormones are known 933*

FOCUS ON Anabolic Steroids and Other Abused Hormones 916

48 REPRODUCTION 936

Asexual and Sexual Reproduction 937
- *Asexual reproduction is an efficient strategy 937*
- *Sexual reproduction is the most common type of animal reproduction 937*

Human Reproduction: The Male 939
- *The testes produce gametes and hormones 939*
- *A series of ducts store and transport sperm 940*
- *The accessory glands produce the fluid portion of semen 940*
- *The penis transfers sperm to the female 942*
- *The hypothalamus, pituitary, and testes regulate male reproduction 942*

Human Reproduction: The Female 944
- *The ovaries produce gametes and sex hormones 944*
- *The oviducts transport the secondary oocyte 945*
- *The uterus incubates the embryo 946*
- *The vagina receives sperm 946*
- *The vulva are external genital structures 946*
- *The breasts function in lactation 947*
- *The hypothalamus, pituitary, and ovaries interact to regulate female reproduction 947*

Sexual Response 951

Fertilization and Early Development 951

The Birth Process 954

Birth Control Methods 954
- *Most hormone contraceptives prevent ovulation 955*
- *Intrauterine devices are widely used 957*
- *Other common contraceptive methods include the diaphragm and condom 957*
- *Emergency contraception is available 957*
- *Sterilization renders an individual incapable of producing offspring 957*
- *Abortions can be spontaneous or induced 958*

Sexually Transmitted Diseases 959

FOCUS ON Breast Cancer 948

FOCUS ON Novel Origins 952

49 ANIMAL DEVELOPMENT 962

Fertilization 963
- *The first step in fertilization involves contact and recognition 963*
- *Sperm entry is regulated 964*
- *Fertilization activates the egg 964*
- *Sperm and egg pronuclei fuse, restoring the diploid state 965*

Cleavage 965
- *The pattern of cleavage is affected by yolk 965*
- *Cleavage may distribute developmental determinants 967*
- *Cleavage provides building blocks for development 968*

Gastrulation 968
- *The pattern of gastrulation is affected by the amount of yolk 969*

Organogenesis 970

Extraembryonic Membranes 972

Human Development 973
- *The placenta is an organ of exchange 973*
- *Organ development begins during the first trimester 975*
- *Development continues during the second and third trimesters 976*
- *More than one mechanism can lead to a multiple birth 976*
- *Environmental factors affect the embryo 976*
- *The neonate must adapt to its new environment 976*
- *Aging is not a uniform process 978*
- *Homeostatic response to stress decreases during aging 978*

50 ANIMAL BEHAVIOR 981

Understanding Behavior 982

Interaction of Genes and Environment 982
- *Behavior depends on physiological readiness 983*
- *Many behavior patterns depend on motor programs 983*

Learning from Experience 984
- *An animal habituates to irrelevant stimuli 985*
- *Imprinting occurs during an early critical period 985*
- *In classical conditioning, a reflex becomes associated with a new stimulus 985*
- *In operant conditioning, spontaneous behavior is reinforced 986*
- *Insight learning uses recalled events to solve new problems 987*
- *Play may be practice behavior 987*

Biological Rhythms and Migration 987
- *Biological rhythms affect behavior 988*
- *Migration involves interactions among biological rhythms, physiology, and environment 988*

Foraging Behavior 989

Social Behavior 990
- *Communication is necessary for social behavior 991*
- *Dominance hierarchies are social rankings 992*
- *Many animals defend a territory 993*

Some species that engage in social behavior form societies 994
Sociobiology explains human social behavior in terms of adaptation 996

Sexual Selection 996
Animals seek quality mates 996
Sexual selection favors polygynous mating systems 997
Some animals care for their young 998

Helping Behavior 999
Altruistic behavior can be explained by inclusive fitness 999
Cooperative behavior may have alternate explanations 999

Part 8 THE INTERACTIONS OF LIFE: ECOLOGY

51 INTRODUCTION TO ECOLOGY: POPULATION ECOLOGY 1003

Features of Populations 1004
Density and dispersion are important features of populations 1004

Changes in Population Size 1006
Dispersal affects the growth rate in some populations 1006
Each population has a characteristic intrinsic rate of increase 1006
No population can increase exponentially indefinitely 1007

Factors Influencing Population Size 1008
Density-dependent factors regulate population size 1008
Density-independent factors are generally abiotic 1010

Life History Traits 1011
Life tables and survivorship curves indicate mortality and survival 1012

Metapopulations 1014

Human Populations 1015
Not all countries have the same growth rate 1017
The age structure of a country helps predict future population growth 1018
Environmental degradation is related to population growth and resource consumption 1019

52 COMMUNITY ECOLOGY 1023

Community Structure and Functioning 1024
The niche is a species' ecological role in the community 1025
Biotic and abiotic factors influence a species' ecological niche 1026
Competition is intraspecific or interspecific 1026
Natural selection shapes the body forms and behaviors of both predator and prey 1029
Symbiosis involves a close association between species 1031
Keystone species and dominant species affect the character of a community 1034

Community Biodiversity 1035
Ecologists seek to explain why some communities have more species than others 1035
Species richness may promote community stability 1037

Community Development 1038
Disturbance influences succession and species richness 1038
Ecologists continue to study community structure 1039

FOCUS ON Batesian Butterflies Disproved 1032

53 ECOSYSTEMS AND THE BIOSPHERE 1043

Energy Flow Through Ecosystems 1044
Ecological pyramids illustrate how ecosystems work 1046
Ecosystems vary in productivity 1048

Cycles of Matter in Ecosystems 1049
Carbon dioxide is the pivotal molecule in the carbon cycle 1049
Bacteria are essential to the nitrogen cycle 1051
The phosphorus cycle lacks a gaseous component 1053
Water moves among the ocean, land, and atmosphere in the hydrologic cycle 1054

Ecosystem Regulation from the Bottom Up and the Top Down 1055

Abiotic Factors in Ecosystems 1056
The sun warms Earth 1056
The atmosphere contains several gases essential to organisms 1058
The global ocean covers most of Earth's surface 1059

Climate profoundly affects organisms 1060
Fires are a common disturbance in some ecosystems 1062

FOCUS ON Food Chains and Poisons in the Environment 1045

FOCUS ON Life Without the Sun 1056

54 ECOLOGY AND THE GEOGRAPHY OF LIFE 1065

Biomes 1066
Tundra is the cold, boggy plains of the far north 1066
Taiga is the evergreen forest of the north 1068
Temperate rain forest has cool weather, dense fog, and high precipitation 1068
Temperate deciduous forest has a canopy of broad-leaf trees 1070
Temperate grasslands occur in areas of moderate precipitation 1071
Chaparral is a thicket of evergreen shrubs and small trees 1072
Deserts are arid ecosystems 1072
Savanna is a tropical grassland with scattered trees 1073
There are two basic types of tropical forests 1074

Aquatic Ecosystems 1075
Freshwater ecosystems are closely linked to land and marine ecosystems 1075
Estuaries occur where fresh water and salt water meet 1079
Marine ecosystems dominate Earth's surface 1080

Ecotones 1084

Biogeography 1084
Land areas are divided into six biogeographical realms 1085

FOCUS ON The Distribution of Vegetation on Mountains 1067

55 HUMANS IN THE ENVIRONMENT 1088

The Biodiversity Crisis 1089
Human activities contribute to declining biological diversity 1091
Where is the problem of declining biological diversity greatest? 1093
Conservation biology addresses the issue of declining biological diversity 1094

Deforestation 1098
Where and why are forests disappearing? 1098

Global Warming 1100
Greenhouse gases cause global warming 1100
What are the probable effects of global warming? 1102
There are many possible ways to deal with global warming 1103

Declining Stratospheric Ozone 1104
Certain chemicals destroy stratospheric ozone 1105
Ozone depletion harms organisms 1105
International cooperation can prevent significant depletion of the ozone layer 1106

Connections Among Environmental Problems 1106

A View of Life

Jim Olive/Peter Arnold Inc.

Human genome research. A gel containing DNA is loaded into a sequencing machine. On the screen is the information from the gel which is ordered into the DNA base sequences. This image was taken at the Baylor College of Medicine at the Texas Medical Center in Houston.

CHAPTER OUTLINE

- Characteristics of Life
- Biological Organization
- Information Transfer
- Evolution: The Basic Unifying Concept of Biology
- The Energy of Life
- The Process and Method of Science

This is an exciting time to begin studying **biology,** the science of life. Almost daily, biologists are making remarkable new discoveries about the human species and about the millions of other organisms with which we share this planet. One of the most rapidly expanding areas of biological research is genetics, the biologic science that focuses on the mechanisms of heredity.

For 13 years, an international group of scientists worked in 20 sequencing centers in six countries to map the chain of 3 billion letters that make up the **human genome,** the complete set of genes that make up human genetic material. Genes, which are made up of segments of DNA, control specific characteristics, such as eye color and height. In 2003, the International Consortium for the Sequencing of the Human Genome announced the completion of the **Human Genome Project.** One stunning finding of the project has been that the DNA sequences that make up the estimated 30,000 genes of the human genome are 99.9% identical in all humans. Scientists have hailed the completion of the human genome project as a brilliant achievement, a big step toward deciphering the "book of life."

Locating the genes is just the first step, however. Scientists need to refine what has been done to determine which genes do what and how they function. The next level of research will focus on the proteins for which the genes code. Certain proteins make up the structural framework of an organism. Others are enzymes, catalysts that regulate the biochemical reactions essential to life. Geneticists are also carrying out detailed analyses of the genomes of bacteria and other organisms, including primates.

Dr. Francis Collins, director of the genome center at the National Institutes of Health, has said that the completion of the Human Genome Project "marks the start of an exciting new era—the era of the genome in medicine and health." Genome research

BiologyNow™ Seeing BiologyNow throughout the text indicates an opportunity for you to test yourself on key concepts, and to explore animations and interactions on your BiologyNow CD-ROM.

is already contributing to the new science of gene therapy and is opening new avenues for preventing, diagnosing, and treating many human disorders. The science of **genomics,** the analysis of the complete DNA sequence of an organism, will have a worldwide effect on health by increasing knowledge of genetic susceptibility and the body's responses to infectious diseases.

In 1990, geneticists had identified fewer than 100 genes associated with human disease. By 2003, they had identified more than 1400. Using genomics, researchers are identifying hereditary factors in diseases such as cardiovascular disease, cancer, and diabetes. Knowing the locations of genes involved in disease is an important step toward understanding their molecular mechanisms. In turn, this understanding will lead to improved methods for diagnosis and new therapeutic approaches. Researchers are working toward "individualized medicine," in which treatment is tailored to each person's genetic profile.

In addition to its promise in health and medicine, genomics has important implications for agriculture, environmental science, and many other arenas. For example, as they gain knowledge about the genetics of plants, researchers can develop tools to increase crop production. The U.S. Department of Energy's Genomes to Life Program focuses on understanding the molecular biology of thousands of microbe species. Scientists in this program plan to use the new findings to solve major environmental problems such as removing excess carbon dioxide from the atmosphere, cleaning up environments contaminated with toxic wastes, and developing clean fuel sources.

The era of the genome brings with it ethical concerns and responsibilities. How do people safeguard the privacy of genetic information? How can we be certain knowledge of our individual genetic codes would not be used against us when we seek employment or health insurance? Scientists must be ethically responsible and must help educate people about their work, including its benefits relative to its risks. Interestingly, at the very beginning of the Human Genome Project, part of its budget was allocated for research on the ethical, legal, and social implications of its findings. Appropriate legislation may help reduce society's fears about misuse of genetic information.

Genetics is only one of many exciting areas of biology that have an impact on our lives. Whatever your college major or career goals, knowledge of biological concepts is a vital tool for understanding this world and for meeting many of the personal, societal, and global challenges that confront us. Among these challenges are decreasing biological diversity, diminishing natural resources, the expanding human population, and prevention and cure of diseases, such as cancer, Alzheimer's disease, malaria, and acquired immunodeficiency syndrome (AIDS). Meeting these challenges will require the combined efforts of biologists and other scientists, politicians, and biologically informed citizens.

This book is a starting point for an exploration of biology. It provides you with the basic knowledge and the tools to become a part of this fascinating science and a more informed member of society. In this first chapter we introduce three basic themes of biology: (1) the evolution of life, (2) transmission of information, and (3) the flow of energy through living systems. Scientists have accumulated a wealth of evidence showing that the diverse life forms on this planet are related and that organisms have evolved through time from earlier forms of life. The process of evolution is the framework for the science of biology and is a major theme of this book.

Evolution, as well as the survival and function of every organism, depends on the orderly transmission of information. In turn, transmitting information, and all other life processes, including the thousands of chemical transactions that maintain life's organization, require a continuous input of energy. Evolution, information transmission, and energy flow are the forces that give life its unique characteristics. We begin this study of biology by developing a more precise understanding of the fundamental characteristics of living systems. ■

CHARACTERISTICS OF LIFE

Learning Objective

1 Distinguish between living and nonliving things by describing the features that characterize living organisms.

We easily recognize that a pine tree, a butterfly, and a horse are living things, whereas a rock is not. Despite their diversity, the organisms that inhabit our planet share a common set of characteristics that distinguish them from nonliving things. These features include a precise kind of organization, growth and development, self-regulated metabolism, the ability to respond to stimuli, reproduction, and adaptation to environmental change.

Organisms are composed of cells

Although they vary greatly in size and appearance, all organisms consist of basic units called **cells.** New cells are formed only by the division of previously existing cells. These concepts are expressed in the **cell theory** (discussed in Chapter 4), a fundamental unifying concept of biology. Some of the simplest life forms, such as protozoa, are *unicellular organisms,* meaning that each consists of a single cell (Fig. 1-1). In contrast, the body of a cat or a maple tree is made of billions of cells. In such complex *multicellular organisms,* life processes depend on the coordinated functions of component cells that may be organized to form tissues, organs, and organ systems.

Every cell is enveloped by a protective **plasma membrane** that separates it from the surrounding external environment. The plasma membrane regulates passage of materials between cell and environment. Cells have specialized molecules that

Mike Abbey/Visuals Unlimited

FIGURE **1-1** **Unicellular and multicellular life forms.**

(a) Unicellular organisms are generally smaller than multicellular organisms and consist of one intricate cell that performs all the functions essential to life. Ciliates, such as this *Paramecium,* move about by beating their hairlike cilia.

contain genetic instructions. In most cells, the genetic instructions are encoded in deoxyribonucleic acid, more simply known as **DNA.** Cells typically have internal structures called **organelles** that are specialized to perform specific functions.

There are two fundamentally different types of cells: prokaryotic and eukaryotic. **Prokaryotic cells** are exclusive to bacteria and to microscopic organisms called *archaea.* All other organisms are characterized by their **eukaryotic cells.** These cells typically contain a variety of organelles enclosed by membranes, including a **nucleus,** which houses DNA. Prokaryotic cells are structurally simpler: They do not have a nucleus or other membrane-enclosed organelles.

Organisms grow and develop

Biological growth involves an increase in the size of individual cells of an organism, in the number of cells, or in both. Growth may be uniform in the various parts of an organism, or it may be greater in some parts than in others, causing the body proportions to change as growth occurs. Some organisms—most trees, for example—continue to grow throughout their lives. Many animals have a defined growth period that terminates when a characteristic adult size is reached. An intriguing aspect of the growth process is that each part of the organism typically continues to function as it grows.

Living organisms develop as well as grow. **Development** includes all the changes that take place during an organism's life. Just like many other organisms, every human begins life as a fertilized egg that then grows and develops. The structures and body form that develop are exquisitely adapted to the functions the organism must perform.

Organisms regulate their metabolic processes

Within all organisms, chemical reactions and energy transformations occur that are essential to nutrition, the growth and repair of cells, and the conversion of energy into usable forms. The sum of all the chemical activities of the organism is its **metabolism.** Metabolic processes occur continuously in every living organism, and they must be carefully regulated to maintain **homeostasis,** an appropriate, balanced internal environment. When enough of a cell product has been made, its manufacture must be decreased or turned off. When a particular substance is needed, cell processes that produce it must be turned on. These *homeostatic mechanisms* are self-regulating control systems that are remarkably sensitive and efficient.

The regulation of glucose (a simple sugar) concentration in the blood of complex animals is a good example of a homeostatic mechanism. Your cells require a constant supply of glucose, which they break down to obtain energy. The circulatory system delivers glucose and other nutrients to all the cells. When the concentration of glucose in the blood rises above normal limits, glucose is stored in the liver and in muscle cells. When the concentration begins to fall (between meals), stored nutrients are converted to glucose so that the concentration in the blood returns to normal levels. When glucose becomes depleted, you also feel hungry and restore nutrients by eating.

Organisms respond to stimuli

All forms of life respond to **stimuli,** physical or chemical changes in their internal or external environment. Stimuli that evoke a response in most organisms are changes in the color, intensity, or direction of light; changes in temperature, pressure, or sound; and changes in the chemical composition of the surrounding soil,

air, or water. Responding to stimuli involves movement, though not always locomotion (moving from one place to another).

In simple organisms, the entire individual may be sensitive to stimuli. Certain unicellular organisms, for example, respond to bright light by retreating. In some organisms, locomotion is achieved by the slow oozing of the cell, the process of *amoeboid movement.* Other organisms move by beating tiny, hairlike extensions of the cell called **cilia** or longer structures known as **flagella** (Fig. 1-2). Some bacteria move by means of rotating flagella.

Most animals move very obviously. They wiggle, crawl, swim, run, or fly by contracting muscles. Sponges, corals, and oysters have free-swimming larval stages but do not move from place to place as adults. Even though these adults are sessile, meaning they remain firmly attached to a surface, they may have cilia or flagella. These structures beat rhythmically, moving the surrounding water, which contains needed food and oxygen. In complex animals such as polar bears and humans, certain highly specialized cells of the body respond to specific types of stimuli. For example, cells in the retina of the eye respond to light.

Although their responses may not be as obvious as those of animals, plants do respond to light, gravity, water, touch, and other stimuli. For example, plants orient their leaves to the sun and grow toward light. Many plant responses involve different growth rates of various parts of the plant body.

A few plants, such as the Venus flytrap of the Carolina swamps, are very sensitive to touch and catch insects (Fig. 1-3). Their leaves are hinged along the midrib, and they have a scent that attracts insects. Trigger hairs on the leaf surface detect the arrival of an insect and stimulate the leaf to fold. When the edges come together, the hairs interlock, preventing the insect's escape. The leaf then secretes enzymes that kill and digest the insect. The Venus flytrap usually grows in soil deficient in nitrogen. The plant obtains part of the nitrogen required for its growth from the insect it "eats."

In sexual reproduction, two parents each contribute a gamete (sperm or egg). Gametes fuse to produce the offspring, which has a combination of the traits of both parents.

scientists, including the Italian physician Francesco Redi in the 17th century and French chemist Louis Pasteur in the 19th century, we now know that an organism can come only from previously existing organisms.

Simple organisms, such as amoebas, perpetuate themselves by **asexual reproduction,** without the fusion of egg and sperm to form a fertilized egg (Fig. 1-4a). When an amoeba has grown to a certain size, it reproduces by splitting in half to form two new amoebas. Before an amoeba divides, its hereditary material (set of genes) duplicates, and one complete set is distributed to each new cell. Except for size, each new amoeba is similar to the parent cell. The only way that variation occurs among asexually reproducing organisms is by genetic *mutation,* a permanent change in the genes.

In most plants and animals, **sexual reproduction** is carried out by the fusion of egg and sperm cells to form a fertilized egg (Fig. 1-4b). The new organism develops from the fertilized egg. Offspring produced by sexual reproduction are the product of the interaction of various genes contributed by the mother and the father. This genetic variation is important in the vital processes of evolution and adaptation.

Image not available due to copyright restrictions

Populations evolve and become adapted to the environment

The ability of a population to evolve (change over time) and adapt to its environment equips it to survive in a changing world. **Adaptations** are characteristics that enhance an organism's ability to survive in a particular environment. The long, flexible tongue of the frog is an adaptation for catching insects, the feathers and lightweight bones of birds are adaptations for flying, and the thick fur coat of the polar bear is an adaptation for surviving frigid temperatures. Adaptations may be structural, physiological, behavioral, or a combination of all three (Fig. 1-5). Every biologically successful organism is a complex collection of coordinated adaptations produced through evolutionary processes.

BIOLOGICAL ORGANIZATION

Learning Objective

2 Construct a hierarchy of biological organization, including levels of an individual organism and ecological levels.

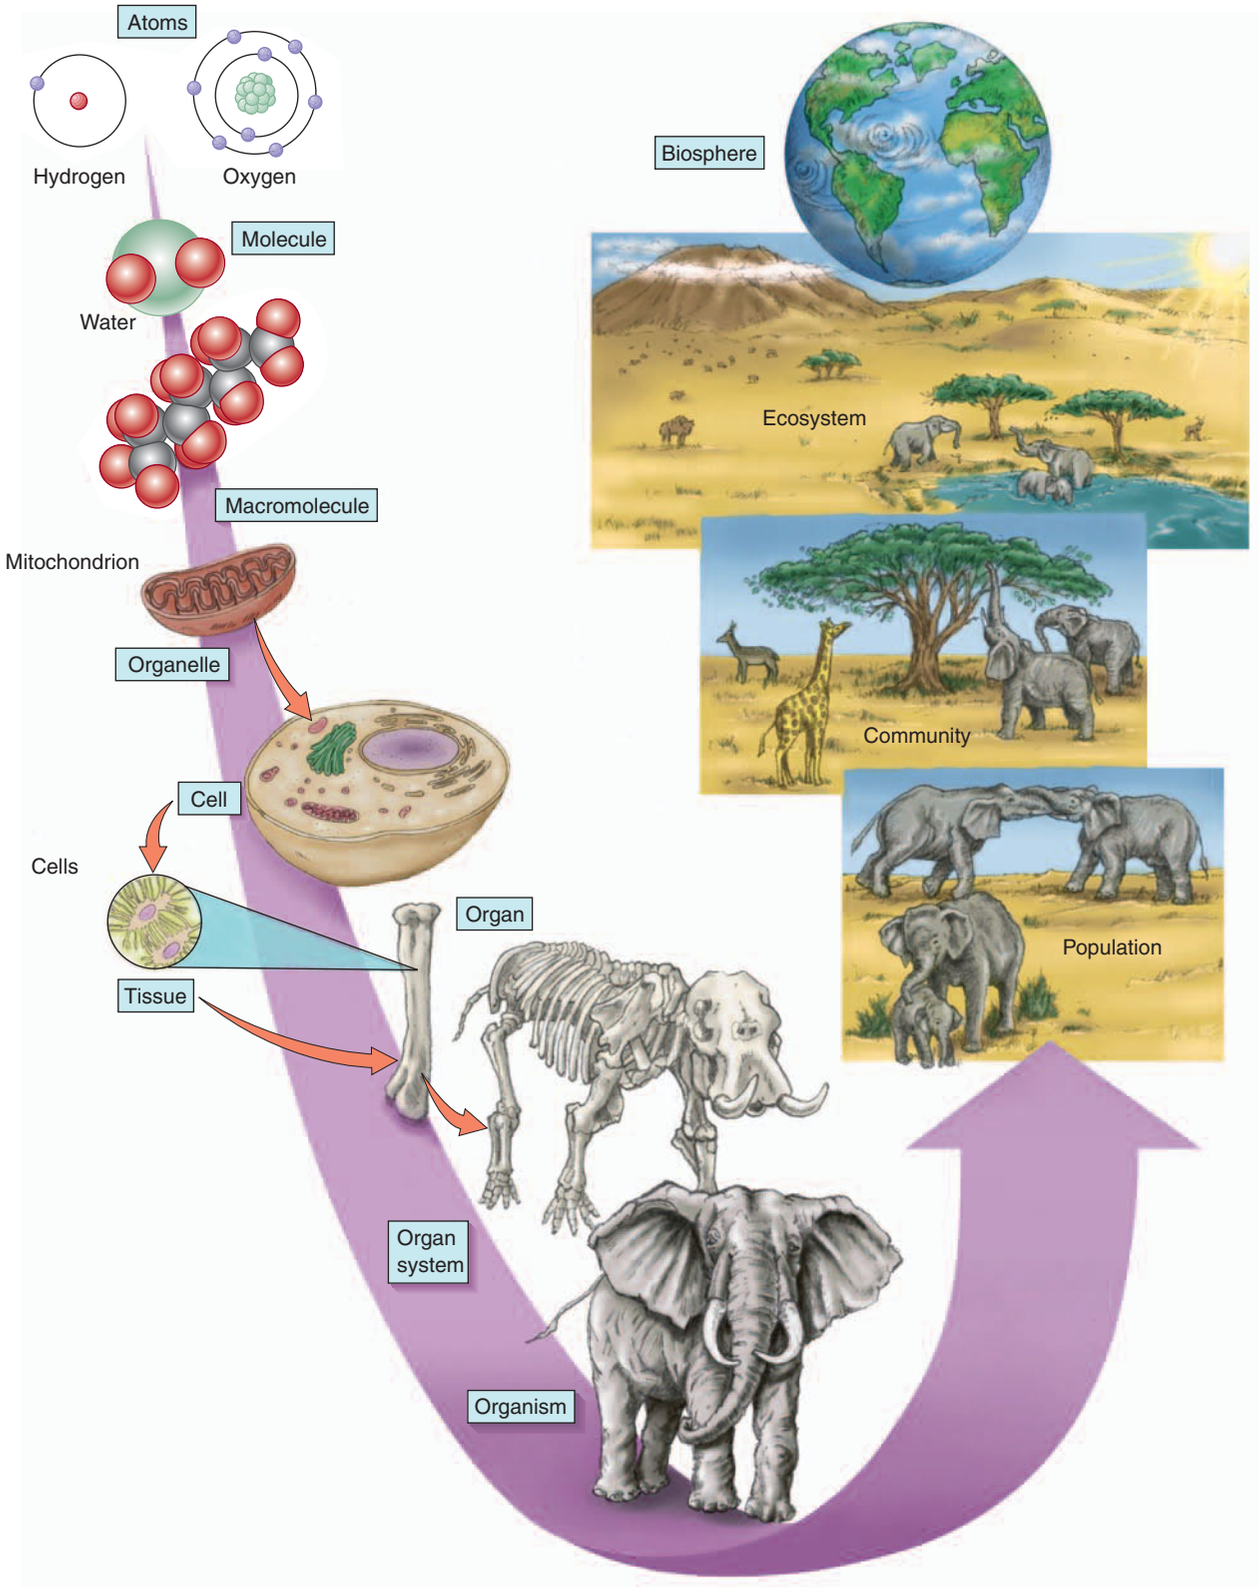

FIGURE **1-6** **The hierarchy of biological organization.**

Atoms join to form molecules of varying size, including very large macromolecules such as proteins and DNA. Atoms and molecules form organelles, such as the cell's nucleus or mitochondria (the site of energy transformations). Many organelles work together to perform the various functions of the cell. Cells associate to form tissues, such as bone tissue. Tissues form organs, such as bones, that in turn comprise organ systems. The skeletal system and other organ systems work together to make up the functioning organism. A population consists of organisms of the same species. The populations of different species that inhabit a particular area make up a community, which together with the nonliving environment form an ecosystem. Earth and all its communities constitute the biosphere.

Whether we study a single complex organism or the world of life as a whole, we can identify a hierarchy of biological organization (Fig. 1-6). At every level, structure and function are precisely coordinated. One way to study a particular level is by looking at its components. For example, biologists can learn about cells by studying atoms and molecules. Learning about a structure by studying its parts is called **reductionism.** However, the whole is more than the sum of its parts. Each level has **emergent properties,** characteristics not found at lower levels. For example, populations have emergent properties such as population density, age structure, and birth and death rates. The individuals that make up a population lack these characteristics.

Organisms have several levels of organization

The chemical level, the most basic level of organization, includes atoms and molecules. An **atom** is the smallest unit of a chemical element that retains the characteristic properties of that element. For example, an atom of iron is the smallest possible amount of iron. Atoms combine chemically to form **molecules.** Two atoms of hydrogen combine with one atom of oxygen to form a single molecule of water. Although composed of two types of atoms that are gases, water is a liquid with very different properties, an example of emergent properties.

At the cell level many different types of atoms and molecules associate with one another to form cells. However, a cell is much more than a heap of atoms and molecules. Its emergent properties make it the basic structural and functional unit of life, the simplest component of living matter that can carry on all the activities necessary for life.

During the evolution of multicellular organisms, cells associated to form **tissues.** For example, most animals have muscle tissue and nervous tissue, and plants have epidermis, a tissue that serves as a protective covering. In most complex organisms, tissues organize into functional structures called **organs,** such as the heart and stomach in animals and roots and leaves in plants. In animals, each major group of biological functions is performed by a coordinated group of tissues and organs called an organ system. The circulatory and digestive systems are examples of organ systems. Functioning together with great precision, organ systems make up a complex, multicellular **organism.** Again, emergent properties are evident. An organism is much more than its component organ systems.

Several levels of ecological organization can be identified

Organisms interact to form still more complex levels of biological organization. All the members of one species that live in the same geographic area at the same time make up a **population.** The populations of organisms that inhabit a particular area and interact with one another form a **community.** A community can consist of hundreds of different types of organisms. As populations within a community evolve, the community changes.

A community together with its nonliving environment is referred to as an **ecosystem.** An ecosystem can be as small as a pond (or even a puddle) or as vast as the Great Plains of North America or the Arctic tundra. All of Earth's ecosystems together are known as the **biosphere.** The biosphere includes all of Earth that is inhabited by living organisms—the atmosphere, the hydrosphere (water in any form), and the lithosphere (Earth's crust). The study of how organisms relate to one another and to their physical environment is called **ecology** (derived from the Greek *oikos,* meaning "house").

Review

- What are the levels of ecological organization?

Biology Now™ Assess your understanding of hierarchical **biological organization** by taking the pretest on your BiologyNow CD-ROM.

INFORMATION TRANSFER

Learning Objective

3 Summarize the importance of information transfer to living systems, giving specific examples.

For an organism to grow, develop, carry on self-regulated metabolism, respond to stimuli, and reproduce, it must have precise instructions and its cells must be able to communicate. The information an organism needs to carry on these life processes is coded and delivered in the form of chemical substances and electrical impulses. Organisms must also communicate information to each other.

DNA transmits information from one generation to the next

Humans give birth only to human babies, not to giraffes or rose bushes. In organisms that reproduce sexually, each offspring is a combination of the traits of its parents. In 1953, James Watson and Francis Crick worked out the structure of **DNA,** the large molecule that makes up the **genes,** the units of hereditary material (Fig. 1-7). Watson and Crick's work led to the understanding of the genetic code that transmits genetic information from generation to generation. This code works somewhat like an alphabet; it can "spell" an amazing variety of instructions for making organisms as diverse as bacteria, frogs, and redwood trees. The genetic code is a dramatic example of the unity of life because it is used to specify instructions for making every living organism.

Information is transmitted by chemical and electrical signals

Genes control the development and functioning of every organism. DNA contains the "recipes" for making all the proteins needed by the organism. **Proteins** are large molecules important in determining the structure and function of cells and tissues. Brain cells differ from muscle cells in large part because they have different types of proteins. Some proteins are important in communication within and among cells. Certain proteins on

FIGURE **1-7** **DNA.**

Organisms transmit information from one generation to the next by way of its DNA, the hereditary material. As shown in this model, DNA consists of two chains of atoms twisted into a helix. Each chain consists of subunits called nucleotides. The sequence of nucleotides makes up the genetic code.

the surface of a cell serve as markers so that other cells "recognize" them. Some cell surface proteins serve as receptors that combine with chemical messengers.

Cells use proteins and many other types of molecules to communicate with one another. In a multicellular organism, chemical compounds secreted by cells help regulate growth, development, and metabolic processes in other cells. The mechanisms involved in **cell signaling** are complex, often involving multistep biochemical sequences, and cell signaling is currently an area of intense research. A major focus has been the transfer of information among cells of the immune system. A better understanding of how cells communicate promises new insights into how the body protects itself against disease organisms. Learning to manipulate cell signaling may lead to new methods of delivering drugs into cells and new treatments for cancer and other diseases. Throughout this book we discuss examples of cell signaling.

Hormones are molecules that function as chemical messengers that transmit information from one part of an organism to another. A hormone can signal cells to produce or secrete a certain protein or other substance.

Many organisms use electrical signals to transmit information. Most animals have nervous systems that transmit information by way of both electrical impulses and chemical compounds known as **neurotransmitters.** Information transmitted from one part of the body to another is important in regulating life processes. In complex animals, the nervous system transmits signals from sensory receptors such as the eyes and ears to the brain, giving the animal information about its outside environment.

Information must also be transmitted from one organism to another. Mechanisms for this type of communication include the release of chemicals, visual displays, and sounds. Typically, organisms use a combination of several types of communication signals. For example, a dog may signal aggression by growling, using a particular facial expression, and laying its ears back. Many animals perform complex courtship rituals in which they display parts of their bodies, often elaborately decorated, to attract a mate.

EVOLUTION: THE BASIC UNIFYING CONCEPT OF BIOLOGY

Learning Objectives

4 Demonstrate the binomial system of nomenclature using several specific examples, and classify an organism (such as a human) in its domain, kingdom, phylum, class, order, family, genus, and species.

5 Identify the six kingdoms of living organisms, and give examples of organisms assigned to each group.

6 Give a brief overview of the theory of evolution, and explain why it is the principal unifying concept in biology.

7 Apply the theory of natural selection to any given adaptation, suggesting a logical explanation of how the adaptation may have evolved.

The theory of **evolution,** which explains how populations of organisms have changed over time, has become the most important unifying concept of biology. Some element of an evolutionary perspective is present in every specialized field within biology. Biologists try to understand the structure, function, and behavior of organisms and their interactions with one another by considering them in light of the long, continuing process of evolution. Although we discuss evolution in depth in Chapters 17 through 21, we present a brief overview here in Chapter 1 to give you the background necessary to understand other aspects of biology. First we examine how biologists organize the millions of organisms that have evolved, and then we summarize the mechanisms that drive evolution.

Biologists use a binomial system for naming organisms

About 1.7 million species of extant (currently living) organisms have been scientifically identified, and biologists estimate that several million more remain to be discovered. To study life, we need a system for organizing, naming, and classifying its myriad forms. **Systematics** is the field of biology that studies the diversity of organisms and their evolutionary relationships. **Taxonomy,** a subspecialty of systematics, is the science of naming and classifying organisms.

In the 18th century Carolus Linnaeus, a Swedish botanist, developed a hierarchical system of naming and classifying organisms that, with some modification, is still used today. The lowest category of classification is the **species,** a group of organisms with similar structure, function, and behavior; in nature, they breed only with each other. Members of a species have a common gene pool and share a common ancestry. Closely related species are grouped together in the next higher category of classification, the **genus** (pl. *genera*).

The Linnaean system of naming species is known as the **binomial system of nomenclature** because each species is assigned a two-part name. The first part of the name is the genus, and the second part, the **species epithet,** designates a particular species belonging to that genus. The species epithet is often a descriptive word expressing some quality of the organism. It is always used together with the full or abbreviated generic name preceding it. The generic name is always capitalized; the species epithet is generally not capitalized. Both names are always italicized or underlined. For example, the domestic dog, *Canis familiaris* (abbreviated *C. familiaris*), and the timber wolf, *Canis lupus (C. lupus),* belong to the same genus. The domestic cat, *Felis catus,* belongs to a different genus. The scientific name of the American white oak is *Quercus alba,* whereas the name of the European white oak is *Quercus robur.* Another tree, the white willow, *Salix alba,* belongs to a different genus. The scientific name for our own species is *Homo sapiens* ("wise man").

Taxonomic classification is hierarchical

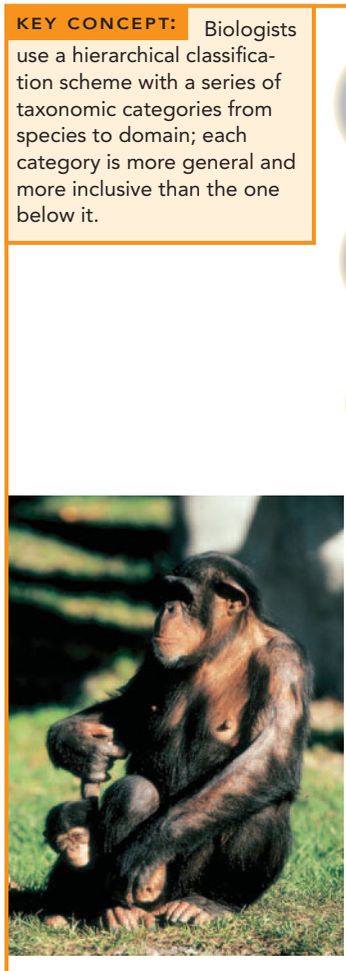
Just as closely related species may be grouped together in a common genus, related genera can be grouped in a more inclusive group, a **family.** Families are grouped into **orders,** orders into **classes,** and classes into **phyla** (sing., *phylum*). Biologists group phyla into **kingdoms,** and kingdoms are assigned to **domains.** Each formal grouping at any given level is a **taxon** (pl., *taxa*). Note that each taxon is more inclusive than the taxon below it. Together they form a hierarchy ranging from species to domain (Table 1-1; Fig. 1-8).

Consider a specific example. The family Canidae, which includes all doglike carnivores (animals that eat mainly meat), consists of 12 genera and about 34 living species. Family Canidae, along with family Ursidae (bears), family Felidae (catlike animals), and several other families that eat mainly meat, are all placed in order Carnivora. Order Carnivora, order Primates (to

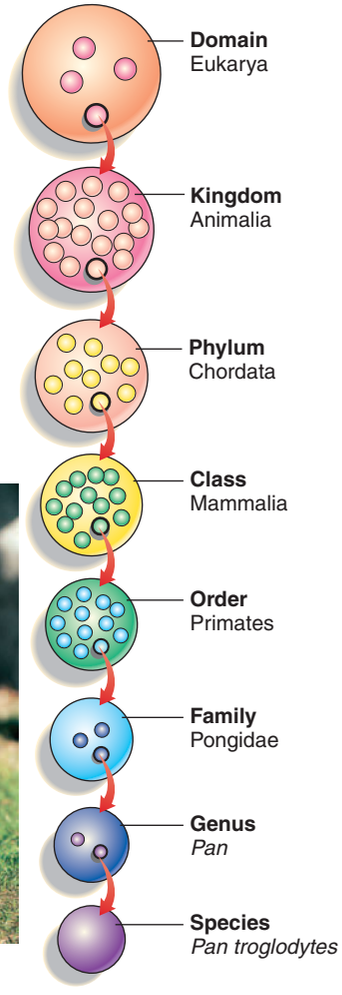
TABLE **1-1** **Taxonomic Classification**

Category	Cat	Human	White Oak
Domain	Eukarya	Eukarya	Eukarya
Kingdom	Animalia	Animalia	Plantae
Phylum	Chordata	Chordata	Anthophyta
Subphylum	Vertebrata	Vertebrata	None
Class	Mammalia	Mammalia	Dicotyledones
Order	Carnivora	Primates	Fagales
Family	Felidae	Hominidae	Fagaceae
Genus and Species	*Felis catus*	*Homo sapiens*	*Quercus alba*

KEY CONCEPT: Biologists use a hierarchical classification scheme with a series of taxonomic categories from species to domain; each category is more general and more inclusive than the one below it.



T. Whittaker/ Dembinsky Photo Associates



ACTIVE FIGURE **1-8** **Classification of the chimpanzee *(Pan troglodytes).***

As illustrated by this example, the classification scheme used by biologists is hierarchical. The smaller circles within each large circle represent the categories below it. For example, the four smaller circles in domain Eukarya represent the four kingdoms in this domain.

BiologyNow™ Learn more about **biological classification** by clicking on this figure on your BiologyNow CD-ROM.

which chimpanzees and humans belong), and several other orders belong to class Mammalia (mammals). Class Mammalia is grouped with several other classes that include fishes, amphibians, reptiles, and birds in subphylum Vertebrata. The vertebrates belong to phylum Chordata, which is part of kingdom Animalia. Animals are assigned to domain Eukarya.

Organisms can be assigned to three domains and six kingdoms

Systematics has itself evolved as scientists have developed new molecular techniques. As researchers report new data, the classification of organisms changes. Although not all biologists agree on how organisms are related or on how to classify them, many biologists now assign organisms to three domains and six kingdoms.

Bacteria and archaebacteria are unicellular prokaryotic cells; they differ from all other organisms in that they are **prokaryotes.** Two distinct groups have been recognized among the prokaryotes, and biologists assign them to two domains: **Eubacteria** and **Archaea.** The **eukaryotes,** organisms with eukaryotic cells, are classified in domain **Eukarya.**

In the classification system used in this book, every organism is also assigned to one of six **kingdoms** (Fig. 1-9). Two kingdoms correspond to the prokaryotic domains: Kingdom **Archaebacteria** corresponds to domain Archaea, and kingdom Eubacteria corresponds to domain Eubacteria. The remaining four kingdoms are assigned to domain Eukarya. Kingdom **Protista** consists of protozoa, algae, water molds, and slime molds. These are unicellular or simple multicellular organisms. Some protists are adapted to carry out photosynthesis, the process in which light energy is converted to the chemical energy of food molecules. Kingdom **Fungi** is composed of the yeasts, mildews, molds, and mushrooms. These organisms do not photosynthesize. They obtain their nutrients by secreting digestive enzymes into food and then absorbing the predigested food.

Members of kingdom **Plantae** are complex multicellular organisms adapted to carry out photosynthesis. Among characteristic plant features are the *cuticle* (a waxy covering over aerial parts that reduces water loss), *stomata* (tiny openings in stems and leaves for gas exchange), and multicellular *gametangia* (organs that protect developing reproductive cells). Kingdom Plantae includes both nonvascular plants (mosses) and vascular plants (ferns, conifers, and flowering plants), those that have tissues specialized for transporting materials throughout the plant body.

Kingdom **Animalia** is made up of multicellular organisms that eat other organisms for nutrition. Complex animals exhibit considerable tissue specialization and body organization. These characters have evolved along with complex sense organs, nervous systems, and muscular systems.

We discuss the diversity of life in more detail in Chapters 22 through 30, and we summarize classification in Appendix B. We refer to these groups repeatedly throughout this book, as we consider the many kinds of challenges living organisms face and the various adaptations that have evolved in response to them.

Species adapt in response to changes in their environment

Every organism is the product of complex interactions between environmental conditions and the genes of its ancestors. If all individuals of a species were exactly alike, any change in the environment might be disastrous to all, and the species would become extinct. Adaptations to changes in the environment occur as a result of evolutionary processes that take place over time and involve many generations.

Natural selection is an important mechanism by which evolution proceeds

Although philosophers and naturalists discussed the concept of evolution for centuries, Charles Darwin and Alfred Wallace first brought a theory of evolution to general attention and suggested a plausible mechanism, **natural selection,** to explain it. In his book *The Origin of Species by Natural Selection,* published in 1859, Darwin synthesized many new findings in geology and biology. He presented a wealth of evidence that the present forms of life descended, with modifications, from previously existing forms. Darwin's book raised a storm of controversy in both religion and science, some of which still lingers.

Darwin's theory of evolution has helped shape the biological sciences to the present day. His work generated a great wave of scientific observation and research that has provided much additional evidence that evolution governs the great diversity of organisms on our planet. Even today, the details of the process of evolution are a major focus of investigation and discussion.

Darwin based his theory of natural selection on the following four observations: (1) Individual members of a species show some variation from one another. (2) Organisms produce many more offspring than will survive to reproduce (Fig. 1-10). (3) Organisms compete for necessary resources such as food, sunlight, and space. Individuals with characteristics that enable them to obtain and use resources are more likely to survive to reproductive maturity and thus produce offspring. (4) The survivors that reproduce pass their adaptations for survival on to their offspring. Thus the best adapted individuals of a population leave, on average, more offspring than do other individuals. Because of this differential reproduction, a greater proportion of the population becomes adapted to the prevailing environmental conditions. The environment *selects* the best adapted organisms for survival. Note that adaptation involves changes in populations rather than in individual organisms.

Darwin did not know about DNA or understand the mechanisms of inheritance. Scientists now understand that most variations among individuals are a result of different varieties of genes that code for each characteristic. The ultimate source of these variations is random **mutations,** chemical or physical changes in DNA that persist and can be inherited. Mutations modify genes; by this process they provide the raw material for evolution.

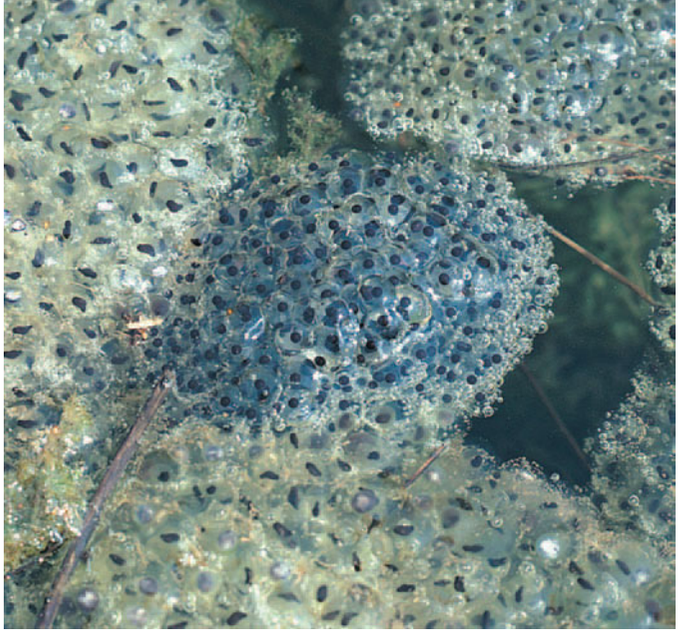
The fly agaric is poisonous and causes delirium, raving, and profuse sweating when ingested.



J. Serrao/Photo Researchers, Inc.

FIGURE **1-10** **Egg masses of the wood frog *(Rana sylvatica).***

Many more eggs are produced than can possibly develop into adult frogs. Random events are largely responsible for determining which of these developing frogs will hatch, reach adulthood, and reproduce. However, certain traits of each organism also contribute to its probability for success in its environment. Not all organisms are as prolific as the frog, but the generalization that more organisms are produced than survive is true throughout the living world.

Populations evolve as a result of selective pressures from changes in the environment

All the genes present in a population make up its **gene pool.** By virtue of its gene pool, a population is a reservoir of variation. Natural selection acts on individuals within a population. Selection favors individuals with genes that specify traits that enable them to respond effectively to pressures exerted by the environment. These organisms are most likely to survive and produce offspring. As these successful organisms pass on their genetic recipe for survival, their traits become more widely distributed in the population. Over time, as organisms continue to change (and as the environment itself changes, bringing different selective pressures), the members of the population become better adapted to their environment and less like their ancestors.

As members of a population adapt to environmental pressures and exploit new opportunities for finding food, maintaining safety, and avoiding predators, the population diversifies and new species may evolve. The Hawaiian honeycreepers, a group of related birds, are a good example. When honeycreeper ancestors first reached Hawaii, few other birds were present, so there was little competition. Honeycreepers moved into a variety of food zones, and evolved various types of bills (Fig. 1-11; see also Chapter 19 and Fig. 19-15). Some honeycreepers now have long, curved bills, adapted for feeding on nectar from tubular flowers. Others have short, thick bills for foraging for insects, and still others have adapted for eating seeds.

THE ENERGY OF LIFE

Learning Objective

8 Summarize the flow of energy through ecosystems, contrasting the roles of producers, consumers, and decomposers.

Life depends on a continuous input of energy from the sun, because every activity of a living cell or organism requires energy. Whenever energy is used to perform biological work, some is converted to heat and dispersed into the environment.

Jack Jeffrey, Inc.

FIGURE **1-11** **Adaptation and diversification in Hawaiian honeycreepers.**

(a) The bill of this ‘Akiapola’au male *(Hemignathus munroi)* is adapted for extracting insect larvae from bark. The lower mandible (jaw) is used to peck at and pull off bark, whereas the upper mandible and tongue remove the prey. **(b)** ‘I’iwi *(Vestiaria coccinea)* in ‘ohi’a blossoms. The bill is adapted for feeding on nectar in tubular flowers. **(c)** Palila *(Loxiodes bailleui)* in mamane tree. This finch-billed honeycreeper feeds on immature seeds in pods of the mamane tree. It also eats insects, berries, and young leaves. All three species shown here are endangered, mainly because their habitats have been destroyed by humans.

Energy flows through cells and organisms

Recall that all the energy transformations and chemical processes that occur within an organism are referred to as its *metabolism.* Energy is necessary to carry on the metabolic activities essential for growth, repair, and maintenance. Each cell of an organism requires nutrients that contain energy. Certain nutrients are used as fuel for **cellular respiration,** a process during which some of the energy stored in the nutrient molecules is released for use by the cells (Fig. 1-12). This energy can be used for cell work or for the synthesis of needed materials, such as new cell components. Virtually all cells carry on cellular respiration.

Energy flows through ecosystems

Like individual organisms, ecosystems depend on a continuous input of energy. A self-sufficient ecosystem contains three types of organisms—producers, consumers, and decomposers—and has a physical environment appropriate for their survival. These organisms depend on each other and on the environment for nutrients, energy, oxygen, and carbon dioxide. However, there is a one-way flow of energy through ecosystems. Organisms can neither create energy nor use it with complete efficiency. During every energy transaction, some energy disperses into the environment as heat and is no longer available to the organism (Fig. 1-13).

Producers, or **autotrophs,** are plants, algae, and certain bacteria that produce their own food from simple raw materials. Most of these organisms use sunlight as an energy source and carry out **photosynthesis,** the process in which producers synthesize complex molecules from carbon dioxide and water. The light energy is transformed into chemical energy, which is stored within the chemical bonds of the food molecules produced. Oxygen, which is required not only by plant cells but also by the cells of most other organisms, is produced as a by-product of photosynthesis:

Carbon dioxide + water + light energy
⟶ sugars (food) + oxygen

Animals are **consumers,** or **heterotrophs**—that is, organisms that depend on producers for food, energy, and oxygen.

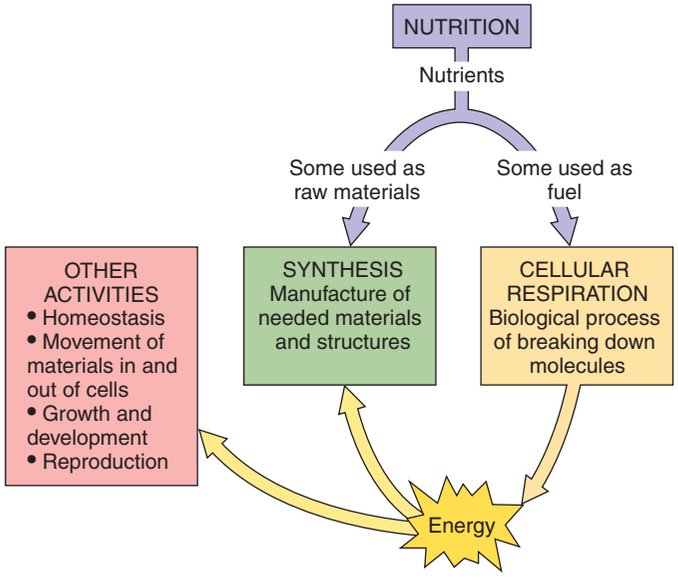

FIGURE **1-12** **Relationships among metabolic processes.**

These processes occur continuously in the cells of living organisms. Cells use some of the nutrients in food to synthesize needed materials and cell parts. Cells use other nutrients as fuel for cellular respiration, a process that releases energy stored in food. This energy is needed for synthesis and for other forms of cell work.

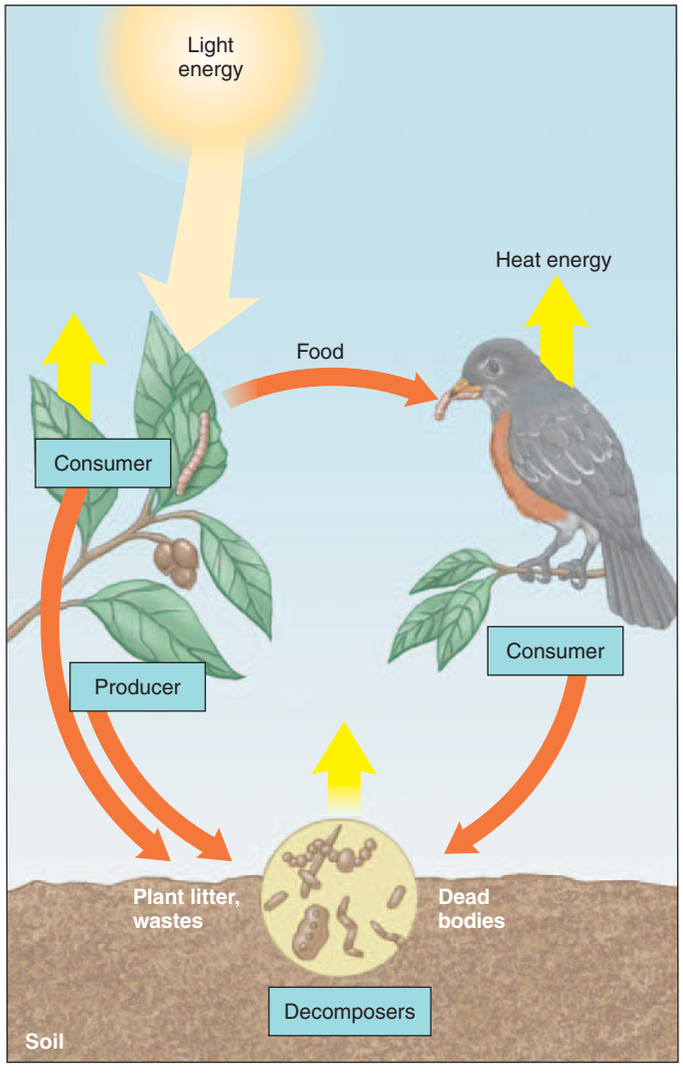

FIGURE **1-13** **Energy flow.**

Continuous energy input from the sun operates the biosphere. During photosynthesis, producers use the energy from sunlight to make complex molecules from carbon dioxide and water. Consumers, such as the caterpillar and robin shown here, obtain energy, carbon, and other needed materials when they eat producers or consumers that have eaten producers. Wastes and dead organic material supply decomposers with energy and carbon. During every energy transaction, some energy is lost to biological systems, dispersing into the environment as heat.

Consumers obtain energy by breaking down sugars and other food molecules originally produced during photosynthesis. When chemical bonds are broken during this process of cellular respiration, their stored energy is made available for life processes:

Sugars (and other food molecules) + oxygen
⟶ carbon dioxide + water + energy

Consumers contribute to the balance of the ecosystem. For example, consumers produce carbon dioxide needed by producers. (Note that producers also carry on cellular respiration.) The metabolism of consumers and producers helps maintain the life-sustaining mixture of gases in the atmosphere.

Bacteria and fungi are **decomposers,** heterotrophs that obtain nutrients by breaking down nonliving organic material such as wastes, dead leaves and branches, and the bodies of dead organisms. In their process of obtaining energy, decomposers make the components of these materials available for reuse. If decomposers did not exist, nutrients would remain locked up in dead bodies, and the supply of elements required by living systems would soon be exhausted.

Review

- What components do you think a balanced forest ecosystem might have?
- In what ways do consumers depend on producers? On decomposers? Include energy considerations in your answer.

THE PROCESS AND METHOD OF SCIENCE

Learning Objective

9 Design an experiment to test a given hypothesis, using the procedure and terminology of the scientific method.

PROCESS OF SCIENCE

Biologists work in laboratories and out in the field (Fig. 1-14). Their investigations range from the study of molecular biology and viruses to the interactions of the communities of our biosphere. Perhaps you will decide to become a research biologist and help unravel the complexities of the human brain, discover new hormones that cause plants to flower, identify new species of animals or bacteria, or develop new stem cell strategies to treat cancer, AIDS, or heart disease. Applications of basic biological research have provided the technology to transplant kidneys, livers, and hearts, manipulate genes, treat many diseases, and increase world food production. Biology has been a powerful force in providing the quality of life that most of us enjoy. You may choose to enter an applied field of biology, such as environmental science, dentistry, medicine, pharmacology, or veterinary medicine. Several interesting careers in the biological sciences are discussed in the Career Visions on our Web site.

Mark Moffett/Minden Pictures

FIGURE **1-14** **Biologist at work.**

This biologist studying the rainforest canopy in Costa Rica is part of an international effort to study and preserve tropical rain forests. Researchers study the interactions of organisms and the effects of human activities on the rain forests.

Biology is a science. The word *science* comes from a Latin word meaning "to know." Science is a way of thinking and a method of investigating the world around us in a systematic manner. Science enables us to uncover ever more about the world we live in and leads us to an expanded appreciation of our universe.

The **process of science** is investigative, dynamic, and often controversial. Because it is influenced by cultural, social, and historical contexts, as well as by the personalities of scientists themselves, the process changes over time. The observations made, the range of questions posed, and the design of experiments depend on the creativity of the individual scientist. In contrast, the **scientific method** involves a series of ordered steps and is a framework that most scientists use.

Using the scientific method, scientists make careful observations, ask critical questions, and develop **hypotheses,** which are testable statements. Using their hypotheses, scientists make predictions that can be tested, and test their predictions by making further observations or by performing experiments (Fig. 1-15; also see On the Cutting Edge: New Possibilities for Environmentally Friendly Pest-Control Strategies). They interpret the results of their experiments and draw conclusions from them. Even results that do not support the hypothesis may be valuable and may lead to new hypotheses. If the results do support a hypothesis, a scientist may use them to generate related hypotheses.

Science is systematic. Scientists organize, and often quantify, knowledge, making it readily accessible to all who wish to build on its foundation. In this way, science is both a personal and a social endeavor. Science is not mysterious. Anyone who understands its rules and procedures can take on its challenges. What

distinguishes science is its insistence on rigorous methods to examine a problem. Science seeks to give precise knowledge about those aspects of the world that are accessible to its methods of inquiry. It is not a replacement for philosophy, religion, or art. Being a scientist does not prevent one from participating in other fields of human endeavor, just as being an artist does not prevent one from practicing science.

Science requires systematic thought processes

Two types of systematic thought processes scientists use are deduction and induction. With **deductive reasoning,** we begin with supplied information, called *premises,* and draw conclusions on the basis of that information. Deduction proceeds from general principles to specific conclusions. For example, if you accept the premise that all birds have wings and the second premise that sparrows are birds, you can conclude deductively that sparrows have wings. Deduction helps us discover relationships among known facts.

Inductive reasoning is the opposite of deduction. We begin with specific observations and draw a conclusion or discover a general principle. For example, if you know sparrows have wings and are birds, and you know robins, eagles, pigeons, and hawks have wings and are birds, you might induce that all birds have wings. In this way, you can use the inductive method to organize raw data into manageable categories by answering the question, What do all these facts have in common?

A weakness of inductive reasoning is that conclusions generalize the facts to all possible examples. When we formulate the general principle, we go from many observed examples to all possible examples. This is known as an *inductive leap.* Without it, we could not arrive at generalizations. However, we must be sensitive to exceptions and to the possibility that the conclusion is not valid. For example, the kiwi bird of New Zealand does *not* have functional wings! The generalizations in inductive conclusions come from the creative insight of the human mind, and creativity, however admirable, is not infallible.

Scientists make careful observations and ask critical questions

Chance and luck are often involved in recognizing a phenomenon or problem, but significant discoveries are usually made by those who are in the habit of looking critically at nature. Necessary technology for investigating the problem must also be available. In 1928, British bacteriologist Alexander Fleming observed that a blue mold had invaded one of his bacterial cultures. He almost discarded it, but then he noticed that the area contaminated by the mold was surrounded by a zone where bacterial colonies did not grow well.

The bacteria were disease organisms of the genus *Staphylococcus,* which can cause boils and skin infections. Anything that could kill them was interesting! Fleming saved the mold, a variety of *Penicillium* (blue bread mold). Later, scientists discovered that the mold produced a substance that slowed reproduction of the bacterial population but was usually harmless to laboratory animals and humans. The substance was penicillin, the first antibiotic.

You may wonder how many times the same type of mold grew on the cultures of other bacteriologists who failed to make the connection and simply threw away their contaminated cultures. Fleming benefited from chance, but his mind was prepared

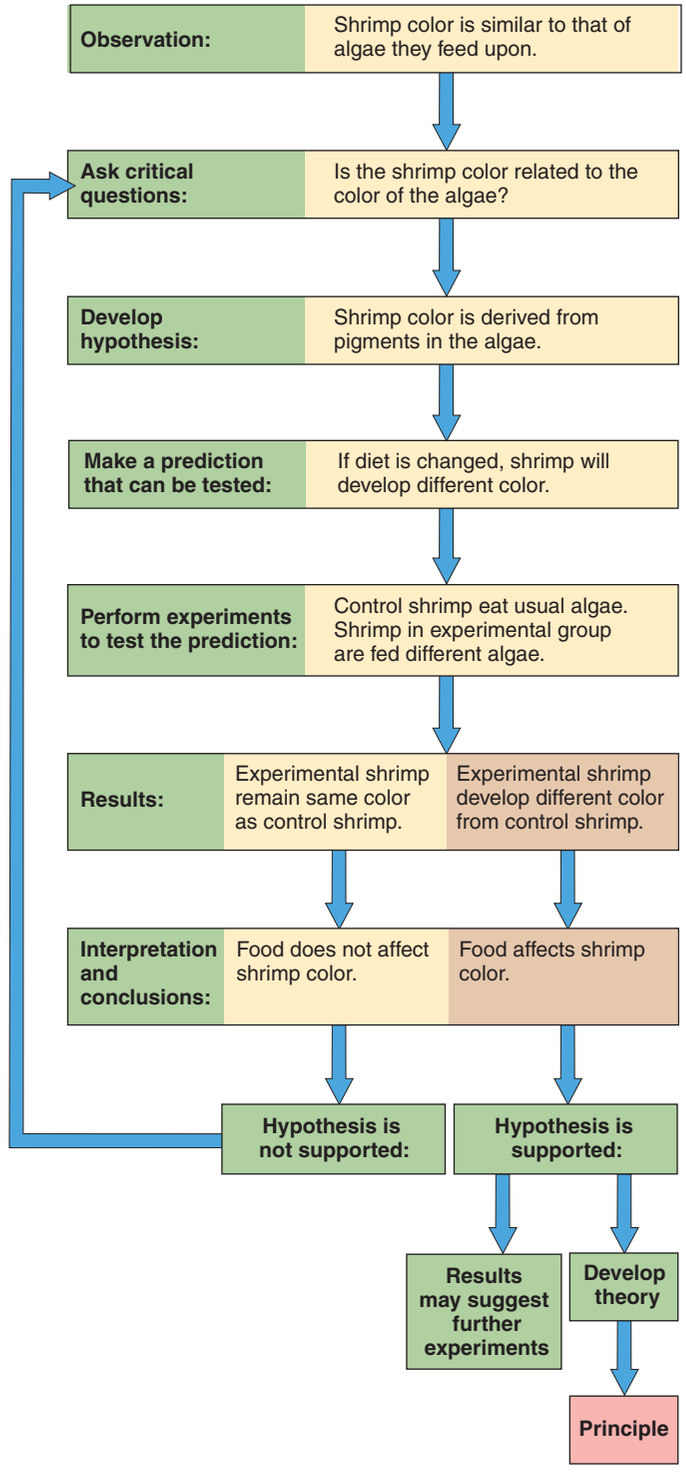

FIGURE **1-15** **The scientific method.**
Scientists use the scientific method as a framework for their research.

ON THE CUTTING EDGE New Possibilities for Environmentally Friendly Pest-Control Strategies

Hypothesis: When attacked by insects that eat them, plants emit airborne chemicals that reduce the number of herbivores (animals that eat plants) feeding on them.

Method: Researchers conducted a field study in which they examined volatile chemicals released by wild tobacco plants during attack by insect herbivores. The researchers also mimicked the release of each of five commonly released volatile chemicals.

Results: The plants emitted volatile chemicals that reduced the number of eggs laid by some herbivores and increased predation of the herbivore eggs by carnivorous insects.

Conclusion: By releasing certain volatile chemicals, plants significantly reduce the number of herbivores feeding on them.

In 1983, while still an undergraduate at Dartmouth College in the United States, Ian Baldwin and his mentor, biologist Jack Schultz, published a controversial hypothesis stating that airborne chemical signals from damaged maple and poplar trees appear to increase the chemical defenses of undamaged trees nearby. Other biologists were not receptive to the idea that plants could communicate with one another, and for some time Baldwin and Schultz had difficulty obtaining funding for their research. Eventually these researchers produced experimental results that changed their colleagues' attitudes. During the past few years, several research teams have studied plant signaling in laboratory or agricultural settings.

In 2001, Andre Kessler, a graduate student at the Max Planck Institute for Chemical Ecology in Jena, Germany, and Ian Baldwin, now director of molecular ecology research at the Max Planck Institute, reported in *Science** that they had studied volatile chemicals released by wild tobacco plants (*Nicotiana attenuate*) in a natural environment—the desert of southwestern Utah. These researchers quantified volatile chemicals released by the tobacco plants during attack by three species of herbivorous insects. They also studied five of these volatile chemicals individually by mimicking their release by plants.

Kessler and Baldwin first established that wild tobacco releases volatile chemicals in response to attack by herbivorous insects. Then they studied predation of the herbivore eggs by leaf bugs. They glued the eggs of herbivorous insects onto tobacco leaves that they treated with a single synthetic volatile chemical similar to the compounds released by the plants. In some experiments, they treated the leaves with *jasmonate,* a plant hormone that stimulates the release of volatile chemicals.

Kessler and Baldwin reported that some volatile chemicals discouraged herbivorous insects from laying eggs. Furthermore, in response to certain volatile chemicals, predators ate more of the herbivore eggs. The researchers found that discouraging herbivores and attracting their predators, reduced the number of herbivore eggs laid on the tobacco leaves by about 90%. Thus the results of Kessler and Baldwin's experiments strongly support the hypothesis that when attacked by herbivores, plants release volatile chemicals that reduce the number of herbivores feeding on them. Natural selection has resulted in plant signals that herbivorous insects detect and avoid and that carnivorous insects detect and approach. This system of information transfer protects plants from attacking herbivorous insects.

In 2003, Jorg Degenhardt, of the Max Planck Institute, and his colleagues reported that humans now have the technology to genetically engineer crop plants to release volatile chemicals for attracting enemies of herbivores.† These researchers suggest that plant breeders can modify the types and amounts of volatile chemical signals released, increasing the ability of attacked plants to defend themselves. These findings are exciting because they may lead to environmentally friendly pest-control strategies. At present, farmers depend mainly on pesticides, which also kill beneficial insects, birds, and other animal species. Pesticides have also been associated with long-term environmental contamination and with human disease. Pesticides poison about 67,000 people annually in the United States alone.

In addition to its potential importance to agriculture, plant signaling has gained the attention of the military. Jack Schultz and Ramesh Raina of Pennsylvania State University have received a $3.5-million grant from the U.S. Department of Defense to study how plants respond to various environmental stressors. Their goal is to genetically engineer plants to detect the use of biological or chemical weapons, and to alert people by emitting volatile signals.

*A. Kessler and I.T. Baldwin, "Defensive Function of Herbivore-Induced Plant Volatile Emissions in Nature," *Science,* Vol. 291, 16 March 2001.

†J. Degenhardt, J. Gershenzon, I.T. Baldwin, and A. Kessler, "Attracting Friends to Feast on Foes: Engineering Terpene Emission to Make Crop Plants More Attractive to Herbivore Enemies," *Current Opinion in Biotechnology, 14,* (2003), 169–176.

to make observations and formulate critical questions, and his pen was prepared to publish them. However, even though Fleming recognized the potential practical benefit of penicillin, he did not develop the chemical techniques needed to purify it, and more than 10 years passed before the drug was put to significant use.

In 1939, Sir Howard Florey and Ernst Boris Chain developed chemical procedures to extract and produce the active agent penicillin from the mold. Florey took the process to laboratories in the United States, and penicillin was first produced to treat wounded soldiers in World War II. In 1945, Fleming, Florey, and Chain shared the Nobel Prize in Medicine.

A hypothesis is a testable statement

In the early stages of an investigation, a scientist typically thinks of many possible hypotheses. Hypotheses have many potential sources, including preliminary direct observations or even computer simulations. Increasingly in biology, hypotheses may be derived from *models* that scientists have developed to provide a comprehensive explanation for a large number of previous observations. Examples of such testable models include the model of the structure of DNA and the model of the structure of the plasma membrane (see Chapter 5). After generating hypotheses, the scientist decides which, if any, could and should be subjected to experimental test. Why not test them all? Time and money are important considerations in conducting research. Scientists must establish priority among the hypotheses to decide which to test first. Fortunately, some guidelines exist. A good hypothesis exhibits the following: (1) It is reasonably consistent with well-established facts. (2) It is capable of being tested; that is, it should generate definite predictions, whether the results are positive or negative. Test results should also be repeatable

by independent observers; (3) it is falsifiable, which means it can be proven false.

A hypothesis cannot really be proven true, but in theory (though not necessarily in practice) a well-stated hypothesis can be proved false. Belief in an unfalsifiable hypothesis (such as the existence of invisible and undetectable angels) must be rationalized on grounds other than scientific ones.

Consider the following hypothesis: All female mammals (animals that have hair and produce milk for their young) bear live young. The hypothesis is based on the observations that dogs, cats, cows, lions, and humans all are mammals and all bear live young. Consider further that a new species, species X, is identified as a mammal. Biologists predict that females of species X will bear live young. When a female of the new species gives birth to offspring, this supports the hypothesis. Yet it does not really *prove* the hypothesis.

Before the Southern Hemisphere was explored, most people would probably have accepted the hypothesis without question, because all known furry, milk-producing animals did, in fact, bear live young. But biologists discovered that two Australian animals (the duck-billed platypus and the spiny anteater) had fur and produced milk for their young but laid eggs (Fig. 1-16). The hypothesis, as stated, was false no matter how many times it had previously been supported. As a result, biologists either had to consider the platypus and the spiny anteater as nonmammals or had to broaden their definition of mammals to include them. (They chose to do the latter.)

A hypothesis is not true just because some of its predictions (the ones people happen to have thought of or have thus far been able to test) have been shown to be true. After all, they could be true by coincidence. Failure to observe a predicted outcome does not make a hypothesis false, but neither does it show the hypothesis is true.

Tom McHugh/Photo Researchers, Inc.

FIGURE **1-16** **Is this animal a mammal?**

The duck-billed platypus *(Ornithorhynchus anatinus)* is classified as a mammal because it has fur and produces milk for its young. However, unlike most mammals, it lays eggs.

Predictions can be tested by experiment

A hypothesis is an abstract idea, so there is no way to test it directly. But hypotheses suggest certain logical consequences, that is, observable things that cannot be false if the hypothesis is true. In contrast, if the hypothesis is in fact false, other definite predictions should disclose that. As used here, then, a **prediction** is a deductive, logical consequence of a hypothesis. It does not have to be a future event.

A prediction can be tested by controlled experiments. Early biologists observed that the nucleus was the most prominent part of the cell, and they hypothesized that it might be essential for the well-being of the cell. They predicted that if the nucleus were removed from the cell, the cell would die. Biologists then experimented, surgically removing the nucleus of a unicellular amoeba. The amoeba continued to live and move, but it did not grow, and after a few days it died. These results suggested that the nucleus is necessary for the metabolic processes that provide for growth and cell reproduction.

But, the investigators asked, what if the operation itself, not the loss of the nucleus, caused the amoeba to die? They performed a controlled experiment, subjecting two groups of amoebas to the same operative trauma (Fig. 1-17). However, in the experimental group the nucleus was removed; in the control group, it was not. An **experimental group** differs from a control group only with respect to the variable being studied. In the **control group,** the researcher inserted a microloop into each amoeba and pushed it around inside the cell to simulate removal of the nucleus; then the needle was withdrawn, leaving the nucleus inside. Amoebas treated with such a sham operation recovered and subsequently grew and divided, but the amoebas without nuclei died. This experiment showed that the removal of the nucleus, not simply the operation, caused the death of the amoebas. The data supported the hypothesis that the nucleus is essential for the well-being of the cell.

In scientific studies, researchers must avoid bias. For example, to prevent bias most medical experiments today are carried out in a double-blind fashion. When a drug is tested, one group of patients receives the new medication, whereas a second similar group of patients (the control group) receives a placebo (a harmless starch pill similar in size, shape, color, and taste to the pill being tested). This is a *double-blind study,* because neither the patient nor the physician knows who is getting the experimental drug and who is getting the placebo. The pills or treatments are coded in some way, and the code is broken only after the experiment is over and the results are recorded. Not all experiments can be so neatly designed; for one thing, it is often difficult to establish appropriate controls.

Scientists interpret the results of experiments and make conclusions

Scientists gather data in an experiment, interpret their results, and then formulate conclusions. For example, in the amoeba experiment described earlier, investigators concluded the nucleus was essential for the cell's well-being.

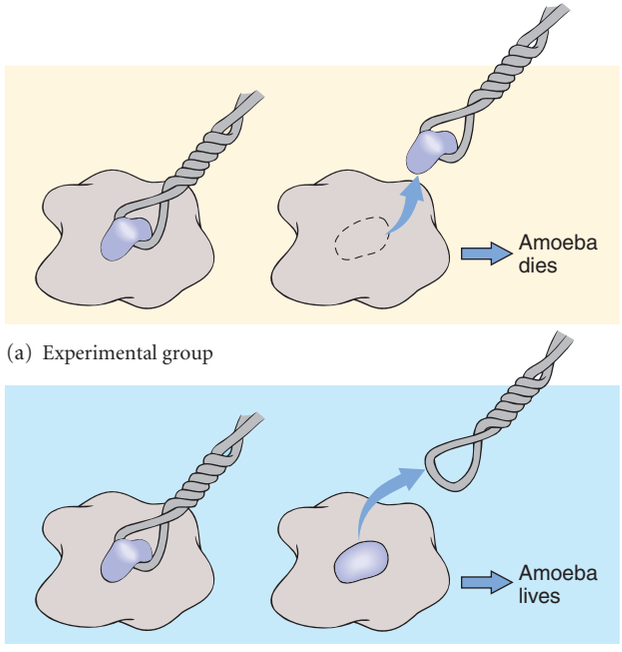

FIGURE **1-17** **Testing a prediction.**

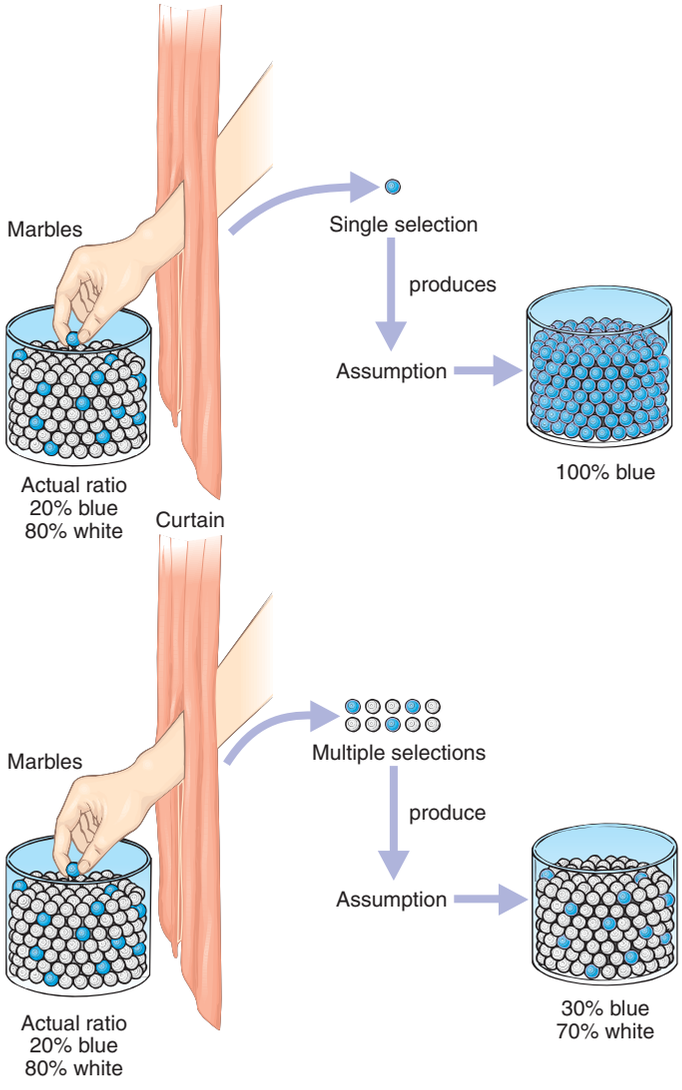
An early controlled experiment tested the prediction that if the nucleus is removed from a cell, the cell would die. The data gathered from this and similar experiments supported the hypothesis that the nucleus is essential for the cell's well-being. **(a)** When its nucleus is surgically removed with a microloop, the amoeba dies. **(b)** Control amoebas subjected to similar surgical procedures (including insertion of a microloop), but without actual removal of the nucleus, do not die.



ACTIVE FIGURE **1-18** **Statistical probability.**

Taking a single selection can result in sampling error. If the only marble selected is blue, we might assume all the marbles are blue. The greater the number of selections we take of an unknown, the more likely we can make valid assumptions about it.

BiologyNow™ Do your own random sampling by clicking on this figure on your BiologyNow CD-ROM.

One reason for inaccurate conclusions is *sampling error*. Because not *all* cases of what is being studied can be observed or tested (scientists cannot study every amoeba), scientists must be content with a sample. Yet how can you know whether that sample is truly representative of whatever you are studying? In the first place, if the sample is too small it may be different owing to random factors. A study with only two, or even nine, amoebas may not yield reliable data that can be generalized to other amoebas. If you test a large number of subjects, you are more likely to draw accurate scientific conclusions (Fig. 1-18). The scientist seeks to state with some level of confidence that any specific conclusion has a certain statistical probability of being correct.

Experiments must also be repeatable. When researchers publish their findings in a scientific journal, they typically describe their methods and procedures so other scientists can repeat the experiments. When the findings are replicated, the conclusions are, of course, strengthened.

A well-supported hypothesis may lead to a theory

Nonscientists often use the word *theory* incorrectly to refer to a hypothesis. A **theory** is actually an integrated explanation of a number of hypotheses, each supported by consistent results from many observations or experiments. A theory relates data that previously appeared unrelated. A good theory grows, building on additional facts as they become known. It predicts new facts and suggests new relationships among phenomena. It may even suggest practical applications.

A good theory, by showing the relationships among classes of facts, simplifies and clarifies our understanding of natural phenomena. As Einstein wrote, "In the whole history of science from Greek philosophy to modern physics, there have been constant attempts to reduce the apparent complexity of natural phenomena to simple, fundamental ideas and relations."

Science has ethical dimensions

Scientific investigation depends on a commitment to practical ideals, such as truthfulness and the obligation to communicate results. Honesty is particularly important in science. Consider the great (though temporary) damage done whenever an unprincipled or even desperate researcher, whose career may depend on the publication of a research study, knowingly disseminates false data. Until the deception is uncovered, researchers may devote thousands of dollars and hours of precious professional labor to futile lines of research inspired by erroneous reports. Deception can also be dangerous, especially in medical research. Fortunately, science tends to correct itself through consistent use of the scientific process. Sooner or later, someone's experimental results are sure to cast doubt on false data.

In addition to being ethical about their own work, scientists face many broad ethical issues surrounding areas such as genetic research, stem cell research, cloning, and human and animal experimentation. For example, some stem cells that show the greatest potential for treating human disease come from early embryos. The cells can be taken from 5- or 6-day-old human embryos and then cultured in laboratory glassware. Such cells could be engineered to treat failing hearts or brains harmed by stroke, injury, Parkinson's disease, or Alzheimer's disease. They could save the lives of burn victims and perhaps be engineered to treat specific cancers. Scientists, and the larger society, will need to determine whether the potential benefits of any type of research outweigh its ethical risks.

Review

- What is meant by a "controlled" experiment?
- What are the characteristics of a good hypothesis?

BiologyNow™ Assess your understanding of **the process and method of science** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Distinguish between living and nonliving things by describing the features that characterize living organisms.

- A living organism can grow and develop, carry on self-regulated metabolism, respond to stimuli, and reproduce. Species evolve and adapt to their environment.
- All living organisms are composed of one or more **cells.**
- Organisms grow by increasing the size and/or number of their cells.
- **Metabolism** includes all the chemical activities that take place in the organism, including the chemical reactions essential to nutrition, growth and repair, and conversion of energy to usable forms. **Homeostasis** is the tendency of organisms to maintain an appropriate, balanced internal environment.
- Organisms respond to **stimuli,** physical or chemical changes in their external or internal environment. Responses typically involve movement. Some organisms use tiny extensions of the cell, called **cilia,** or longer **flagella** to move from place to place. Some organisms are sessile and remain rooted to some surface.
- In **asexual reproduction,** offspring are typically identical to the single parent; in **sexual reproduction,** offspring are the product of the fusion of gametes, and genes are typically contributed by two parents.
- Populations evolve and become adapted to their environment. **Adaptations** are traits that increase an organism's ability to survive in its environment.

2 Construct a hierarchy of biological organization, including levels of an individual organism and ecological levels.

- Biologic organization is hierarchical. A complex organism is organized at the chemical, cell, **tissue, organ,** and **organ system** levels.
- The basic unit of ecological organization is the **population.** Various populations form **communities;** a community and its physical environment are an **ecosystem;** all of Earth's ecosystems together make up the **biosphere.**

3 Summarize the importance of information transfer to living systems, giving specific examples.

- Organisms transmit information chemically, electrically, and behaviorally.
- DNA, which makes up the **genes,** contains the instructions for the development of an organism and for carrying out life processes. DNA codes for **proteins,** which are important in determining the structure and function of cells and tissues.
- Information encoded in **DNA** is transmitted from one generation to the next.
- **Hormones,** chemical messengers that transmit messages from one part of an organism to another, are an important type of **cell signaling.**
- Many organisms use electrical signals to transmit information; most animals have nervous systems that transmit electrical impulses and release **neurotransmitters.**

4 Demonstrate the binomial system of nomenclature using several specific examples, and classify an organism (such as a human) in its domain, kingdom, phylum, class, order, family, genus, and species.

- Millions of species have evolved. A **species** is a group of organisms with similar structure, function, and behavior that, in nature, breed only with each other. Members of a species have a common **gene pool** and share a common ancestry.
- Biologists use a **binomial system of nomenclature** in which the name of each species includes a **genus** name and a **specific epithet.**
- Taxonomic classification is hierarchical; it includes species, genus, **family, order, class, phylum, kingdom,** and **domain.** Each grouping is referred to as a **taxon.**

5 Identify the six kingdoms of living organisms, and give examples of organisms assigned to each group.

- Bacteria and archaebacteria have **prokaryotic cells;** all other organisms have **eukaryotic cells.**
- Organisms can be classified into three domains: **Archaea, Eubacteria,** and **Eukarya,** and six kingdoms: **Archaebacteria, Eubacteria, Protista** (protozoa, algae, water molds, and slime molds), **Fungi** (molds and yeasts), **Plantae,** and **Animalia.**

SUMMARY WITH KEY TERMS *(continued)*

6 Give a brief overview of the theory of evolution, and explain why it is the principal unifying concept in biology.

- **Evolution** is the process by which populations change over time in response to changes in the environment. The theory of evolution explains how millions of species came to be and helps us understand the structure, function, behavior, and interactions of organisms.
- **Natural selection,** the mechanism by which evolution proceeds, favors individuals with traits that enable them to cope with environmental changes. These individuals are most likely to survive and to produce offspring.
- Charles Darwin based his theory of natural selection on his observations that individuals of a species vary; organisms produce more offspring than survive to reproduce; individuals that are best adapted to their environment are more likely to survive and reproduce; as successful organisms pass on their hereditary information, their traits become more widely distributed in the population.
- The source of variation in a population is random **mutation.**

7 Apply the theory of natural selection to any given adaptation, suggesting a logical explanation of how the adaptation may have evolved.

- When the ancestors of Hawaiian honeycreepers first reached Hawaii, few other birds were present, so there was little competition for food. Through many generations, honeycreepers with longer, more curved bills became adapted for feeding on nectar from tubular flowers. Perhaps those with the longest, most curved bills were best able to survive in this food zone and lived to transmit their genes to their offspring. Those with shorter, thicker bills were more successful foraging for insects and passed their genes to new generations of offspring. Eventually different species evolved, adapted to specific food zones.

8 Summarize the flow of energy through ecosystems, contrasting the roles of producers, consumers, and decomposers.

- Activities of living cells require energy; life depends on continuous energy input from the sun.
- During **photosynthesis** plants, algae, and certain bacteria use the energy of sunlight to synthesize complex molecules from carbon dioxide and water.
- Virtually all cells carry on **cellular respiration,** a biochemical process in which they capture the energy stored in nutrients by producers. Some of that energy is then used to synthesize needed materials or to carry out other cell activities.
- A self-sufficient ecosystem includes **producers,** or **autotrophs,** which make their own food; **consumers,** which eat producers or organisms that have eaten producers; and **decomposers,** which obtain energy by breaking down wastes and dead organisms. Consumers and decomposers are **heterotrophs,** organisms that depend on producers as an energy source and for food and oxygen.

9 Design an experiment to test a given hypothesis, using the procedure and terminology of the scientific method.

- The **process of science** is a dynamic approach to investigation. The **scientific method** is a framework that scientists use in their work; it includes observing, recognizing a problem or stating a critical question, developing a hypothesis, making a prediction that can be tested, performing experiments, interpreting results, and drawing conclusions that support or falsify the hypothesis.
- Deductive reasoning and inductive reasoning are two categories of systematic thought used in the scientific method. **Deductive reasoning** proceeds from general principles to specific conclusions and helps people discover relationships among known facts. **Inductive reasoning** begins with specific observations and draws conclusions from them. Inductive reasoning helps people discover general principles.
- A **hypothesis** is a testable statement about the nature of an observation or relationship.
- A properly designed scientific experiment includes both a **control group** and an **experimental group,** and must be as free as possible from bias. The experimental group differs from a control group only with respect to the variable being studied.
- When a number of related hypotheses have been supported by conclusions from many experiments, scientists may develop a **theory** based on them.
- Science has important ethical dimensions.

POST-TEST

1. Metabolism (a) is the sum of all the chemical activities of an organism (b) results from an increase in the number of cells (c) is characteristic of plant and animal kingdoms only (d) refers to chemical changes in an organism's environment (e) does not take place in producers
2. Homeostasis (a) is the tendency of organisms to maintain an appropriate, balanced internal environment (b) generally depends on the action of cilia (c) is the long-term response of organisms to changes in their environment (d) occurs at the ecosystem level, not in cells or organisms (e) may be sexual or asexual
3. Structures used by some organisms for locomotion are (a) cilia and nuclei (b) flagella and DNA (c) nuclei and membranes (d) cilia and sessiles (e) cilia and flagella
4. The splitting of an amoeba into two is best described as an example of (a) locomotion (b) neurotransmission (c) asexual reproduction (d) sexual reproduction (e) metabolism
5. Cells (a) are the building blocks of living organisms (b) always have nuclei (c) are not found among the bacteria (d) answers a, b, and c are correct (e) only answers a and b are correct
6. An increase in the size or number of cells best describes (a) homeostasis (b) biological growth (c) chemical level of organization (d) asexual reproduction (e) adaptation
7. DNA (a) makes up the genes (b) transmits information from one species to another (c) cannot be changed (d) is a neurotransmitter (e) is produced during cellular respiration
8. Cellular respiration (a) is a process whereby sunlight is used to synthesize cell components with the release of energy (b) occurs in heterotrophs only (c) is carried on by both autotrophs and heterotrophs (d) causes chemical changes in DNA (e) occurs in response to environmental changes
9. Which of the following is a correct sequence of levels of biological organization? (a) cell, organ, tissue, organ system (b) chemical,

POST-TEST *(continued)*

cell, organ, tissue (c) chemical, cell, tissue, organ (d) tissue, organ, cell, organ system (e) chemical, cell, population, species

10. Which of the following is a correct sequence of levels of biological organization? (a) organism, population, ecosystem, community (b) organism, population, community, ecosystem (c) population, biosphere, ecosystem, community (d) species, population, ecosystem, community (e) ecosystem, population, community, biosphere
11. Protozoa are assigned to kingdom (a) Protista (b) Fungi (c) Archaebacteria (d) Animalia (e) Plantae
12. Yeasts and molds are assigned to kingdom (a) Protista (b) Fungi (c) Archaebacteria (d) Animalia (e) Plantae
13. In the binomial system of nomenclature, the first part of an organism's name designates the (a) species epithet (b) genus (c) class (d) kingdom (e) phylum
14. Which of the following is a correct sequence of levels of classification (a) genus, species, family, order, class, phylum, kingdom (b) genus, species, order, phylum, class, kingdom (c) genus, species, order, family, class, phylum, kingdom (d) species, genus, family, order, class, phylum, kingdom (e) species, genus, order, family, class, kingdom, phylum
15. Darwin suggested that evolution takes place by (a) mutation (b) changes in the individuals of a species (c) natural selection (d) interaction of hormones (e) homeostatic responses to each change in the environment
16. A testable statement is a(an) (a) theory (b) hypothesis (c) principle (d) inductive leap (e) critical question
17. Ideally, an experimental group differs from a control group (a) only with respect to the hypothesis being tested (b) only with respect to the variable being studied (c) by being less subject to bias (d) in that it is less vulnerable to sampling error (e) in that its subjects are more reliable

CRITICAL THINKING

1. How might a firm understanding of evolutionary processes help a biologist doing research in (a) animal behavior, (b) ocean ecology, or (c) the development of a vaccine against human immunodeficiency virus, which causes AIDS?
2. Make a prediction and devise a suitably controlled experiment to test each of the following hypotheses: (a) A type of mold found in your garden does not produce an effective antibiotic. (b) The growth rate of a bean seedling is affected by temperature. (c) Estrogen alleviates symptoms of Alzheimer's disease in elderly women.

BIOLOGY NOW RESOURCES

BiologyNow™ The BiologyNow CD-ROM packaged free with your text, uses a learning system that allows you to review your general understanding of a concept. First you answer a series of diagnostic review questions. Based on your answers, BiologyNow will provide you with a customized learning plan that links you to the text, study guide, animations, Genetics Problem-Solving Guide, and CNN Video for focused study that maximizes your learning. You can also connect to V-Mentor for one-on-one tutoring help from experienced biology teachers.

Web Site

The Web site for this book contains a wealth of helpful study aids, as well as many ideas for further reading and research. Log on to: **http://biology.brookscole.com/solomon7**

- For study and review, **Chapter Outline** gives you an outline of the chapter, **Chapter Summary** allows you to review the chapter's main ideas, and **Glossary** lists concepts and terms for the chapter along with their definitions.
- To test your mastery of important terminology for this chapter, you can use the electronic **Flash Cards,** which may be sorted by definition or by term.
- For testing your knowledge and preparing for in-class examinations, our **Quizzes** pose multiple choice and/or true-false questions based on each chapter.
- **Hypercontents** takes you to an extensive list of current links to Internet sites with news, research, and images related to individual subjects in the chapter.
- **Internet Exercises** are critical thinking questions that involve research on the Internet with starter URLs provided.

InfoTrac Exercises leads you to Critical Thinking Projects that use InfoTrac College Edition® as a research tool. For more readings, go to *InfoTrac College Edition,* your online research library, at: **http://infotrac.thomsonlearning.com**

Atoms and Molecules: The Chemical Basis of Life

Frans Lanting/Minden Pictures

A jaguar (*Panthera onca*), the largest cat in the Western Hemisphere, pauses to drink water from a rainforest stream. Water is a basic requirement for all life.

CHAPTER OUTLINE

- Elements and Atoms
- Chemical Reactions
- Chemical Bonds
- Redox Reactions
- Water
- Acids, Bases, and Salts

A knowledge of chemistry is essential for understanding organisms and how they function. This jaguar and the plants of the tropical rain forest, as well as abundant unseen insects and microorganisms, share fundamental similarities in their chemical composition and basic metabolic processes. These chemical similarities provide strong evidence for the evolution of all organisms from a common ancestor and explain why much of what biologists learn from studying bacteria or rats in laboratories can be applied to other organisms, including humans. Furthermore, the basic chemical and physical principles governing organisms are not unique to living things, for they apply to nonliving systems as well.

The success of the Human Genome Project (introduced in Chapter 1) relied heavily on biochemistry and **molecular biology,** the chemistry and physics of the molecules that constitute living things. A biochemist may investigate the precise interactions among a cell's atoms and molecules that maintain the energy flow essential to life, and a molecular biologist may study how proteins interact with deoxyribonucleic acid (DNA) in ways that control the expression of certain genes. However, an understanding of chemistry is essential to *all* biologists. An evolutionary biologist may study evolutionary relationships by comparing the DNA of different types of organisms. An ecologist may study how energy is transferred among the organisms living in an estuary or monitor the biological effects of changes in the salinity of the water. A botanist may study unique compounds produced by plants and may even be a "chemical prospector," seeking new sources of medicinal agents.

In this chapter we lay a foundation for understanding how the structure of atoms determines the way they form chemical bonds to produce complex compounds. Most of our discussion focuses on small, simple substances known as **inorganic compounds.** Among the biologically important groups of inorganic compounds are water, many simple acids and bases, and simple salts. We pay particular attention to water, the most abundant substance in organisms and on Earth's surface, and we examine how its unique properties affect living things as well as their nonliving environment. In Chapter 3 we extend our discus-

sion to **organic compounds,** carbon-containing compounds that are generally large and complex. In all but the simplest organic compounds, two or more carbon atoms are bonded to each other to form the backbone, or skeleton, of the molecule. ■

ELEMENTS AND ATOMS

Learning Objectives

1. Name the principal chemical elements in living things, and give an important function of each.
2. Compare the physical properties (mass and charge) and locations of electrons, protons, and neutrons. Distinguish between the atomic number and the mass number of an element.
3. Define the terms *orbital* and *electron shell.* Relate electron shells to principal energy levels.

Elements are substances that cannot be broken down into simpler substances by ordinary chemical reactions. Each element has a **chemical symbol:** usually the first letter or first and second letters of the English or Latin name of the element. For example, O is the symbol for oxygen, C for carbon, H for hydrogen, N for nitrogen, and Na for sodium (Latin *natrium*).

Just four elements—oxygen, carbon, hydrogen, and nitrogen—are responsible for more than 96% of the mass of most organisms. Others, such as calcium, phosphorus, potassium, and magnesium, are also consistently present but in smaller quantities. Some elements, such as iodine and copper, are known as *trace elements,* because they are required only in minute amounts. Table 2-1 lists the elements that make up organisms, and briefly explains the importance of each in typical plants and animals.

An **atom** is defined as the smallest portion of an element that retains its chemical properties. Atoms are much smaller than the tiniest particle visible under a light microscope. By scanning tunneling microscopy, magnified as high as 5 million times, researchers have been able to photograph the positions of some large atoms in molecules.

Physicists have discovered a number of subatomic particles, but for our purposes we need consider only three: electrons, protons, and neutrons. An **electron** is a particle that carries a unit of negative electrical charge; a **proton** carries a unit of positive charge; and a **neutron** is an uncharged particle. In an electrically neutral atom, the number of electrons is equal to the number of protons.

Clustered together, protons and neutrons compose the **atomic nucleus.** Electrons, however, have no fixed locations and move rapidly through the mostly empty space surrounding the atomic nucleus.

TABLE 2-1 **Functions of Elements in Organisms**

Element (chemical symbol)	Functions
Oxygen (O)	Required for cellular respiration; present in most organic compounds; component of water
Carbon (C)	Forms backbone of organic molecules; each carbon atom can form four bonds with other atoms
Hydrogen (H)	Present in most organic compounds; component of water; hydrogen ion (H^+) is involved in some energy transfers
Nitrogen (N)	Component of proteins and nucleic acids; component of chlorophyll in plants
Calcium (Ca)	Structural component of bones and teeth; calcium ion (Ca^{2+}) is important in muscle contraction, conduction of nerve impulses, and blood clotting; associated with plant cell wall
Phosphorus (P)	Component of nucleic acids and of phospholipids in membranes; important in energy transfer reactions; structural component of bone
Potassium (K)	Potassium ion (K^+) is a principal positive ion (cation) in interstitial (tissue) fluid of animals; important in nerve function; affects muscle contraction; controls opening of stomata in plants
Sulfur (S)	Component of most proteins
Sodium (Na)	Sodium ion (Na^+) is a principal positive ion (cation) in interstitial (tissue) fluid of animals; important in fluid balance; essential for conduction of nerve impulses; important in photosynthesis in plants
Magnesium (Mg)	Needed in blood and other tissues of animals; activates many enzymes; component of chlorophyll in plants
Chlorine (Cl)	Chloride ion (Cl^-) is principal negative ion (anion) in interstitial (tissue) fluid of animals; important in water balance; essential for photosynthesis
Iron (Fe)	Component of hemoglobin in animals; activates certain enzymes

*Other elements found in very small (trace) amounts in animals, plants, or both include iodine (I), manganese (Mn), copper (Cu), zinc (Zn), cobalt (Co), fluorine (F), molybdenum (Mo), selenium (Se), boron (B), silicon (Si), and a few others.

An atom is uniquely identified by its number of protons

Every element has a fixed number of protons in the atomic nucleus, known as the **atomic number.** It is written as a subscript to the left of the chemical symbol. Thus, $_1$H indicates that the hydrogen nucleus contains 1 proton, and $_8$O means that the oxygen nucleus contains 8 protons. The atomic number determines an atom's identity and defines the element.

The **periodic table** is a chart of the elements arranged in order by atomic number (Fig. 2-1 and Appendix A). The periodic table is useful because it lets us simultaneously correlate many of the relationships among the various elements.

Figure 2-1 includes representations of the **electron configurations** of several elements important in organisms. These *Bohr models,* which show the electrons arranged in a series of concentric circles around the nucleus, are convenient to use but inaccurate. The space outside the nucleus is actually extremely large compared to the nucleus, and, as you will see, electrons do not actually circle the nucleus in fixed concentric pathways.

Protons plus neutrons determine atomic mass

The mass of a subatomic particle is exceedingly small, much too small to be conveniently expressed in grams or even micro-

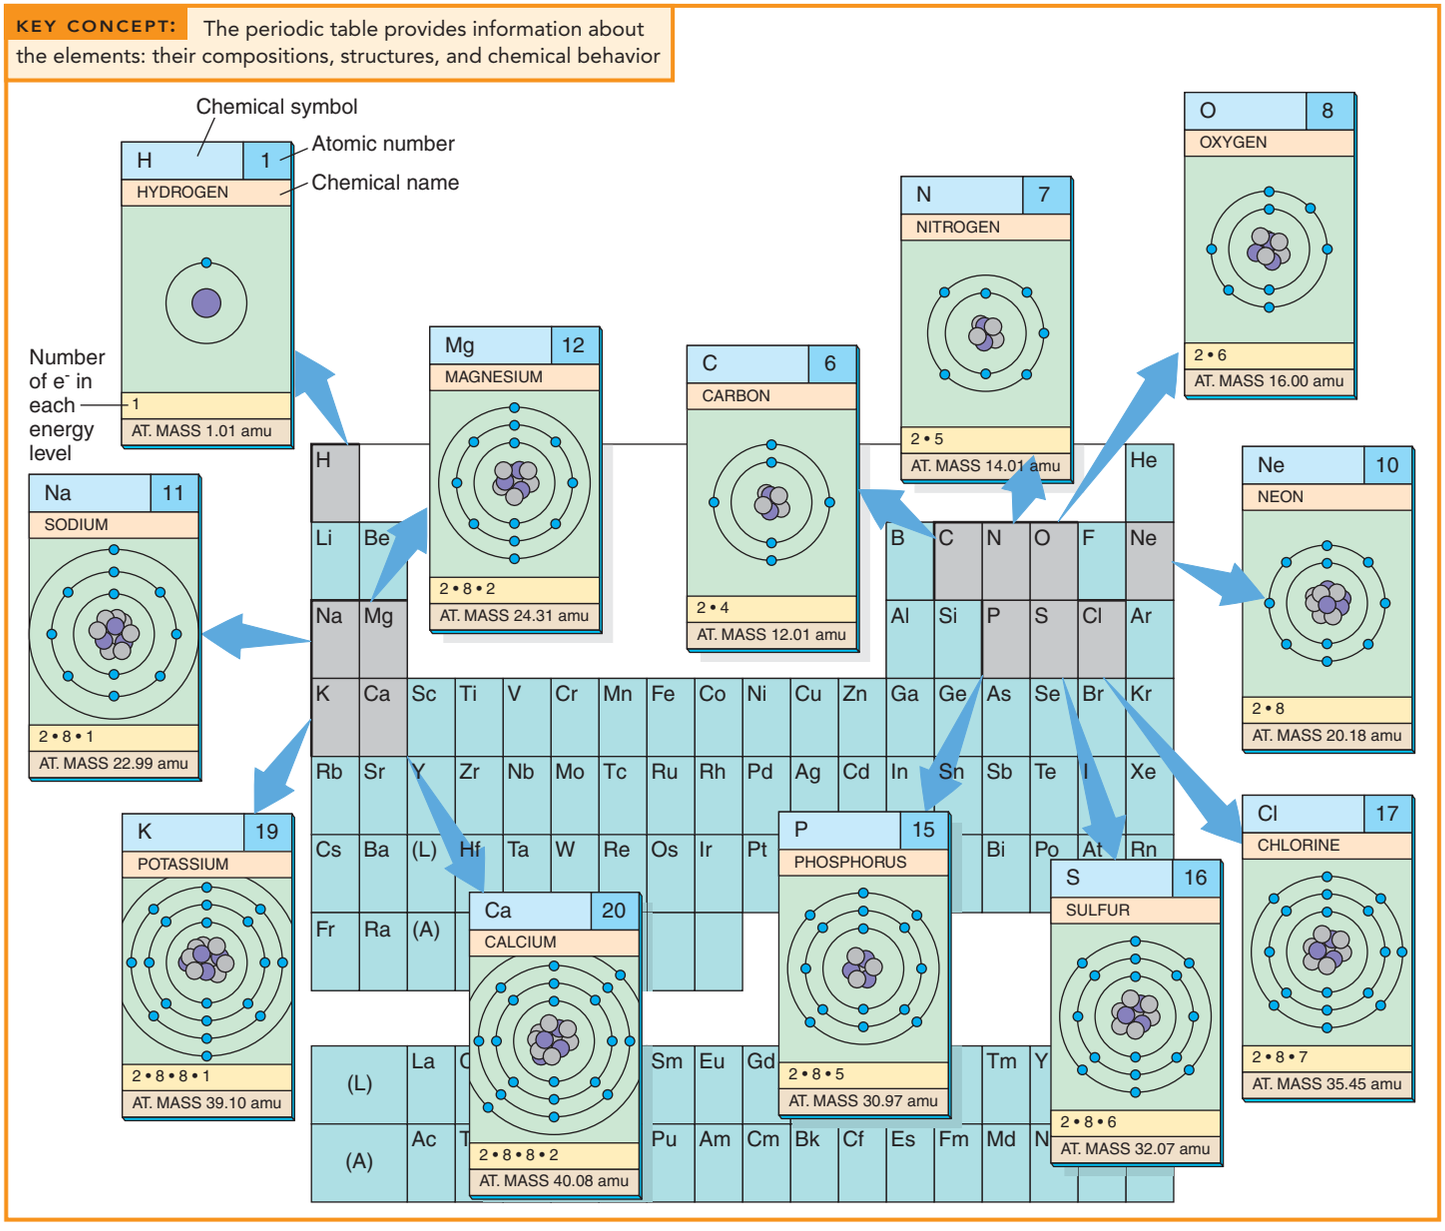

FIGURE **2-1** **The periodic table.**

Note the Bohr models depicting the electron configuration of atoms of some biologically important elements. Although the Bohr model does not depict electron configurations accurately, it is commonly used because of its simplicity and convenience. A complete periodic table is given in Appendix B.

grams.[1] Such masses are expressed in terms of the **atomic mass unit (amu),** also called the **dalton** in honor of John Dalton, who formulated an atomic theory in the early 1800s. One amu is equal to the approximate mass of a single proton or a single neutron. Protons and neutrons make up almost all the mass of an atom. The mass of a single electron is only about 1/1800 the mass of a proton or neutron.

The **atomic mass** of an atom is a number that indicates approximately how much matter it contains compared with another atom. This value is determined by adding the number of protons to the number of neutrons and expressing the result in atomic mass units or daltons.[2] The mass of the electrons is ignored because it is so small. The atomic mass number is indicated by a superscript to the left of the chemical symbol. The common form of the oxygen atom, with 8 protons and 8 neutrons in its nucleus, has an atomic number of 8 and a mass of 16 atomic mass units. It is indicated by the symbol $^{16}_{8}O$.

[1] Tables of commonly used units of scientific measurement are printed inside the back cover of this text.

[2] Unlike weight, mass is independent of the force of gravity. For convenience, however, we consider mass and weight equivalent. Atomic weight has the same numerical value as atomic mass, but it has no units.

The characteristics of protons, electrons, and neutrons are summarized in the following table:

Particle	Charge	Approximate Mass	Location
Proton	Positive	1 amu	Nucleus
Neutron	Neutral	1 amu	Nucleus
Electron	Negative	Approx. 1/1800 amu	Outside nucleus

Isotopes of an element differ in number of neutrons

Most elements consist of a mixture of atoms with different numbers of neutrons and thus different masses. Such atoms are called **isotopes.** Isotopes of the same element have the same number of protons and electrons; only the number of neutrons varies. The three isotopes of hydrogen, $^{1}_{1}H$ (ordinary hydrogen), $^{2}_{1}H$ (deuterium), and $^{3}_{1}H$ (tritium), contain 0, 1, and 2 neutrons, respectively. Figure 2-2 shows Bohr models of two isotopes of carbon, $^{12}_{6}C$ and $^{14}_{6}C$. The mass of an element is expressed as an average of the masses of its isotopes (weighted by their relative abundance in nature). For example, the atomic mass of hydrogen is not 1.0 amu, but 1.0079 amu, reflecting the natural occurrence of small amounts of deuterium and tritium in addition to the more abundant ordinary hydrogen.

Because they have the same number of electrons, all isotopes of a given element have essentially the same chemical characteristics. However, some isotopes are unstable and tend to break down, or decay, to a more stable isotope (usually becoming a different element); such **radioisotopes** emit radiation when they decay. For example, the radioactive decay of $^{14}_{6}C$ occurs as a neutron decomposes to form a proton and a fast-moving electron, which is emitted from the atom as a form of radiation known as a beta (β) particle. The resulting stable atom is the common form of nitrogen, $^{14}_{7}N$. Using sophisticated instruments, scientists can detect and measure β particles and other types of radiation. Radioactive decay can also be detected by a method known as **autoradiography,** in which radiation causes the appearance of dark silver grains in photographic film (Fig. 2-3).

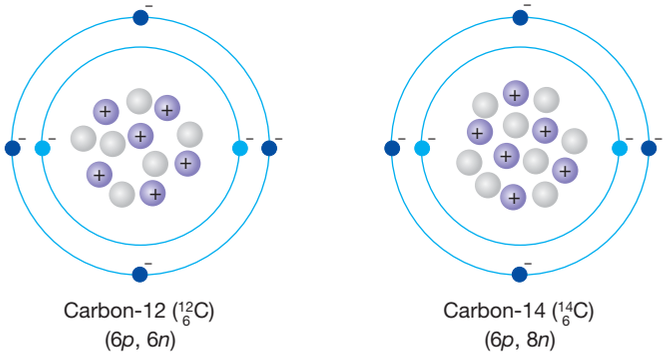

FIGURE **2-2** **Isotopes.**

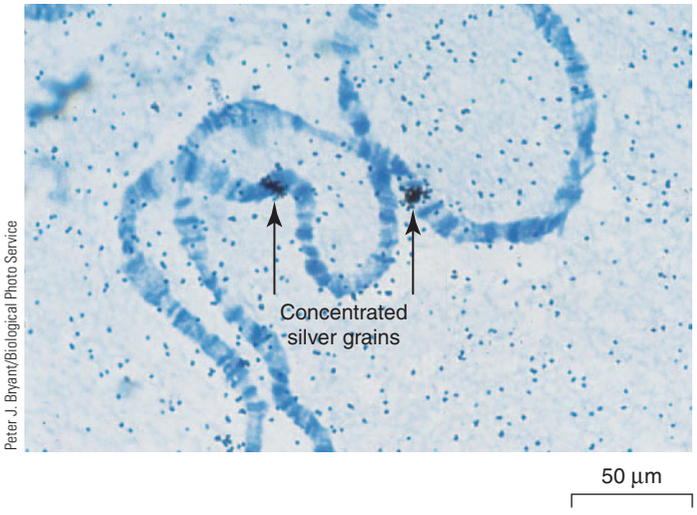
Carbon-12 ($^{12}_{6}C$) is the most common isotope of carbon. Its nucleus contains 6 protons and 6 neutrons, so its atomic mass is 12. Carbon-14 ($^{14}_{6}C$) is a rare radioactive carbon isotope. It contains 8 neutrons, so its atomic mass is 14.



Peter J. Bryant/Biological Photo Service

FIGURE **2-3** **Autoradiography.**

The chromosomes of the fruit fly, *Drosophila melanogaster,* shown in this light micrograph, have been covered with photographic film in which silver grains *(dark spots)* are produced when tritium (^{3}H) that has been incorporated into DNA undergoes radioactive decay. The concentrations of silver grains *(arrows)* mark the locations of specific DNA molecules.

Because the different isotopes of a given element have the same chemical characteristics, they are essentially interchangeable in molecules. Molecules containing radioisotopes are usually metabolized and/or localized in the organism in a similar way to their nonradioactive counterparts, and they can be substituted. For this reason, radioisotopes such as ^{3}H (tritium), ^{14}C, and ^{32}P are extremely valuable research tools used in areas such as dating fossils (see Fig. 17-9), tracing biochemical pathways, determining the sequence of genetic information in DNA (see Fig. 14-10), and understanding sugar transport in plants.

In medicine, radioisotopes are used for both diagnosis and treatment. The location and/or metabolism of a substance such as a hormone or drug can be followed in the body by labeling the substance with a radioisotope such as carbon-14 or tritium. Radioisotopes are used to test thyroid gland function, to provide images of blood flow in the arteries supplying the heart muscle, and to study many other aspects of body function and chemistry. Because radiation can interfere with cell division, radioisotopes have been used therapeutically in treating cancer, a disease often characterized by rapidly dividing cells.

Electrons move in orbitals corresponding to energy levels

Electrons move through characteristic regions of 3-D space, or **orbitals.** Each orbital contains a maximum of 2 electrons. Because it is impossible to know an electron's position at any given

time, orbitals are most accurately depicted as "electron clouds," shaded areas whose density is proportional to the probability that an electron is present there at any given instant. The energy of an electron depends on the orbital it occupies. Electrons in orbitals with similar energies, said to be at the same **principal energy level,** make up an **electron shell** (Fig. 2-4).

In general, electrons in a shell distant from the nucleus have greater energy than those in a shell close to the nucleus. This is because to move a negatively charged electron farther away from the positively charged nucleus, energy is required. The most energetic electrons, known as **valence electrons,** are said to occupy the **valence shell.** The valence shell is represented as the outermost concentric ring in a Bohr model.

An electron can move to an orbital farther from the nucleus by receiving more energy, or it can give up energy and sink to a lower energy level in an orbital nearer the nucleus. Changes in electron energy levels are important in energy conversions in organisms. For example, during photosynthesis, light energy absorbed by chlorophyll molecules causes electrons to move to a higher energy level (see Fig. 8-3).

Review

- Do all atoms of an element have the same atomic number? The same atomic mass?
- What is a radioisotope? What are some ways radioisotopes are used in biological research?
- How do electrons in different orbitals of the same electron shell compare with respect to their energy?

BiologyNow™ Assess your understanding of **elements and atoms** by taking the pretest on your BiologyNow CD-ROM.

CHEMICAL REACTIONS

Learning Objectives

4 Explain how the number of valence electrons of an atom is related to its chemical properties.

5 Distinguish among simplest, molecular, and structural chemical formulas.

6 Explain why the mole concept is so useful to chemists.

The chemical behavior of an atom is determined primarily by the number and arrangement of its valence electrons. The valence shell of hydrogen or helium is full (stable) when it contains 2 electrons. The valence shell of any other atom is full when it contains 8 electrons. When the valence shell is not full, the atom tends to lose, gain, or share electrons to achieve a full outer shell. The valence shells of all isotopes of an element are identical; this is why they have similar chemical properties and can substitute for each other in chemical reactions (for example, tritium can substitute for ordinary hydrogen).

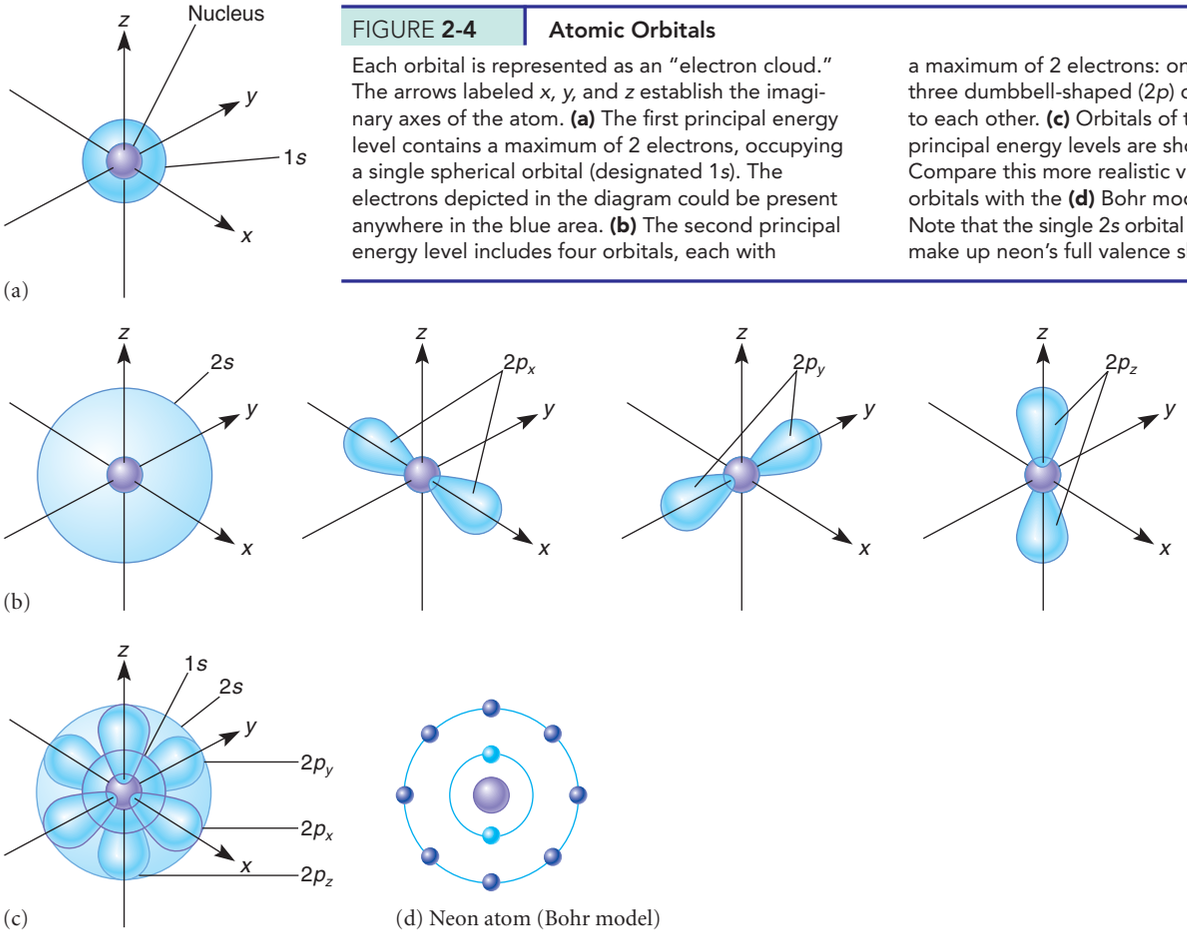


FIGURE **2-4** **Atomic Orbitals**

Each orbital is represented as an "electron cloud." The arrows labeled *x*, *y*, and *z* establish the imaginary axes of the atom. **(a)** The first principal energy level contains a maximum of 2 electrons, occupying a single spherical orbital (designated 1*s*). The electrons depicted in the diagram could be present anywhere in the blue area. **(b)** The second principal energy level includes four orbitals, each with a maximum of 2 electrons: one spherical (2*s*) and three dumbbell-shaped (2*p*) orbitals at right angles to each other. **(c)** Orbitals of the first and second principal energy levels are shown superimposed. Compare this more realistic view of the atomic orbitals with the **(d)** Bohr model of a neon atom. Note that the single 2*s* orbital plus three 2*p* orbitals make up neon's full valence shell of 8 electrons.

Elements in the same vertical column (belonging to the same *group*) of the periodic table have similar chemical properties because their valence shells have similar tendencies to lose, gain, or share electrons. For example, chlorine and bromine, included in a group commonly known as the *halogens,* are highly reactive. Because their valence shells have 7 electrons, they tend to gain an electron in chemical reactions. By contrast, hydrogen, sodium, and potassium each have a single valence electron, which they tend to give up or share with another atom. Helium (He) and neon (Ne) belong to a group referred to as the "noble gases." They are quite unreactive, because their valence shells are full. Notice the incomplete valence shells of some of the elements important in organisms, including carbon, hydrogen, oxygen, and nitrogen, in Figure 2-1, and compare them with the full valence shell of neon in Figure 2-4d.

Atoms form compounds and molecules

Two or more atoms may combine chemically. When atoms of *different* elements combine, the result is a chemical compound. A **chemical compound** consists of atoms of two or more different elements combined in a fixed ratio. For example, water is a chemical compound composed of hydrogen and oxygen in a ratio of 2:1. Common table salt, sodium chloride, is a chemical compound made up of sodium and chlorine in a 1:1 ratio.

Two or more atoms may become joined very strongly to form a stable particle called a **molecule.** For example, when two atoms of oxygen combine chemically, a molecule of oxygen is formed. Water is a molecular compound, with each molecule consisting of two atoms of hydrogen and one of oxygen. However, as you will see, not all compounds are made up of molecules. Sodium chloride is an example of a compound that is not molecular.

Simplest, molecular, and structural chemical formulas give different information

A **chemical formula** is a shorthand expression that describes the chemical composition of a substance. Chemical symbols indicate the types of atoms present, and subscript numbers indicate the ratios among the atoms. There are several types of chemical formulas, each providing specific kinds of information.

In a **simplest formula** (also known as an *empirical formula*), the subscripts give the smallest whole-number ratios for the atoms present in a compound. For example, the simplest formula for hydrazine is NH_2, indicating a 1:2 ratio of nitrogen to hydrogen. (Note that when a single atom of a type is present, the subscript number 1 is never written.)

In a **molecular formula,** the subscripts indicate the actual numbers of each type of atom per molecule. The molecular formula for hydrazine is N_2H_4, which indicates that each molecule of hydrazine consists of two atoms of nitrogen and four atoms of hydrogen. The molecular formula for water, H_2O, indicates that each molecule consists of two atoms of hydrogen and one atom of oxygen.

A **structural formula** shows not only the types and numbers of atoms in a molecule but also their arrangement. For example, the structural formula for water is H—O—H. As you will learn in Chapter 3, it is common for complex organic molecules with different structural formulas to share the same molecular formula.

One mole of any substance contains the same number of units

The **molecular mass** of a compound is the sum of the atomic masses of the component atoms of a single molecule; thus, the molecular mass of water, H_2O, is (hydrogen: 2×1 amu) + (oxygen: 1×16 amu), or 18 amu. (Because of the presence of isotopes, atomic mass values are not whole numbers, but for easy calculation each atomic mass value has been rounded off to a whole number.) Similarly, the molecular mass of glucose ($C_6H_{12}O_6$), a simple sugar that is a key compound in cell metabolism, is (carbon: 6×12 amu) + (hydrogen: 12×1 amu) + (oxygen: 6×16 amu), or 180 amu.

The amount of an element or compound whose mass in grams is equivalent to its atomic or molecular mass is 1 **mole (mol).** Thus 1 mol of water is 18 grams (g), and 1 mol of glucose has a mass of 180 g. The mole is an extremely useful concept, because it lets us make meaningful comparisons between atoms and molecules of very different mass. This is because *1 mol of any substance always has exactly the same number of units,* whether they are small atoms or large molecules. The very large number of units in a mole, 6.02×10^{23}, is known as **Avogadro's number,** named for the Italian physicist Amadeo Avogadro, who first calculated it. Thus 1 mol (180 g) of glucose contains 6.02×10^{23} molecules, as does 1 mol (2 g) of molecular hydrogen (H_2). Although it is impossible to count atoms and molecules individually, a scientist can calculate them simply by weighing a sample. Molecular biologists usually deal with smaller values, either millimoles (mmol, one thousandth of a mole) or micromoles (μmol, one millionth of a mole).

The mole concept also lets us make useful comparisons among solutions. A 1-molar solution, represented by 1 *M,* contains 1 mol of that substance dissolved in a total volume of 1 liter (L). For example, we can compare 1 L of a 1-*M* solution of glucose with 1 L of a 1-*M* solution of sucrose (table sugar, a larger molecule). They differ in the mass of the dissolved sugar (180 g and 340 g, respectively), but they each contain 6.02×10^{23} sugar molecules.

Chemical equations describe chemical reactions

During any moment in the life of an organism—a bacterial cell, a mushroom, or a butterfly—many complex chemical reactions are taking place. Chemical reactions, such as the reaction between glucose and oxygen, can be described by means of chemical equations:

$$\underset{\text{Glucose}}{C_6H_{12}O_6} + \underset{\text{Oxygen}}{6\,O_2} \longrightarrow \underset{\text{Carbon dioxide}}{6\,CO_2} + \underset{\text{Water}}{6\,H_2O} + \text{energy}$$

In a chemical equation, the **reactants,** the substances that participate in the reaction, are generally written on the left side, and the **products,** the substances formed by the reaction, are written on the right side. The arrow means "yields" and indicates the direction in which the reaction proceeds.

Chemical compounds react with each other in quantitatively precise ways. The numbers preceding the chemical symbols or formulas (known as *coefficients*) indicate the relative number of atoms or molecules reacting. For example, 1 mol of glucose burned in a fire or metabolized in a cell reacts with 6 mol of oxygen to form 6 mol of carbon dioxide and 6 mol of water.

Many reactions can proceed simultaneously in the reverse direction (to the left) as well as in the forward direction (to the right). At **dynamic equilibrium,** the rates of the forward and reverse reactions are equal (see Chapter 6). Reversible reactions are indicated by double arrows:

$$\underset{\text{Carbon dioxide}}{CO_2} + \underset{\text{Water}}{H_2O} \rightleftharpoons \underset{\text{Carbonic acid}}{H_2CO_3}$$

In this example, the arrows are drawn in different lengths to indicate that when the reaction reaches equilibrium, there will be more reactants (CO_2 and H_2O) than product (H_2CO_3).

Review

- Why is a radioisotope able to substitute for an ordinary (nonradioactive) atom of the same element in a molecule?
- Which kind of chemical formula provides the most information?
- How many atoms would be included in 1 gram of hydrogen atoms? in 2 grams of hydrogen molecules?

Biology Now™ Assess your understanding of **chemical reactions** by taking the pretest on your BiologyNow CD-ROM.

CHEMICAL BONDS

Learning Objective

7 Distinguish among covalent bonds, ionic bonds, and hydrogen bonds. Compare them in terms of the mechanisms by which they form and their relative bond strengths.

The atoms of a compound are held together by forces of attraction called **chemical bonds.** Each bond represents a certain amount of chemical energy. **Bond energy** is the energy necessary to break a chemical bond. The valence electrons dictate how many bonds an atom can participate in. The two principal types of strong chemical bonds are covalent bonds and ionic bonds.

In covalent bonds electrons are shared

Covalent bonds involve the sharing of electrons between atoms in a way that results in each atom having a filled valence shell. A compound consisting mainly of covalent bonds is called a **covalent compound.** A simple example of a covalent bond is the joining of two hydrogen atoms in a molecule of hydrogen gas, H_2. Each atom of hydrogen has 1 electron, but 2 electrons are required to complete its valence shell. The hydrogen atoms have equal capacities to attract electrons, so neither donates an electron to the other. Instead, the two hydrogen atoms share their single electrons so that the two electrons are attracted simultaneously to the 2 protons in the two hydrogen nuclei. The 2 electrons thus whirl around both atomic nuclei, joining the two atoms.

A simple way of representing the electrons in the valence shell of an atom is to use dots placed around the chemical symbol of the element. Such a representation is called the *Lewis structure* of the atom, named for G. N. Lewis, an American chemist who developed this type of notation. In a water molecule, two hydrogen atoms are covalently bonded to an oxygen atom:

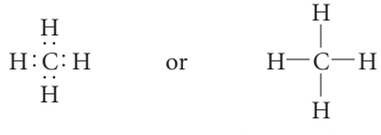
$$H\cdot + H\cdot + \cdot\ddot{O}\cdot \longrightarrow H:\ddot{O}:H$$

Oxygen has 6 valence electrons; by sharing electrons with two hydrogen atoms, it completes its valence shell of 8. At the same time each hydrogen atom obtains a complete valence shell of 2. (Note that in the structural formula H—O—H, each pair of shared electrons constitutes a covalent bond, represented by a solid line. Unshared electrons are usually omitted in a structural formula.)

The carbon atom has 4 electrons in its valence shell, all of which are available for covalent bonding:

$$\cdot\dot{C}\cdot$$

When one carbon and four hydrogen atoms share electrons, a molecule of methane, CH_4, is formed:

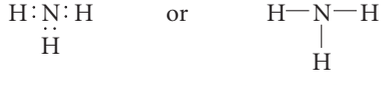


Lewis structure — Structural formula

The nitrogen atom has 5 electrons in its valence shell. Recall that each orbital can hold a maximum of 2 electrons. Usually 2 electrons occupy one orbital, leaving 3 available for sharing with other atoms:

$$\cdot\ddot{N}\cdot$$

When a nitrogen atom shares electrons with three hydrogen atoms, a molecule of ammonia, NH_3, is formed:



Lewis structure — Structural formula

When one pair of electrons is shared between two atoms, the covalent bond is called a **single covalent bond** (Fig. 2-5a). Two oxygen atoms may achieve stability by forming covalent bonds with one another. Each oxygen atom has 6 electrons in its outer shell. To become stable, the two atoms share two pairs of electrons, forming molecular oxygen (Fig. 2-5b). When two pairs of electrons are shared in this way, the covalent bond is called a **double covalent bond,** which is represented by two parallel solid lines. Similarly, a **triple covalent bond** is formed when three pairs of electrons are shared between two atoms (represented by three parallel solid lines).

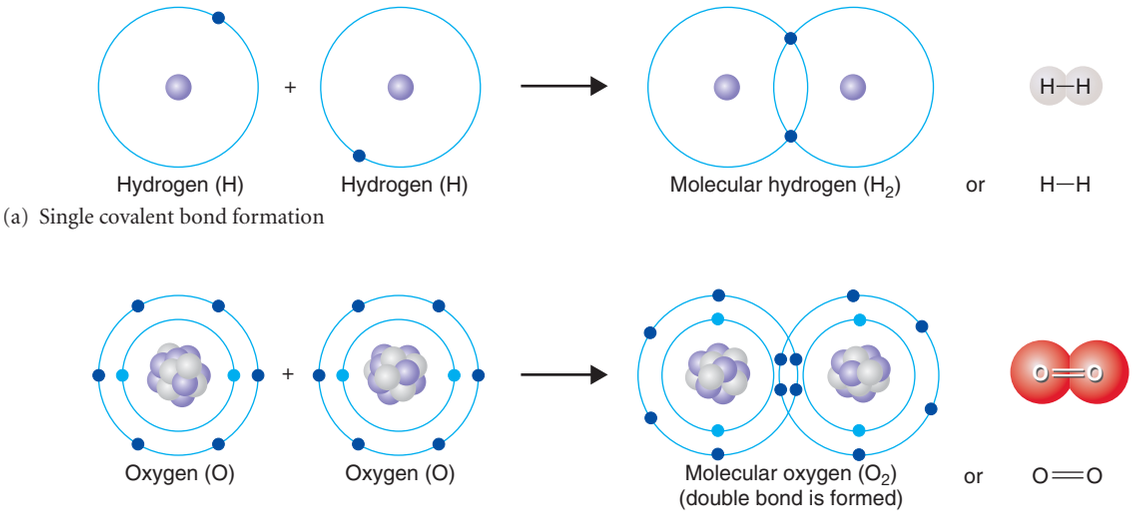


FIGURE **2-5** **Electron sharing in covalent compounds.**

(a) Two hydrogen atoms achieve stability by sharing a pair of electrons, thereby forming a molecule of hydrogen. In the structural formula on the right, the straight line between the hydrogen atoms represents a single covalent bond. **(b)** In molecular oxygen, two oxygen atoms share two pairs of electrons, forming a double covalent bond.

The number of covalent bonds usually formed by the atoms in biologically important molecules is summarized as follows:

Atom	Symbol	Covalent Bonds
Hydrogen	H	1
Oxygen	O	2
Carbon	C	4
Nitrogen	N	3
Phosphorus	P	5
Sulfur	S	2

The function of a molecule is related to its shape

In addition to being composed of atoms with certain properties, each kind of molecule has a characteristic size and a general overall shape. Although the shape of a molecule may change (within certain limits), the functions of molecules in living cells are dictated largely by their geometric shapes. A molecule that consists of two atoms is linear. Molecules composed of more than two atoms may have more complicated shapes. The geometric shape of a molecule provides the optimal distance between the atoms to counteract the repulsion of electron pairs.

When an atom forms covalent bonds with other atoms, the orbitals in the valence shell may become rearranged in a process known as **orbital hybridization,** thereby affecting the shape of the resulting molecule. For example, when four hydrogen atoms combine with a carbon atom to form a molecule of methane (CH_4), the hybridized valence shell orbitals of the carbon form a geometric structure known as a *tetrahedron,* with one hydrogen atom present at each of its four corners (Fig. 2-6; see Fig. 3-2b).

Covalent bonds can be nonpolar or polar

Atoms of different elements vary in their affinity for electrons. **Electronegativity** is a measure of an atom's attraction for shared electrons in chemical bonds. Very electronegative atoms such as oxygen, nitrogen, fluorine, and chlorine are sometimes called "electron greedy." When covalently bonded atoms have similar electronegativities, the electrons are shared equally, and the covalent bond is described as **nonpolar.** The covalent bond of the hydrogen molecule is nonpolar, as are the covalent bonds of molecular oxygen and methane.

In a covalent bond between two different elements, such as oxygen and hydrogen, the electronegativities of the atoms may be different. If so, electrons are pulled closer to the atomic nucleus of the element with the greater electron affinity (in this case, oxygen). A covalent bond between atoms that differ in electronegativity is called a **polar covalent bond.** Such a bond has two dissimilar ends (or poles), one with a partial positive charge

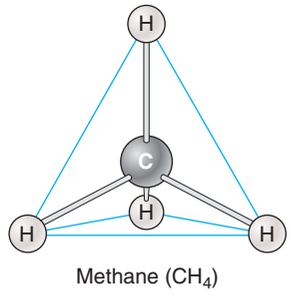

FIGURE **2-6** **Orbital hybridization in methane.**

The four hydrogens are located at the corners of a tetrahedron owing to hybridization of the valence shell orbitals of carbon.

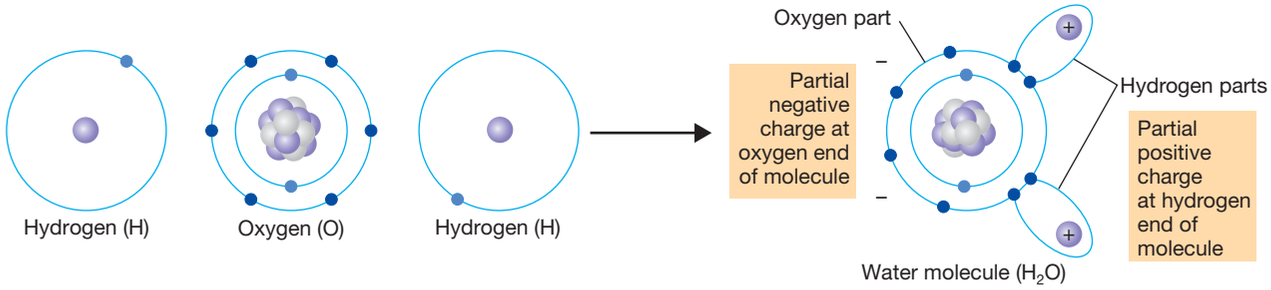

FIGURE 2-7 **Water, a polar molecule.**

Note that the electrons tend to stay closer to the nucleus of the oxygen atom than to the hydrogen nuclei. This results in a partial negative charge on the oxygen portion of the molecule and a partial positive charge at the hydrogen end. Although the water molecule as a whole is electrically neutral, it is a polar covalent compound.

and the other with a partial negative charge. Each of the two covalent bonds in water is polar, because there is a partial positive charge at the hydrogen end of the bond and a partial negative charge at the oxygen end, where the "shared" electrons are more likely to be.

Covalent bonds differ in their degree of polarity, ranging from those in which the electrons are equally shared (as in the nonpolar hydrogen molecule) to those in which the electrons are much closer to one atom than to the other (as in water). Oxygen is quite electronegative and forms polar covalent bonds with carbon, hydrogen, and many other atoms. Nitrogen is also strongly electronegative, although less so than oxygen.

A molecule with one or more polar covalent bonds can be polar even though it is electrically neutral as a whole. This is because a **polar molecule** has one end with a partial positive charge and another end with a partial negative charge. One example is water (Fig. 2-7). The polar bonds between the hydrogens and the oxygen are arranged in a V shape, rather than linearly. The oxygen end constitutes the negative pole of the molecule, and the end with the two hydrogens is the positive pole.

Ionic bonds form between cations and anions

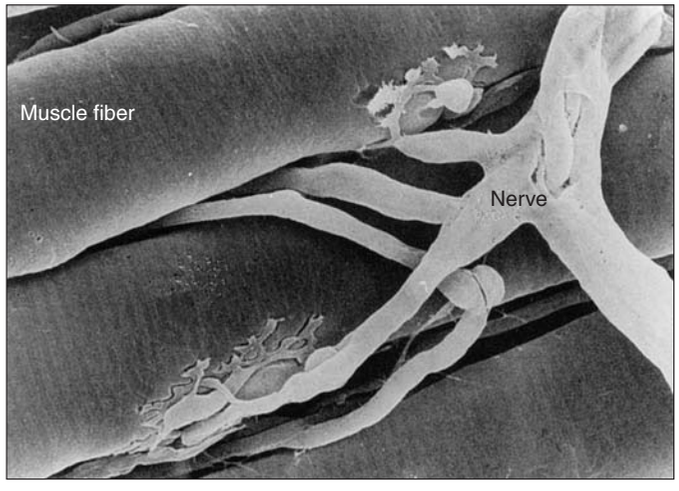
Some atoms or groups of atoms are not electrically neutral. A particle with 1 or more units of electrical charge is called an **ion.** An atom becomes an ion if it gains or loses 1 or more electrons. An atom with 1, 2, or 3 electrons in its valence shell tends to lose electrons to other atoms. Such an atom then becomes positively charged, because its nucleus contains more protons than the number of electrons orbiting around the nucleus. These positively charged ions are termed **cations.** Atoms with 5, 6, or 7 valence electrons tend to gain electrons from other atoms and become negatively charged **anions.**

The properties of ions are quite different from those of the electrically neutral atoms from which they were derived. For example, although chlorine gas is a poison, chloride ions (Cl^-) are essential to life (see Table 2-1). Because their electrical charges provide a basis for many interactions, cations and anions are involved in energy transformations within the cell, the transmission of nerve impulses, muscle contraction, and many other biological processes (Fig. 2-8).

A group of covalently bonded atoms can also become an ion *(polyatomic ion)*. Unlike a single atom, a group of atoms can lose or gain protons (derived from hydrogen atoms) as well as electrons. Therefore, a group of atoms can become a cation if it loses 1 or more electrons or gains 1 or more protons. A group of atoms becomes an anion if it gains 1 or more electrons or loses 1 or more protons.

An **ionic bond** forms as a consequence of the attraction between the positive charge of a cation and the negative charge of an anion. An **ionic compound** is a substance consisting of anions and cations bonded together by their opposite charges.

A good example of how ionic bonds are formed is the attraction between sodium ions and chloride ions. A sodium atom has 1 electron in its valence shell. It cannot fill its valence shell by obtaining 7 electrons from other atoms, because it would then have a large unbalanced negative charge. Instead, it gives up its single valence electron to a very electronegative atom, such as chlorine, which acts as an electron acceptor (Fig. 2-9). Chlorine cannot give up the seven electrons in its valence shell,



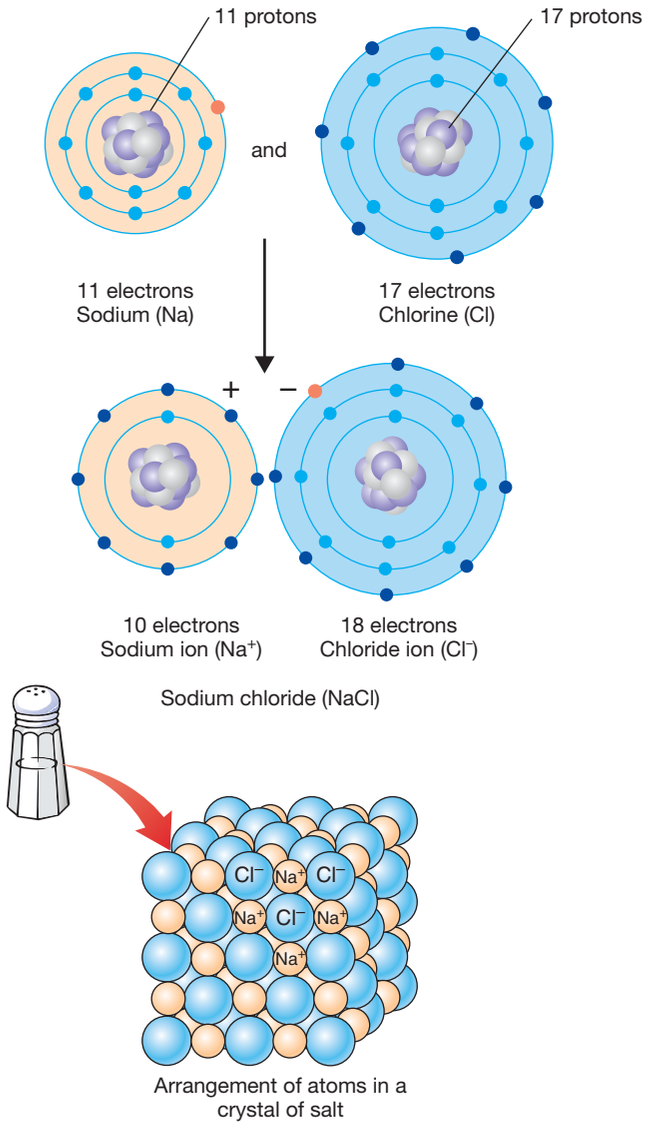
D.W. Fawcett

FIGURE 2-8 **Ions and biological processes.**

Sodium, potassium, and chloride ions are essential for this nerve cell to stimulate these muscle fibers, initiating a muscle contraction. Calcium ions in the muscle cell are required for muscle contraction.

because it would then have a large positive charge. Instead, it strips an electron from an electron donor (sodium, in this example) to complete its valence shell.

When sodium reacts with chlorine, sodium's valence electron is transferred completely to chlorine. Sodium becomes a cation, with 1 unit of positive charge (Na^+). Chlorine becomes an anion, a chloride ion with 1 unit of negative charge (Cl^-). These ions attract each other as a result of their opposite charges. This electrical attraction in ionic bonds holds them together to form NaCl, sodium chloride, or common table salt.



ACTIVE FIGURE **2-9** **Ionic bonding.**

Sodium becomes a positively charged ion when it donates its single valence electron to chlorine, which has 7 valence electrons. With this additional electron, chlorine completes its valence shell and becomes a negatively charged chloride ion. These sodium and chloride ions are attracted to one another by their unlike electrical charges, forming the ionic compound sodium chloride.

BiologyNow™ Learn more about **ionic bonding** by clicking on this figure on your Biology Now CD-ROM.

The term *molecule* does not adequately explain the properties of ionic compounds such as NaCl. When NaCl is in its solid crystal state, each ion is actually surrounded by six ions of opposite charge. The simplest formula, NaCl, indicates that sodium ions and chloride ions are present in a 1:1 ratio, but the actual crystal has no discrete molecules composed of one Na^+ and one Cl^- ion.

Compounds joined by ionic bonds, such as sodium chloride, have a tendency to *dissociate* (separate) into their individual ions when placed in water:

$$\underset{\text{Sodium chloride}}{NaCl} \xrightarrow{\text{in } H_2O} \underset{\text{Sodium ion}}{Na^+} + \underset{\text{Chloride ion}}{Cl^-}$$

In the solid form of an ionic compound (that is, in the absence of water), the ionic bonds are very strong. Water, however, is an excellent **solvent;** as a liquid it is capable of dissolving many substances, particularly those that are polar or ionic. This is because of the polarity of water molecules. The localized partial positive charge (on the hydrogen atoms) and partial negative charge (on the oxygen atom) on each water molecule attract and surround the anions and cations, respectively, on the surface of an ionic solid. As a result, the solid dissolves. A dissolved substance is referred to as a **solute.** In solution, each cation and anion of the ionic compound is surrounded by oppositely charged ends of the water molecules. This process is known as **hydration** (Fig. 2-10). Hydrated ions still interact with each other to some extent, but the transient ionic bonds formed are much weaker than those in a solid crystal.

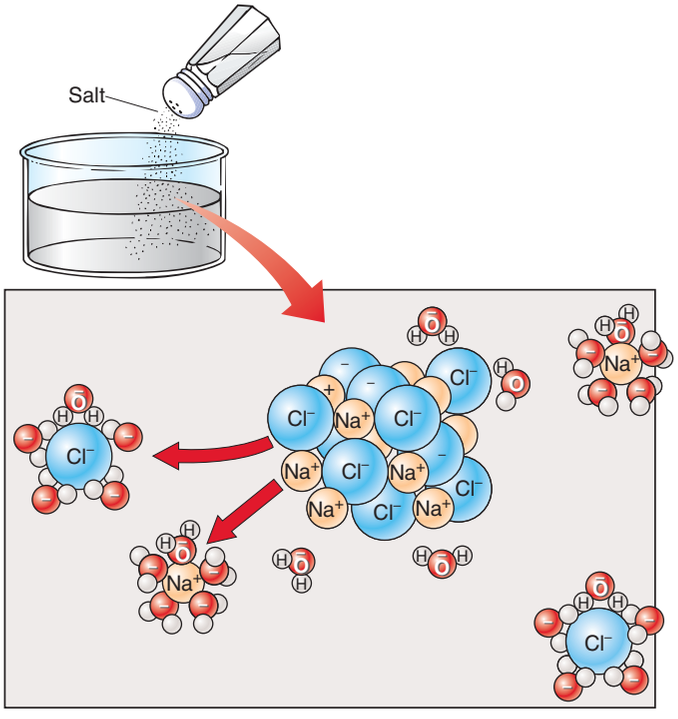


FIGURE **2-10** **Hydration of an ionic compound.**

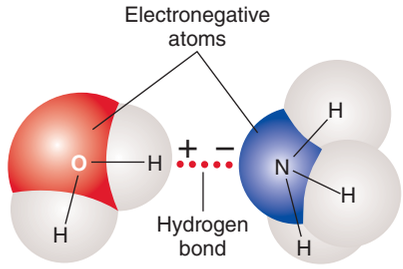
When the crystal of NaCl is added to water, the sodium and chloride ions are pulled apart. When the NaCl is dissolved, each Na^+ and Cl^- is surrounded by water molecules electrically attracted to it.



ACTIVE FIGURE **2-11** **Hydrogen bonding.**

A hydrogen bond (indicated by a dotted line) can form between two molecules with regions of unlike partial charge. Here, the nitrogen atom of an ammonia molecule is joined by a hydrogen bond to a hydrogen atom of a water molecule.

BiologyNow™ Learn more about **hydrogen bonding** by clicking on this figure on your BiologyNow CD-ROM.

Hydrogen bonds are weak attractions

Another type of bond important in organisms is the **hydrogen bond.** When hydrogen combines with oxygen (or with another relatively electronegative atom such as nitrogen), it acquires a partial positive charge because its electron spends more time closer to the electronegative atom. Hydrogen bonds tend to form between an atom with a partial negative charge and a hydrogen atom that is covalently bonded to oxygen or nitrogen (Fig. 2-11). The atoms involved may be in two parts of the same large molecule or in two different molecules. Water molecules interact with each other extensively through hydrogen bond formation.

Hydrogen bonds are readily formed and broken. Although individually relatively weak, hydrogen bonds are collectively strong when present in large numbers. Furthermore, they have a specific length and orientation. As you will see in Chapter 3, these features are very important in determining the 3-D structure of large molecules such as DNA and proteins.

Review

- Are all compounds composed of molecules? Explain.
- What are the ways an atom or molecule can become an anion or a cation?
- How do ionic and covalent bonds differ?

REDOX REACTIONS

Learning Objective

8 Distinguish between the terms *oxidation* and *reduction,* and relate these processes to the transfer of energy.

Many energy conversions that go on in a cell involve reactions in which an electron transfers from one substance to another. This is because the transfer of an electron also involves the transfer of the energy of that electron. Such an electron transfer is known as an oxidation-reduction, or **redox reaction.** Oxidation and reduction always occur together. **Oxidation** is a chemical process in which an atom, ion, or molecule *loses* electrons. **Reduction** is a chemical process in which an atom, ion, or molecule *gains* electrons. (The term refers to the fact that the gain of an electron results in the reduction of any positive charge that might be present.)

Rusting—the combining of iron (symbol Fe) with oxygen—is a simple illustration of oxidation and reduction:

$$4\ Fe + 3\ O_2 \longrightarrow 2\ Fe_2O_3$$

Iron (III) oxide

In rusting, each iron atom becomes oxidized as it loses 3 electrons.

$$4\ Fe \rightarrow 4\ Fe^{3+} + 12e^-$$

The e^- represents an electron; the + superscript in Fe^{3+} represents an electron deficit. (When an atom loses an electron, it acquires 1 unit of positive charge from the excess of 1 proton. In our example, each iron atom loses 3 electrons and acquires 3 units of positive charge.)

Recall that the oxygen atom is very electronegative, able to remove electrons from other atoms. In this reaction, oxygen becomes reduced when it accepts electrons from the iron.

$$3\ O_2 + 12e^- \rightarrow 6\ O^{2-}$$

Redox reactions occur simultaneously because one substance must accept the electrons that are removed from the other. In a redox reaction, one component, the *oxidizing agent,* accepts one or more electrons and becomes reduced. Oxidizing agents other than oxygen are known, but oxygen is such a common one that its name was given to the process. Another reaction component, the *reducing agent,* gives up one or more electrons and becomes oxidized.

In our example, there was a complete transfer of electrons from iron (the reducing agent) to oxygen (the oxidizing agent). Similarly, in Figure 2-9 an electron was transferred from sodium (the reducing agent) to chlorine (the oxidizing agent).

Electrons are not easily removed from covalent compounds unless an entire atom is removed. In cells, oxidation often involves the removal of a hydrogen atom (an electron plus a proton that "goes along for the ride") from a covalent compound; reduction often involves the addition of the equivalent of a hydrogen atom (see Chapter 6).

Review

- Why must oxidation and reduction occur simultaneously?
- Why are redox reactions important in some energy transfers?

BiologyNow™ Assess your understanding of **redox reactions** by taking the pretest on your BiologyNow CD-ROM.

WATER

Learning Objective

9 Explain how hydrogen bonds between adjacent water molecules govern many of the properties of water.

A large part of the mass of most organisms is water. In human tissues the percentage of water ranges from 20% in bones to

Images not available due to copyright restrictions

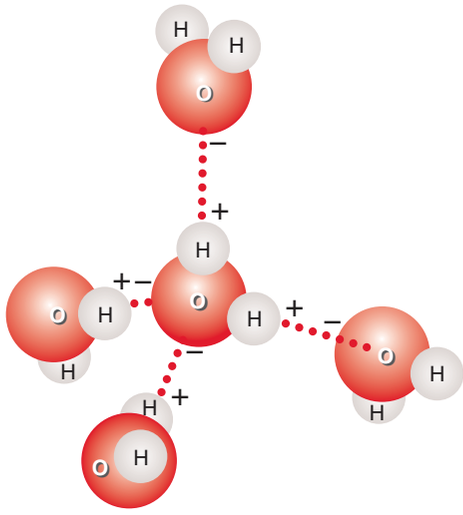

FIGURE **2-13** **Hydrogen bonding of water molecules.**
Each water molecule can form hydrogen bonds *(dotted lines)* with as many as four neighboring water molecules.

85% in brain cells; about 70% of our total body weight is water. As much as 95% of a jellyfish and certain plants is water. Water is the source, through photosynthesis, of the oxygen in the air we breathe, and its hydrogen atoms become incorporated into many organic compounds. Water is also the solvent for most biological reactions and a reactant or product in many chemical reactions.

Water is important not only as an internal constituent of organisms but also as one of the principal environmental factors affecting them (Fig. 2-12). Many organisms live in the ocean or in freshwater rivers, lakes, or puddles. Water's unique combination of physical and chemical properties is considered to have been essential to the origin of life, as well as to the continued survival and evolution of life on Earth.

As discussed, water molecules are polar; that is, one end of each molecule bears a partial positive charge and the other a partial negative charge (see Fig. 2-7). The water molecules in liquid water and in ice associate by hydrogen bonds. The hydrogen atom of one water molecule, with its partial positive charge, is attracted to the oxygen atom of a neighboring water molecule, with its partial negative charge, forming a hydrogen bond. An oxygen atom in a water molecule has two regions of partial negative charge, and each of the two hydrogen atoms has a partial positive charge. Each water molecule can therefore form hydrogen bonds with a maximum of four neighboring water molecules (Fig. 2-13).

Because its molecules are polar, water is an excellent solvent, a liquid capable of dissolving many different kinds of substances, especially polar and ionic compounds. Earlier we discussed how polar water molecules pull the ions of ionic compounds apart so that they dissociate (see Fig. 2-10). Because of its solvent properties and the tendency of the atoms in certain compounds to form ions in solution, water plays an important role in facilitating chemical reactions. Substances that interact readily with water are **hydrophilic** ("water-loving"). Examples include table sugar (sucrose, a polar compound) and table salt (NaCl, an ionic compound), which dissolve readily in water. Not all substances in organisms are hydrophilic, however. Many **hydrophobic** ("water-fearing") substances found in living things are especially important, because of their ability to form associations or structures that are not disrupted or dissolved by water. Examples are fats and other nonpolar substances (see Chapter 3).

Water molecules have a strong tendency to stick to each other, a property known as **cohesion.** This is due to the hydrogen bonds among the molecules. Because of the cohesive nature of water molecules, any force exerted on part of a column of water is transmitted to the column as a whole. The major mechanism of water movement in plants (see Chapter 33) depends on the cohesive nature of water. Water molecules also display **adhesion,** the ability to stick to many other kinds of substances, most notably those with charged groups of atoms or molecules on their surfaces. These adhesive forces explain how water makes things wet.

A combination of adhesive and cohesive forces accounts for **capillary action,** which is the tendency of water to move in narrow tubes, even against the force of gravity (Fig. 2-14). For example, water moves through the microscopic spaces between soil particles to the roots of plants by capillary action.

Water has a high degree of **surface tension** because of the cohesion of its molecules, which have a much greater attraction for each other than for molecules in the air. Thus water molecules at the surface crowd together, producing a strong layer as they are pulled downward by the attraction of other water molecules beneath them (Fig. 2-15).

Water helps maintain a stable temperature

Hydrogen bonding explains the way water responds to changes in temperature. Water exists in three forms, which differ in their

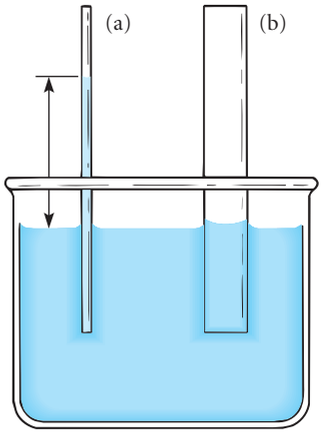

FIGURE **2-14** **Capillary action.**

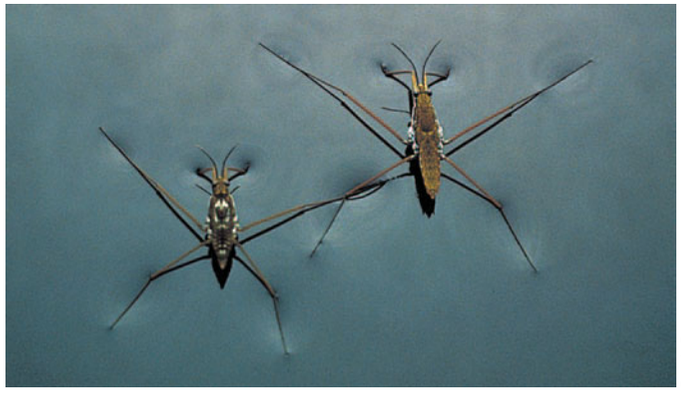
(a) In a narrow tube, there is adhesion between the water molecules and the glass wall of the tube. Other water molecules inside the tube are then "pulled along" because of cohesion, which is due to hydrogen bonds between the water molecules. **(b)** In the wider tube, a smaller percentage of the water molecules line the glass wall. As a result, the adhesion is not strong enough to overcome the cohesion of the water molecules beneath the surface level of the container, and water in the tube rises only slightly.



Dennis Drenner

FIGURE **2-15** **Surface tension of water.**

Hydrogen bonding between water molecules is responsible for the surface tension of water, which is strong enough to support these water striders (*Gerris*) and causes the dimpled appearance of the surface. Although water striders are denser than water, these insects can walk on the surface of a pond, because fine hairs at the ends of their legs spread their weight over a large area.

degree of hydrogen bonding: gas (vapor), liquid, and ice, a crystalline solid (Fig. 2-16). Hydrogen bonds are formed or broken as water changes from one state to another.

Raising the temperature of a substance involves adding heat energy to make its molecules move faster, that is, to increase the energy of motion—**kinetic energy**—of the molecules (see Chapter 6). The term **heat** refers to the *total* amount of kinetic energy in a sample of a substance; **temperature** is a measure of the *average* kinetic energy of the particles. For the molecules to move more freely, some of the hydrogen bonds of water must be broken. Much of the energy added to the system is used up in breaking the hydrogen bonds, and only a portion of the heat energy is available to speed the movement of the water molecules, thereby increasing the temperature of the water. Conversely, when liquid water changes to ice, additional hydrogen bonds must be formed, making the molecules less free to move, and liberating a great deal of heat into the environment.

Heat of vaporization, the amount of heat energy required to change 1 g of a substance from the liquid phase to the vapor phase, is expressed in units called *calories.* A **calorie (cal)** is the amount of heat energy (equivalent to 4.184 joules [J]) required to raise the temperature of 1 g of water 1 degree Celsius (C). Water has a high heat of vaporization—540 cal—because its molecules are held together by hydrogen bonds. The heat of vaporization of most other common liquid substances is much less. As a sample of water is heated, some molecules are moving much faster than others (they have more heat energy). These faster-moving molecules are more likely to escape the liquid phase and enter the vapor phase (see Fig. 2-16a). When they do, they take their heat energy with them, lowering the temperature of the sample, a process called **evaporative cooling.** For this reason, the human body can dissipate excess heat as sweat evaporates from the skin, and a leaf can keep cool in the bright sunlight as water evaporates from its surface.

Hydrogen bonding is also responsible for water's high **specific heat;** that is, the amount of energy required to raise the temperature of water is quite large. The specific heat of water is 1 cal/g of water per degree Celsius. Most other common substances such as metals, glass, and ethyl alcohol have much lower specific heat values. The specific heat of ethyl alcohol, for example, is 0.59 cal/g/1°C (2.46 J/g/1°C).

Because so much heat input is required to raise the temperature of water (and so much heat is lost when the temperature is lowered), the oceans and other large bodies of water have relatively constant temperatures. Thus, many organisms living in the ocean are provided with a relatively constant environmental temperature. The properties of water are crucial in stabilizing temperatures on Earth's surface. Although surface water is only a thin film relative to Earth's volume, the quantity is enormous compared to the exposed land mass. This relatively large mass of water resists both the warming effect of heat and the cooling effect of low temperatures.

Hydrogen bonding causes ice to have unique properties with important environmental consequences. Liquid water expands as it freezes because the hydrogen bonds joining the water molecules in the crystalline lattice keep the molecules far enough apart to give ice a density about 10% less than the density of liquid water (see Fig. 2-16c). When ice has been heated enough to raise its temperature above 0°C (32°F), the hydrogen bonds are broken, freeing the molecules to slip closer together. The density of water is greatest at 4°C, above which water begins to expand again as the speed of its molecules increases. As a result, ice floats on the denser cold water.

This unusual property of water has been important to the evolution of life. If ice had a greater density than water, it would sink; eventually all ponds, lakes, and even the ocean would freeze

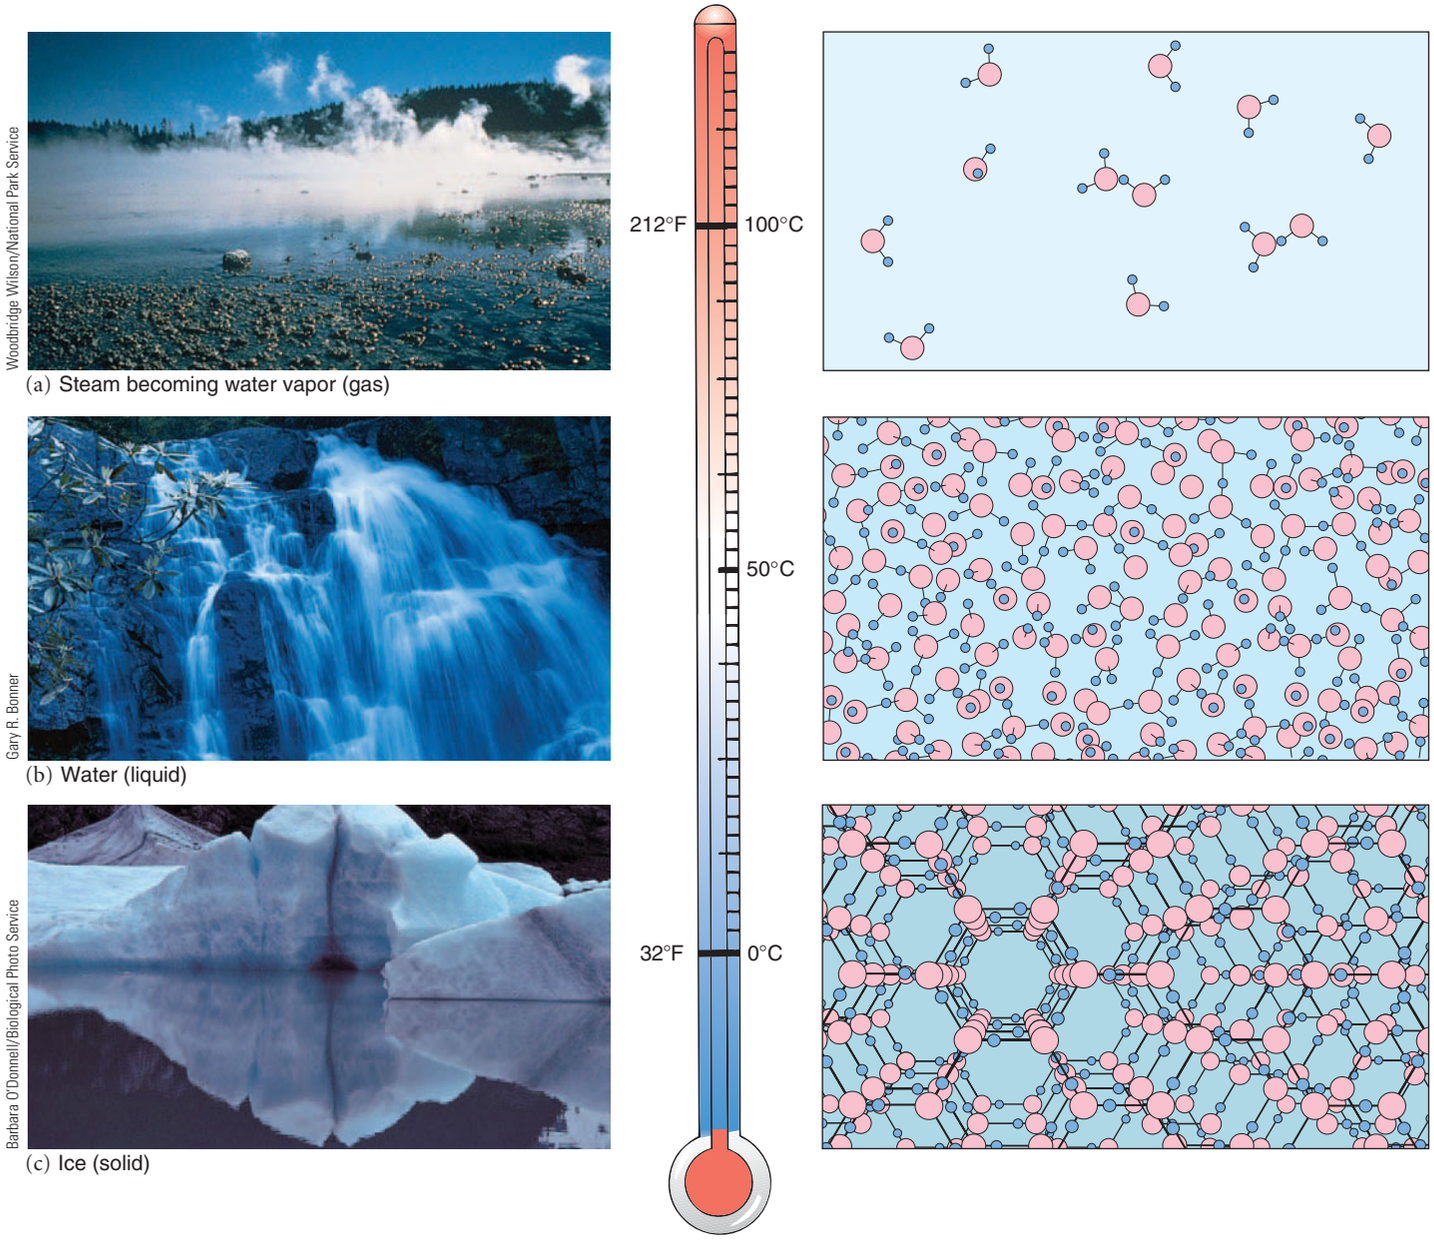


FIGURE **2-16** **Three forms of water.**

(a) When water boils, as in this hot spring at Yellowstone National Park, many hydrogen bonds are broken, causing steam, consisting of minuscule water droplets, to form. If most of the remaining hydrogen bonds break, the molecules move more freely as water vapor (a gas). **(b)** Water molecules in a liquid state continually form, break, and re-form hydrogen bonds with each other. **(c)** In ice, each water molecule participates in four hydrogen bonds with adjacent molecules, resulting in a regular, evenly distanced crystalline lattice structure.

solid from the bottom to the surface, making life impossible. When a deep body of water cools, it becomes covered with floating ice. The ice insulates the liquid water below it, retarding freezing and permitting organisms to survive below the icy surface.

The high water content of organisms helps them maintain relatively constant internal temperatures. Such minimizing of temperature fluctuations is important because biological reactions can take place only within a relatively narrow temperature range.

Review

- Why does water form hydrogen bonds?
- What are some properties of water that result from hydrogen bonding? How do these properties contribute to the role of water as an essential component of organisms?
- How can weak forces, such as hydrogen bonds, have significant effects in organisms?

BiologyNow™ Assess your understanding of **water** by taking the pretest on your BiologyNow CD-ROM.

ACIDS, BASES, AND SALTS

Learning Objectives

10 Contrast acids and bases, and discuss their properties.

11 Convert the hydrogen ion concentration (moles per liter) of a solution to a pH value, and describe how buffers help minimize changes in pH.

12 Describe the composition of a salt, and explain why salts are important in organisms.

Water molecules have a slight tendency to **ionize,** that is, to dissociate into hydrogen ions (H^+) and hydroxide ions (OH^-). The H^+ immediately combines with a negatively charged region of a water molecule, forming a hydronium ion (H_3O^+). However, by convention, H^+, rather than the more accurate H_3O^+, is used. In pure water, a small number of water molecules ionize. This slight tendency of water to dissociate is reversible as hydrogen ions and hydroxide ions reunite to form water:

$$HOH \rightleftharpoons H^+ + OH^-$$

Because each water molecule splits into one hydrogen ion and one hydroxide ion, the concentrations of hydrogen ions and hydroxide ions in pure water are exactly equal (0.0000001 or 10^{-7} mol/L for each ion). Such a solution is said to be neutral, that is, neither acidic nor basic (alkaline).

An **acid** is a substance that dissociates in solution to yield hydrogen ions (H^+) and an anion.

$$\text{Acid} \rightarrow H^+ + \text{Anion}$$

An acid is a proton *donor.* (Recall that a hydrogen ion, or H^+, is nothing more than a proton.) Hydrochloric acid (HCl) is a common organic acid.

A **base** is defined as a proton *acceptor.* Most bases are substances that dissociate to yield a hydroxide ion (OH^-) and a cation when dissolved in water. A hydroxide ion can act as a base by accepting a proton (H^+) to form water. Sodium hydroxide (NaOH) is a common inorganic base.

$$NaOH \rightarrow Na^+ + OH^-$$

$$OH^- + H^+ \rightarrow H_2O$$

Some bases do not dissociate to yield hydroxide ions directly. For example, ammonia (NH_3) acts as a base by accepting a proton from water, producing an ammonium ion (NH_4^+) and releasing a hydroxide ion.

$$NH_3 + H_2O \rightarrow NH_4^+ + OH^-$$

pH is a convenient measure of acidity

The degree of a solution's acidity is generally expressed in terms of **pH,** defined as the negative logarithm (base 10) of the hydrogen ion concentration (expressed in moles per liter):

$$pH = -\log_{10}[H^+]$$

The brackets refer to concentration; therefore, the term $[H^+]$ means "the concentration of hydrogen ions," which is expressed in moles per liter because we are interested in the *number* of hydrogen ions per liter. Because the range of possible pH values is broad, a logarithmic scale (with a 10-fold difference between successive units) is more convenient than a linear scale.

TABLE 2-2 **Calculating pH Values and Hydroxide Ion Concentrations from Hydrogen Ion Concentrations**

Substance	$[H^+]$*	log $[H^+]$	pH	$[OH^-]$†
Gastric juice	$0.01, 10^{-2}$	-2	2	10^{-12}
Pure water, neutral solution	$0.0000001, 10^{-7}$	-7	7	10^{-7}
Household ammonia	$0.00000000001, 10^{-11}$	-11	11	10^{-3}

*$[H^+]$ = hydrogen ion concentration (mol/L)

Hydrogen ion concentrations are nearly always less than 1 mol/L. One gram of hydrogen ions dissolved in 1 L of water (a 1-*M* solution) may not sound impressive, but such a solution would be extremely acidic. The logarithm of a number less than 1 is a negative number; thus the *negative* logarithm corresponds to a *positive* pH value. (Solutions with pH values less than zero can be produced but do not occur under biological conditions.)

Whole-number pH values are easy to calculate. For instance, consider our example of pure water, which has a hydrogen ion concentration of 0.0000001 (10^{-7}) mol/L. The logarithm is -7. The negative logarithm is 7; therefore, the pH is 7. Table 2-2 shows how to calculate pH values from hydrogen ion concentrations, and the reverse. For comparison, the table also includes the hydroxide ion concentrations, which can be calculated because the product of the hydrogen concentration and the hydroxide ion concentration is 1×10^{-14}:

$$[H^+][OH^-] = 1 \times 10^{-14}$$

Pure water is an example of a **neutral solution;** with a pH of 7, it has equal concentrations of hydrogen ions and hydroxide ions (10^{-7} moles per liter). An **acidic solution** has a hydrogen ion concentration that is higher than its hydroxide ion concentration and has a pH value of less than 7. For example, the hydrogen ion concentration of a solution with pH 1 is 10 times that of a solution with pH 2. A **basic solution** has a hydrogen ion concentration that is lower than its hydroxide ion and has a pH greater than 7.

The pH values of some common substances are shown in Figure 2-17. Although some very acidic compartments exist within cells (see Chapter 4), most of the interior of an animal or plant cell is neither strongly acidic nor strongly basic but an essentially neutral mixture of acidic and basic substances. Although certain bacteria are adapted to life in extremely acidic environments (see Chapter 23), a substantial change in pH is incompatible with life for most cells. The pH of most types of plant and animal cells (and their environment) ordinarily ranges from around 7.2 to 7.4.

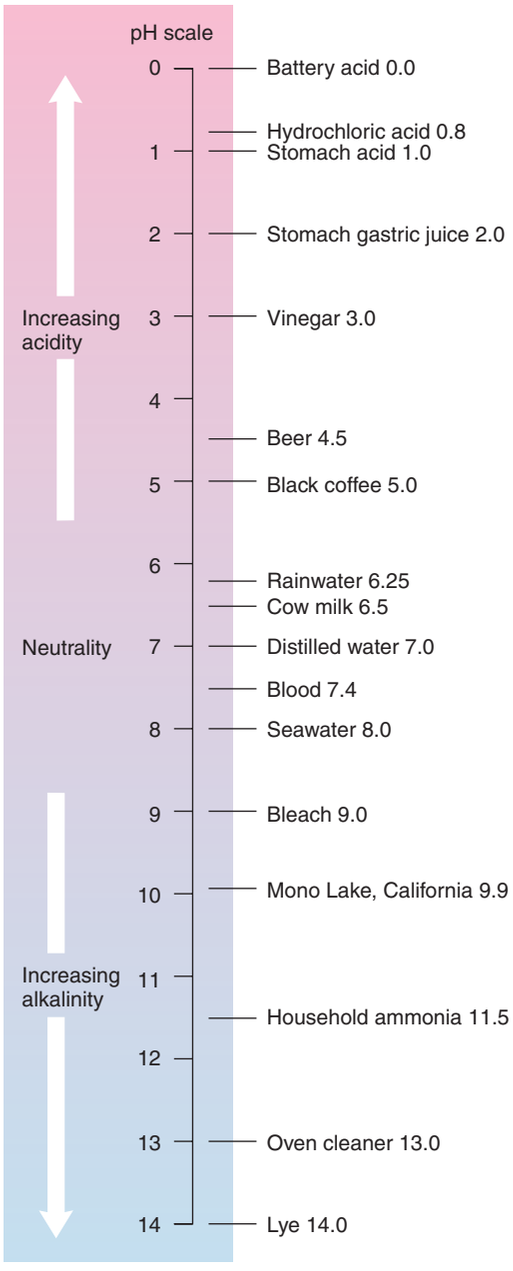

FIGURE **2-17** **pH values of some common solutions.**

A neutral solution (pH 7) has equal concentrations of H^+ and OH^-. Acidic solutions, which have a higher concentration of H^+ than OH^-, have pH values lower than 7; pH values higher than 7 characterize basic solutions, which have an excess of OH^-.

Buffers minimize pH change

Many homeostatic mechanisms operate to maintain appropriate pH values. For example, the pH of human blood is about 7.4 and must be maintained within very narrow limits. If the blood becomes too acidic (for example, as a result of respiratory disease), coma and death may result. Excessive alkalinity can result in overexcitability of the nervous system and even convulsions. Organisms contain many natural buffers. A **buffer** is a substance or combination of substances that resists changes in pH when an acid or base is added. A buffering system includes a weak acid or a weak base. A weak acid or weak base does not ionize completely. At any given instant, only a fraction of the molecules are ionized; most are not dissociated.

One of the most common buffering systems functions in the blood of vertebrates (see Chapter 44). Carbon dioxide, produced as a waste product of cell metabolism, enters the blood, the main constituent of which is water. The carbon dioxide reacts with the water to form carbonic acid, a weak acid that dissociates to yield a hydrogen ion and a bicarbonate ion. The following expression describes the buffering system:

$$\underset{\text{Carbon dioxide}}{CO_2} + \underset{\text{Water}}{H_2O} \rightleftharpoons \underset{\text{Carbonic acid}}{H_2CO_3} \rightleftharpoons H^+ + \underset{\text{Bicarbonate ion}}{HCO_3^-}$$

As the double arrows indicate, all the reactions are reversible. Because carbonic acid is a weak acid, undissociated molecules are always present, as are all the other components of the system. The expression describes the system when it is at *dynamic equilibrium,* that is, when the rates of the forward and reverse reactions are equal and the relative concentrations of the components are not changing. A system at dynamic equilibrium tends to stay at equilibrium unless a stress is placed on it, which causes it to shift to reduce the stress until it attains a new dynamic equilibrium. A change in the concentration of any component is one such stress. Therefore, the system can be "shifted to the right" by adding reactants or removing products. Conversely, it can be "shifted to the left" by adding products or removing reactants.

Hydrogen ions are the important products to consider in this system. The addition of excess hydrogen ions temporarily shifts the system to the left, as they combine with the bicarbonate ions to form carbonic acid. Eventually a new dynamic equilibrium is established. At this point the hydrogen ion concentration is similar to the original concentration, and the product of the hydrogen ion and hydroxide ion concentrations is restored to the equilibrium value of 1×10^{-14}.

If hydroxide ions are added, they combine with the hydrogen ions to form water, effectively removing a product and thus shifting the system to the right. More carbonic acid then ionizes, replacing the hydrogen ions that were removed.

Organisms contain many weak acids and weak bases, which allows them to maintain an essential reserve of buffering capacity and helps them avoid pH extremes.

An acid and a base react to form a salt

When an acid and a base are mixed together in water, the H^+ of the acid unites with the OH^- of the base to form a molecule of water. The remainder of the acid (an anion) combines with the remainder of the base (a cation) to form a salt. For example, hydrochloric acid reacts with sodium hydroxide to form water and sodium chloride:

$$HCl + NaOH \rightarrow H_2O + NaCl$$

A **salt** is a compound in which the hydrogen ion of an acid is replaced by some other cation. Sodium chloride, NaCl, is a salt in which the hydrogen ion of HCl has been replaced by the cation Na^+.

When a salt, an acid, or a base is dissolved in water, its dissociated ions can conduct an electrical current; these substances are called **electrolytes.** Sugars, alcohols, and many other substances do not form ions when dissolved in water; they do not conduct an electrical current and are referred to as **nonelectrolytes.**

Cells and extracellular fluids (such as blood) of animals and plants contain a variety of dissolved salts that are the source of the many important mineral ions essential for fluid balance and acid–base balance. The concentrations and relative amounts of the various cations and anions are kept remarkably constant. Any marked change results in impaired cell functions and may lead to death. Nitrate and ammonium ions from the soil are the important nitrogen sources for plants. In animals, nerve and muscle function, blood clotting, bone formation, and many other aspects of body function depend on ions. Sodium, potassium, calcium, and magnesium are the chief cations present; chloride, bicarbonate, phosphate, and sulfate are important anions.

Review

- A solution has a hydrogen ion concentration of 0.01 mol/L. What is its pH? What is its hydroxide ion concentration? Is it acidic, basic, or neutral? How does this solution differ from one with a pH of 1?
- What would be the consequences of adding or removing a reactant or a product from a reversible reaction that is at dynamic equilibrium?
- Why are buffers important in organisms? Why can't strong acids or bases work as buffers?
- Why are acids, bases, and salts referred to as *electrolytes?*

BiologyNow™ Assess your understanding of **acids, bases, and salts** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Name the principal chemical elements in living things, and give an important function of each.

- An **element** is a substance that cannot be decomposed into simpler substances by normal chemical reactions. About 96% of an organism's mass consists of carbon, the backbone of organic molecules; hydrogen and oxygen, the components of water; and nitrogen, a component of proteins and nucleic acids.

2 Compare the physical properties (mass and charge) and locations of electrons, protons, and neutrons; distinguish between the atomic number and the mass number of an element.

- Each **atom** is composed of a **nucleus** containing positively charged **protons** and uncharged **neutrons.** Negatively charged **electrons** encircle the nucleus.
- An atom is identified by its number of protons (**atomic number**). The **atomic mass** of an atom is equal to the sum of its protons and neutrons.
- A single proton or a single neutron each has a mass equivalent to one **atomic mass unit.** The mass of a single electron is only about 1/1800 amu.

3 Define the terms *orbital* and *electron shell,* and relate electron shells to principal energy levels.

- In the space outside the nucleus, electrons move rapidly in electron **orbitals.** An **electron shell** consists of electrons in orbitals at the same **principal energy level.** Electrons in a shell distant from the nucleus have greater energy than those in a shell closer to the nucleus.

4 Explain how the number of valence electrons of an atom is related to its chemical properties.

- The chemical properties of an atom are determined chiefly by the number and arrangement of its most energetic electrons, known as **valence electrons.** The valence shell of most atoms is full when it contains 8 electrons; that of hydrogen or helium is full when it contains 2. An atom tends to lose, gain, or share electrons to fill its valence shell.

5 Distinguish among simplest, molecular, and structural chemical formulas.

- Different atoms are joined by chemical bonds to form **compounds.** A **chemical formula** gives the types and relative numbers of atoms in a substance.
- A **simplest formula** gives the smallest whole-number ratio of the component atoms. A **molecular formula** gives the actual numbers of each type of atom in a molecule. A **structural formula** shows the arrangement of the atoms in a molecule.

6 Explain why the mole concept is so useful to chemists.

- One **mole** (the atomic or molecular mass in grams) of any substance contains 6.02×10^{23} atoms, molecules, or ions, enabling scientists to "count" particles by weighing a sample. This number is known as **Avogadro's number.**

7 Distinguish among covalent bonds, ionic bonds, and hydrogen bonds. Compare them in terms of the mechanisms by which they form and their relative bond strengths.

- **Covalent bonds** are strong, stable bonds formed when atoms share **valence electrons,** forming molecules. When covalent bonds are formed, the orbitals of the valence electrons may become rearranged in a process known as **orbital hybridization.** Covalent bonds are **nonpolar** if the electrons are shared equally between the two atoms. Covalent bonds are **polar** if one atom is more **electronegative** (has a greater affinity for electrons) than the other.
- An **ionic bond** is formed between a positively charged **cation** and a negatively charged **anion.** Ionic bonds are strong in the absence of water but relatively weak in aqueous solution.
- **Hydrogen bonds** are relatively weak bonds formed when a hydrogen atom with a partial positive charge is attracted to an atom (usually oxygen or nitrogen) with a partial negative charge already bonded to another molecule or in another part of the same molecule.

8 Distinguish between the terms *oxidation* and *reduction,* and relate these processes to the transfer of energy.

SUMMARY WITH KEY TERMS *(continued)*

- **Oxidation** and **reduction** reactions (**redox reactions**) are chemical processes in which electrons (and their energy) are transferred from a reducing agent to an oxidizing agent. In oxidation, an atom, ion, or molecule loses electrons (and their energy). In reduction, an atom, ion, or molecule gains electrons (and their energy).

9 Explain how hydrogen bonds between adjacent water molecules govern many of the properties of water.

- Water is a **polar molecule** because one end has a partial positive charge and the other has a partial negative charge. Because its molecules are polar, water is an excellent **solvent** for ionic or polar **solutes.**
- Water molecules exhibit the property of **cohesion** because they form hydrogen bonds with each other; they also exhibit **adhesion** through hydrogen bonding to substances with ionic or polar regions.
- Because hydrogen bonds must be broken to raise its temperature, water has a high **specific heat,** which helps organisms maintain a relatively constant internal temperature; this property also helps keep the ocean and other large bodies of water at a constant temperature.
- Water has a high **heat of vaporization.** Hydrogen bonds must be broken for molecules to enter the vapor phase. These molecules carry a great deal of heat, which accounts for **evaporative cooling.**
- The hydrogen bonds between water molecules in ice cause it to be less dense than liquid water. The fact that ice floats makes the aquatic environment less extreme than it would be if ice sank to the bottom.

10 Contrast acids and bases, and discuss their properties.

- **Acids** are proton (hydrogen ion, H^+) donors; **bases** are proton acceptors. An acid dissociates in solution to yield H^+ and an anion. Many bases dissociate in solution to yield hydroxide ions (OH^-), which then accept protons to form water.

11 Convert the hydrogen ion concentration (moles per liter) of a solution to a pH value, and describe how buffers help minimize changes in pH.

- The **pH scale** is the negative log of the hydrogen ion concentration of a solution (expressed in moles per liter). A **neutral solution** with equal concentrations of H^+ and OH^- (10^{-7} moles per liter) has a pH of 7, an **acidic solution** has a pH less than 7, and a **basic solution** has a pH greater than 7.
- A buffering system is based on a weak acid or a weak base. A **buffer** resists changes in the pH of a solution when acids or bases are added.

12 Describe the composition of a salt, and explain why salts are important in organisms.

- A **salt** is a compound in which the hydrogen atom of an acid is replaced by some other cation. Salts provide the many mineral ions essential for life functions.

POST-TEST

1. Which of the following elements is *mismatched* with its properties or function? (a) carbon—forms the backbone of organic compounds (b) nitrogen—component of proteins (c) hydrogen—very electronegative (d) oxygen—can participate in hydrogen bonding (e) all of the above are correctly matched
2. Which of the following applies to a neutron? (a) positive charge and located in an orbital (b) negligible mass and located in the nucleus (c) positive charge and located in the nucleus (d) uncharged and located in the nucleus (e) uncharged and located in an orbital
3. $^{32}_{15}P$, a radioactive form of phosphorus, has (a) an atomic number of 32 (b) an atomic mass of 15 (c) an atomic mass of 47 (d) 32 electrons (e) 17 neutrons
4. Which of the following facts allows you to determine that atom A and atom B are isotopes of the same element? (a) they each have 6 protons (b) they each have 4 neutrons (c) in each, the sum of their electrons and neutrons is 14 (d) they each have 4 valence electrons (e) they each have an atomic mass of 14
5. $^{1}_{1}H$ and $^{3}_{1}H$ have (a) different chemical properties, because they have different atomic numbers (b) the same chemical properties, because they have the same number of valence electrons (c) different chemical properties, because they differ in their number of protons and electrons (d) the same chemical properties, because they have the same atomic mass (e) the same chemical properties, because they have the same number of protons, electrons, and neutrons.
6. Sodium and potassium atoms behave similarly in chemical reactions. This is because (a) they have the same number of neutrons (b) each has a single valence electron (c) they have the same atomic mass (d) they have the same number of electrons (e) they have the same number of protons
7. The orbitals comprising an atom's valence electron shell (a) are arranged as concentric spheres (b) contain the atom's least energetic electrons (c) may change shape when covalent bonds are formed (d) never contain more than 1 electron each (e) more than one of the preceding is correct
8. Which of the following bonds and properties are correctly matched? (a) ionic bonds—strong only if the participating ions are hydrated (b) hydrogen bonds—responsible for bonding oxygen and hydrogen to form a single water molecule (c) polar covalent bonds—can occur between two atoms of the same element (d) covalent bonds—may be single, double, or triple (e) hydrogen bonds—stronger than covalent bonds
9. In a redox reaction (a) energy is transferred from a reducing agent to an oxidizing agent (b) a reducing agent becomes oxidized as it accepts an electron (c) an oxidizing agent accepts a proton (d) a reducing agent donates a proton (e) the electrons in an atom move from its valence shell to a shell closer to its nucleus
10. Water has the property of adhesion because (a) hydrogen bonds form between adjacent water molecules (b) hydrogen bonds form between water molecules and hydrophilic substances (c) it has a high specific heat (d) covalent bonds hold an individual water molecule together (e) it has a great deal of kinetic energy
11. The high heat of vaporization of water accounts for (a) evaporative cooling (b) the fact that ice floats (c) the fact that heat is liberated when ice forms (d) the cohesive properties of water (e) capillary action

POST-TEST *(continued)*

12. Water has a high specific heat because (a) hydrogen bonds must be broken to raise its temperature (b) hydrogen bonds must be formed to raise its temperature (c) it is a poor insulator (d) it has low density considering the size of the molecule (e) it can ionize
13. A solution at pH 7 is considered neutral because (a) its hydrogen ion concentration is 0 mol/L (b) its hydroxide ion concentration is 0 mol/L (c) the product of its hydrogen ion concentration and its hydroxide ion concentration is 0 mol/L (d) its hydrogen ion concentration is equal to its hydroxide ion concentration (e) it is nonpolar
14. A solution with a pH of 2 has a hydrogen ion concentration that is _____ the hydrogen ion concentration of a solution with a pH of 4. (a) 1/2 (b) 1/100 (c) 2 times (d) 10 times (e) 100 times
15. Which of the following cannot function as a buffer? (a) phosphoric acid, a weak acid (b) sodium hydroxide, a strong base (c) sodium chloride, a salt that ionizes completely (d) a and c (e) b and c
16. NaOH and HCl react to form Na^+, Cl^-, and water. Which of the following statements is true? (a) Na^+ is an anion, and Cl^- is a cation (b) Na^+ and Cl^- are both anions (c) a hydrogen bond can form between Na^+ and Cl^- (d) Na^+ and Cl^- are electrolytes (e) Na^+ is an acid, and Cl^- is a base
17. Which of the following statements is true? (a) the number of individual particles (atoms, ions, or molecules) contained in one mole varies depending on the substance (b) Avogadro's number is the number of particles contained in one mole of a substance (c) Avogadro's number is 10^{23} particles (d) one mole of ^{12}C has a mass of 12 g (e) both b and d are true

CRITICAL THINKING

1. Element A has 2 electrons in its valence shell (which is complete when it contains 8 electrons). Would you expect element A to share, donate, or accept electrons? What would you expect of element B, which has 4 valence electrons, and element C, which has 7?
2. A hydrogen bond formed between two water molecules is only about 1/20 as strong as a covalent bond between hydrogen and oxygen. In what ways would the physical properties of water be different if these hydrogen bonds were stronger (for example, 1/10 the strength of covalent bonds)?
3. Consider the following reaction (in water).

   $Hcl \longrightarrow H^+ + Cl^-$

   Name the reactant(s) and product(s). Does the expression indicate the reaction is reversible? Could HCl be used as a buffer?

The Chemistry of Life: Organic Compounds

© Momatiuk Eastcott/The Image Works

This young girl is using a leaf to feed her baby brother.

CHAPTER OUTLINE

- Carbon Atoms and Molecules
- Carbohydrates
- Lipids
- Proteins
- Nucleic Acids
- Identifying Biological Molecules

Both inorganic and organic forms of carbon occur widely in nature. Many types of organic compounds will become incorporated into the body of the baby in the photograph as he grows. **Organic compounds** are those in which carbon atoms are covalently bonded to each other to form the backbone of the molecule. Some very simple carbon compounds are considered inorganic if the carbon is not bonded to another carbon or to hydrogen. The carbon dioxide we exhale as a waste product from the breakdown of organic molecules to obtain energy is an example of inorganic carbon. Organic compounds are so named because at one time it was thought that they could be produced only by living (organic) organisms. In 1928 the German chemist Friedrich Wühler synthesized urea, a metabolic waste product. Since that time, scientists have learned to synthesize many organic molecules and have discovered organic compounds not found in any organism.

Organic compounds are extraordinarily diverse; in fact, more than 5 million have been identified. There are many reasons for this diversity. Organic compounds can be produced in a wide variety of three-dimensional (3-D) shapes. Furthermore, the carbon atom can form bonds with a greater number of different elements than any other type of atom. The addition of chemical groups containing atoms of other elements—especially oxygen, nitrogen, phosphorus, and sulfur—can profoundly change the properties of an organic molecule.

Diversity also results from the fact that a great many organic compounds found in organisms are extremely large *macromolecules,* which cells construct from simpler modular subunits. For example, protein molecules are built from smaller compounds called *amino acids.*

As you study this chapter, you will develop an understanding of the major groups of organic compounds found in organisms, including carbohydrates, lipids, proteins, and nucleic acids (DNA and RNA). Why are these compounds of central

importance to all living things? The most obvious answer is that they constitute the structures of cells and tissues. However, they are also responsible for a wide range of other equally important roles as they participate in and regulate metabolic reactions, transmit information, and provide energy for life processes. ■

CARBON ATOMS AND MOLECULES

Learning Objectives

1. Describe the properties of carbon that make it the central component of organic compounds.
2. Define the term *isomer,* and distinguish among the three principal isomer types.
3. Identify the major functional groups present in organic compounds, and describe their properties.
4. Explain the relationship between polymers and macromolecules.

Carbon has unique properties that allow the formation of the carbon backbones of the large, complex molecules essential to life (Fig. 3-1). Because a carbon atom has 4 valence electrons, it can complete its valence shell by forming a total of four covalent bonds (see Fig. 2-2). Each bond can link it to another carbon atom or to an atom of a different element. Carbon is particularly well suited to serve as the backbone of a large molecule because carbon-to-carbon bonds are strong and not easily broken. However, they are not so strong that it would be impossible for cells to break them. Carbon-to-carbon bonds are not limited to single bonds (based on sharing one electron pair). Two carbon atoms can share two electron pairs with each other, forming double bonds:

In some compounds, triple carbon-to-carbon bonds are formed:

As shown in Figure 3-1, **hydrocarbons,** organic compounds consisting only of carbon and hydrogen, can exist as unbranched or branched chains, or as rings. Rings and chains are joined in some compounds.

The molecules in the cell are analogous to the components of a machine. Each component has a shape that allows it to fill certain roles and to interact with other components (often with a complementary shape). Similarly, the shape of a molecule is important in determining its biological properties and function. Carbon atoms are able to link to each other and to other atoms, to produce a wide variety of 3-D molecular shapes. This is because the four covalent bonds of carbon do not form in a single plane. Instead, as discussed in Chapter 2, the valence electron orbitals become elongated and project from the carbon atom toward the corners of a tetrahedron (Fig. 3-2). The structure is highly symmetrical, with an angle of about 109.5 degrees between any two of these bonds. Keep in mind that, for simplicity, many of the figures in this book are drawn as two-dimensional (2-D) graphic representations of 3-D molecules. Even the simplest hydrocarbon chains, such as those in Figure 3-1, are not actually straight but have a 3-D zigzag structure.

Generally, there is freedom of rotation around each carbon-to-carbon single bond. This property permits organic molecules to be flexible and to assume a variety of shapes, depending on the extent to which each single bond is rotated. Double and triple

(a) The 3-D arrangement of the bonds of a carbon atom is responsible for **(b)** the tetrahedral architecture of methane. **(c)** In carbon dioxide, oxygen atoms are joined linearly to a central carbon by polar double bonds.

bonds do not allow rotation, so regions of a molecule with such bonds tend to be inflexible.

Isomers have the same molecular formula, but different structures

One reason for the great number of possible carbon-containing compounds is the fact that the same components usually can link together in more than one pattern, generating an even wider variety of molecular shapes. Compounds with the same molecular formulas, but different structures and thus different properties, are called **isomers.** Isomers do not have identical physical or chemical properties and may have different common names. Cells can distinguish between isomers. Usually, one isomer is biologically active and the other is not. Three types of isomers are structural isomers, geometric isomers, and enantiomers.

Structural isomers are compounds that differ in the covalent arrangements of their atoms. For example, Figure 3-3a illustrates two structural isomers with the molecular formula C_2H_6O. Similarly, there are two structural isomers of the four-carbon hydrocarbon butane (C_4H_{10}), one with a straight chain and the other with a branched chain (isobutane). Large compounds have more possible structural isomers. There are only two structural isomers of butane, but there can be up to 366,319 isomers of $C_{20}H_{42}$.

Geometric isomers are compounds that are identical in the arrangement of their covalent bonds but different in the spatial arrangement of atoms or groups of atoms. Geometric isomers are present in some compounds with carbon-to-carbon double bonds. Because double bonds are not flexible like single bonds, atoms joined to the carbons of a double bond cannot rotate freely about the axis of the bonds. These *cis–trans* isomers may be represented as shown in Figure 3-3b. The designation *cis* (Latin, "on this side") indicates that the two larger components are on the same side of the double bond. If they are on opposite sides of the double bond, the compound is designated a *trans* (Latin, "across") isomer.

Enantiomers are molecules that are mirror images of one another (Fig. 3-3c). Recall that the four groups bonded to a single carbon atom are arranged at the vertices of a tetrahedron. If the four bonded groups are all different, the central carbon is described as asymmetrical. Figure 3-3c illustrates that the four

FIGURE **3-3** **Isomers.**

Isomers have the same molecular formula, but their atoms are arranged differently. **(a)** Structural isomers differ in the covalent arrangement of their atoms. **(b)** Geometric, or *cis–trans*, isomers have identical covalent bonds but differ in the order in which groups of atoms are arranged in space. **(c)** Enantiomers are isomers that are mirror images of one another. The central carbon is asymmetrical because it is bonded to four different groups. Because of their 3-D structure, the two figures cannot be superimposed no matter how they are rotated.

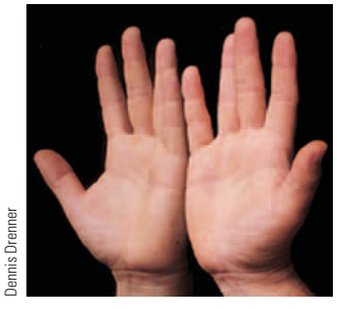
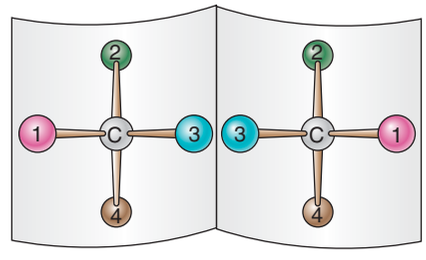
(b) Geometric isomers



Dennis Drenner



(c) Enantiomers

groups can be arranged about the asymmetrical carbon in two different ways that are mirror images of each other. The two molecules are enantiomers if they cannot be superimposed on one another no matter how they are rotated in space. Although enantiomers have similar chemical properties and most of their physical properties are identical, cells recognize the difference in shape, and usually only one form is found in organisms.

Functional groups change the properties of organic molecules

The existence of isomers is not the only source of variety among organic molecules. The addition of various combinations of atoms generates a vast array of molecules with differing properties.

TABLE 3-1 Some Biologically Important Functional Groups

Functional Group and Description	Structural Formula		Class of Compound Characterized by Group
Hydroxyl Polar because electronegative oxygen attracts covalent electrons	$R{-}OH$		Alcohols  Example, ethanol
Carbonyl Aldehydes: Carbonyl group carbon is bonded to at least one H atom; polar because electronegative oxygen attracts covalent electrons			Aldehydes  Example, formaldehyde
Ketones: Carbonyl group carbon is bonded to two other carbons; polar because electronegative oxygen attracts covalent electrons			Ketones  Example, acetone
Carboxyl Weakly acidic; can release an H^+ ion	 Non-ionized	 Ionized	Carboxylic acids (organic acids)  Example, amino acid
Amino Weakly basic; can accept an H^+ ion	 Non-ionized	 Ionized	Amines  Example, amino acid
Phosphate Weakly acidic; one or two H^+ ions can be released	 Non-ionized	 Ionized	Organic Phosphates  Example, phosphate ester (as found in ATP)
Sulfhydryl Helps stabilize internal structure of proteins	$R-SH$		Thiols  Example, cysteine

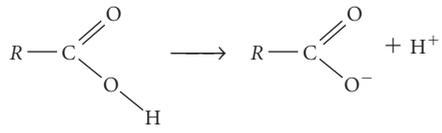
Because covalent bonds between hydrogen and carbon are nonpolar, hydrocarbons lack distinct charged regions. For this reason, hydrocarbons are insoluble in water and tend to cluster together, through **hydrophobic** interactions. "Water fearing," the literal meaning of the term *hydrophobic,* is somewhat misleading. Hydrocarbons interact with water, but much more weakly than the water molecules cohere to each other through hydrogen bonding. Hydrocarbons interact weakly with each other, but the main reason for hydrophobic interactions is that they are driven together in a sense, having been excluded by the hydrogen-bonded water molecules. However, the characteristics of an organic molecule can be changed dramatically by replacing one of the hydrogens with one or more **functional groups,** groups of atoms that determine the types of chemical reactions and associations in which the compound participates. Most functional groups readily form associations, such as ionic and hydrogen bonds, with other molecules. Polar and ionic functional groups are **hydrophilic** because they associate strongly with polar water molecules.

The properties of the major classes of biologically important organic compounds—carbohydrates, lipids, proteins, and nucleic acids—are largely a consequence of the types and arrangement of functional groups they contain. When we know what kinds of functional groups are present in an organic compound, we can predict its chemical behavior. Note that the symbol *R* is used to represent the *remainder* of the molecule of which each functional group is a part. For example, the **methyl group,** a common nonpolar hydrocarbon group, is abbreviated $R—CH_3$. As you read the rest of this section, refer to Table 3-1 for the complete structural formulas of other important functional groups, as well as additional information.

The **hydroxyl group** (abbreviated *R*—OH) is polar because of the presence of a strongly electronegative oxygen atom. (Do not confuse it with the hydroxide ion, OH^-, discussed in Chapter 2.) If a hydroxyl group replaces one hydrogen of a hydrocarbon, the resulting molecule can have significantly altered properties. For example, ethane (see Fig. 3-1a) is a hydrocarbon that is a gas at room temperature. If a hydroxyl group replaces a hydrogen atom, the resulting molecule is ethyl alcohol, or ethanol, which is found in alcoholic beverages (Fig. 3-3a). Ethanol is somewhat cohesive, because the polar hydroxyl groups of adjacent molecules interact; it is therefore liquid at room temperature. Unlike ethane, ethyl alcohol dissolves in water because the polar hydroxyl groups interact with the polar water molecules.

The **carbonyl group** consists of a carbon atom that has a double covalent bond with an oxygen atom. This double bond is polar because of the electronegativity of the oxygen; thus the carbonyl group is hydrophilic. The position of the carbonyl group in the molecule determines the class to which the molecule belongs. An **aldehyde** has a carbonyl group positioned at the end of the carbon skeleton (abbreviated *R*—CHO); a **ketone** has an internal carbonyl group (abbreviated *R*—CO—*R*).

The **carboxyl group** (abbreviated *R*—COOH) in its non-ionized form consists of a carbon atom joined by a double covalent bond to an oxygen atom, and by a single covalent bond to another oxygen, which is in turn bonded to a hydrogen atom. Two electronegative oxygen atoms in such close proximity establish an extremely polarized condition, which can cause the hydrogen atom to be stripped of its electron and released as a hydrogen ion (H^+). The resulting ionized carboxyl group has 1 unit of negative charge ($R—COO^-$):



Carboxyl groups are weakly acidic; only a fraction of the molecules ionize in this way. This group therefore exists in one of two hydrophilic states: ionic or polar. Carboxyl groups are essential constituents of amino acids.

An **amino group** (abbreviated $R—NH_2$) in its non-ionized form includes a nitrogen atom covalently bonded to two hydrogen atoms. Amino groups are weakly basic because they are able to accept a hydrogen ion (proton). The resulting ionized amino group has one unit of positive charge ($R—NH_3^+$). Amino groups are components of amino acids and of nucleic acids.

A **phosphate group** (abbreviated $R—PO_4H_2$) is weakly acidic. The attraction of electrons by the oxygen atoms can result in the release of one or two hydrogen ions, producing ionized forms with one or two units of negative charge. Phosphates are constituents of nucleic acids and certain lipids.

The **sulfhydryl group** (abbreviated *R*—SH), consisting of an atom of sulfur covalently bonded to a hydrogen atom, is found in molecules called *thiols.* As you will see, amino acids that contain a sulfhydryl group can make important contributions to the structure of proteins.

Many biological molecules are polymers

Many biological molecules such as proteins and nucleic acids are very large, consisting of thousands of atoms. Such giant molecules are known as **macromolecules.** Most macromolecules are **polymers,** produced by linking small organic compounds called **monomers** (Fig. 3-4). Just as all the words in this

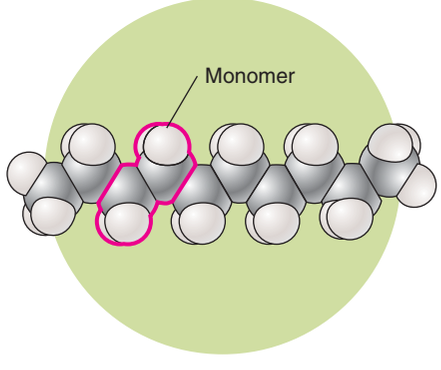


FIGURE **3-4** **A simple polymer.**

This small polymer of polyethylene is formed by linking two-carbon ethylene (C_2H_4) monomers. One such monomer is outlined in red. The structure is represented by a space-filling model, which accurately depicts the actual 3-D shape of the molecule.

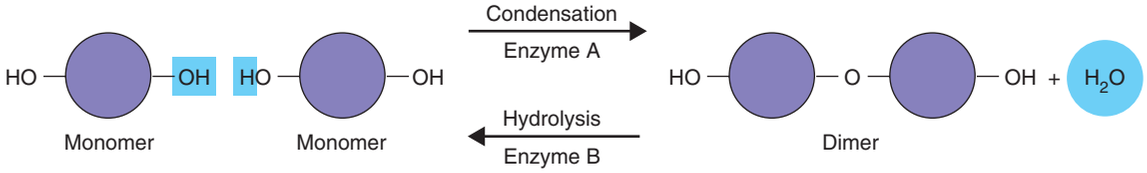

FIGURE **3-5** **Condensation and hydrolysis reactions.**
Joining two monomers yields a dimer; incorporating additional monomers produces a polymer. Note that condensation and hydrolysis reactions are catalyzed by different enzymes.

book have been written by arranging the 26 letters of the alphabet in various combinations, monomers can be grouped together to form an almost infinite variety of larger molecules. The thousands of different complex organic compounds present in organisms are constructed from about 40 small, simple monomers. For example, the 20 monomers called *amino acids* can be linked end-to-end in countless ways to form the polymers known as *proteins.*

Polymers can be degraded to their component monomers by **hydrolysis reactions** ("to break with water"). In a reaction regulated by a specific enzyme, (biological catalyst), a hydrogen from a water molecule attaches to one monomer, and a hydroxyl from water attaches to the adjacent monomer (Fig. 3-5).

Monomers are covalently linked by **condensation reactions.** Because the *equivalent* of a molecule of water is removed during the reactions that combine monomers, the term *dehydration synthesis* is sometimes used to describe condensation (see Fig. 3-5). However, in biological systems the synthesis of a polymer is not simply the reverse of hydrolysis, even though the net effect is the opposite of hydrolysis. Synthetic processes such as condensation require energy and are regulated by different enzymes.

In the following sections we examine carbohydrates, lipids, proteins, and nucleic acids. Our discussion begins with the smaller, simpler forms of these compounds and extends to the linking of these monomers to form macromolecules.

Review

- What are some of the ways that the features of carbon-to-carbon bonds influence the stability and 3-D structure of organic molecules?
- Draw pairs of simple sketches comparing two (a) structural isomers, (b) geometric isomers, and (c) enantiomers. Why are these differences biologically important?
- Sketch the following functional groups: methyl, amino, carbonyl, hydroxyl, carboxyl, and phosphate. Include both non-ionized and ionized forms for acidic and basic groups.
- How is the fact that a group is nonpolar, polar, acidic, or basic related to its hydrophilic or hydrophobic properties?
- Why is the equivalent of a water molecule important to both condensation reactions and hydrolysis reactions?

BiologyNow™ Assess your understanding of **carbon atoms and molecules** by taking the pretest on your BiologyNow CD-ROM.

CARBOHYDRATES

Learning Objective

5 Distinguish among monosaccharides, disaccharides, and polysaccharides; compare storage polysaccharides with structural polysaccharides.

Sugars, starches, and cellulose are **carbohydrates.** Sugars and starches serve as energy sources for cells; cellulose is the main structural component of the walls that surround plant cells. Carbohydrates contain carbon, hydrogen, and oxygen atoms in a ratio of approximately one carbon to two hydrogens to one oxygen $(CH_2O)_n$. The term *carbohydrate,* meaning "hydrate (water) of carbon," reflects the 2:1 ratio of hydrogen to oxygen, the same ratio found in water (H_2O). Carbohydrates contain one sugar unit (monosaccharides), two sugar units (disaccharides), or many sugar units (polysaccharides).

Monosaccharides are simple sugars

Monosaccharides typically contain from three to seven carbon atoms. In a monosaccharide, a hydroxyl group is bonded to each carbon except one; that carbon is double-bonded to an oxygen atom, forming a carbonyl group. If the carbonyl group is at the end of the chain, the monosaccharide is an aldehyde; if the carbonyl group is at any other position, the monosaccharide is a ketone. (By convention, the numbering of the carbon skeleton of a sugar begins with the carbon at or nearest the carbonyl end of the open chain.) The large number of polar hydroxyl groups, plus the carbonyl group, gives a monosaccharide hydrophilic properties.

Figure 3-6 shows simplified, 2-D representations of some common monosaccharides. The simplest carbohydrates are the three-carbon sugars (trioses): glyceraldehyde and dihydroxyacetone. Ribose and deoxyribose are common pentoses, sugars that contain five carbons; they are components of nucleic acids (DNA, RNA, and related compounds). Glucose, fructose, galactose, and other six-carbon sugars are called **hexoses.** (Note that the names of carbohydrates typically end in *-ose.*)

Glucose ($C_6H_{12}O_6$), the most abundant monosaccharide, is used as an energy source in most organisms. During cellular respiration (see Chapter 7), cells oxidize glucose molecules, converting the stored energy to a form that can be readily used for cell work. Glucose is also used as a component in the synthesis of other types of compounds such as amino acids and fatty acids. Glucose is so important in metabolism that mechanisms have evolved to maintain its concentration at relatively constant levels in the blood of humans and other complex animals (see Chapter 47).

Glucose and fructose are structural isomers: They have identical molecular formulas, but their atoms are arranged differently. In fructose (a ketone) the double-bonded oxygen is linked

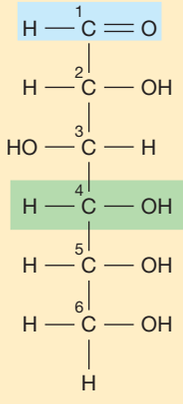
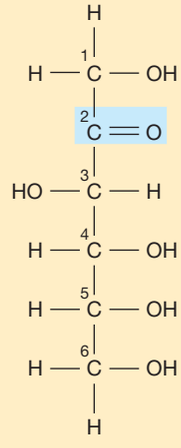
(the sugar component of DNA)

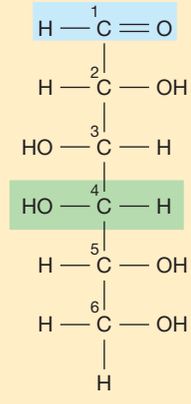
(b) Pentose sugars (5-carbon sugars)



Glucose ($C_6H_{12}O_6$)
(an aldehyde)



Fructose ($C_6H_{12}O_6$)
(a ketone)



Galactose ($C_6H_{12}O_6$)
(an aldehyde)

(c) Hexose sugars (6-carbon sugars)

FIGURE **3-6** **Monosaccharides.**

Shown are 2-D chain structures of **(a)** three-carbon trioses, **(b)** five-carbon pentoses, and **(c)** six-carbon hexoses. Although it is convenient to show monosaccharides in this form, the pentoses and hexoses are more accurately depicted as ring structures, as in Figure 3-7. The carbonyl group is terminal in aldehyde sugars and located in an internal position in ketones (*blue screen*). Deoxyribose differs from ribose because it has one less oxygen; a hydrogen instead of a hydroxyl group is attached to carbon 2 (*green screen*). Glucose and galactose are enantiomers that differ in the arrangement of the hydroxyl group and hydrogen attached to carbon 4 (*green screen*).

to a carbon within the chain, rather than to a terminal carbon as in glucose (an aldehyde). Because of these differences, the two sugars have different properties. For example, fructose, found in honey and some fruits, tastes sweeter than glucose.

Glucose and galactose are both hexoses and aldehydes. However, they are mirror images (enantiomers) because they differ in the arrangement of the atoms attached to asymmetrical carbon atom 4.

The linear formulas in Figure 3-6 give a clear but somewhat unrealistic picture of the structures of some common monosaccharides. As we have mentioned, molecules are not 2-D; in fact, the properties of each compound depend largely on its 3-D structure. Thus, 3-D formulas are helpful in understanding the relationship between molecular structure and biological function. Molecules of glucose and other pentoses and hexoses in solution are actually rings, rather than extended straight carbon chains.

Glucose in solution (as in the cell) typically exists as a ring of five carbons and one oxygen. It assumes this configuration when its atoms undergo a rearrangement, permitting a covalent bond to connect carbon 1 to the oxygen attached to carbon 5 (Fig. 3-7). When glucose forms a ring, two isomeric forms are possible, differing only in orientation of the hydroxyl (—OH) group attached to carbon 1. When this hydroxyl group is on the same side of the plane of the ring as the —CH_2OH side group, the glucose is designated beta glucose (β-glucose). When it is on the side (with respect to the plane of the ring) opposite the —CH_2OH side group, the compound is designated alpha glucose (α-glucose). Although the differences between these isomers may seem small, they have important consequences when the rings join to form polymers.

Disaccharides consist of two monosaccharide units

A **disaccharide** (two sugars) contains two monosaccharide rings joined by a **glycosidic linkage,** consisting of a central oxygen covalently bonded to two carbons, one in each ring (Fig. 3-8). The glycosidic linkage of a disaccharide generally forms between

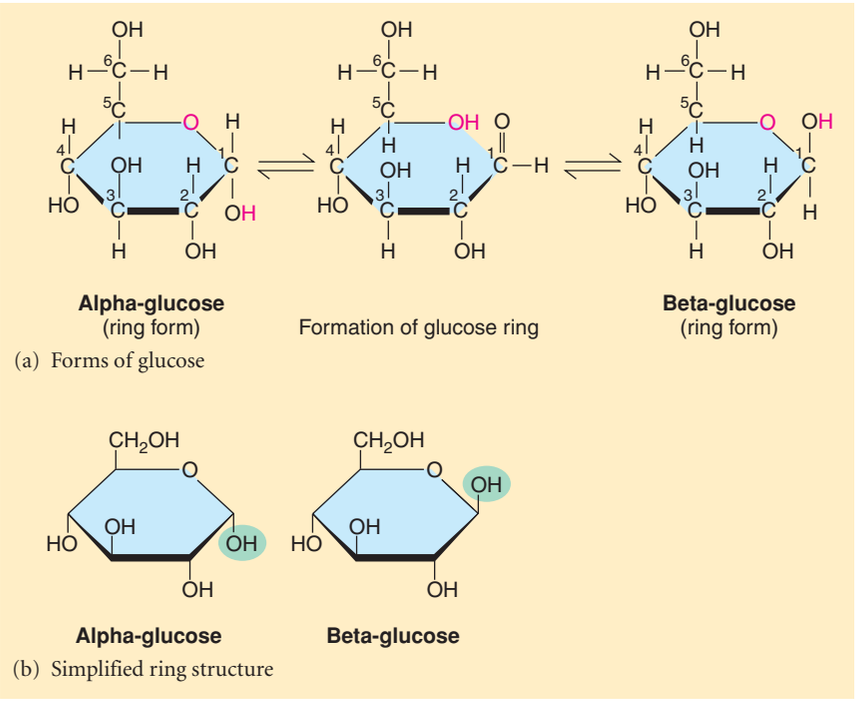


FIGURE **3-7** **α and β forms of glucose.**

(a) When dissolved in water, glucose undergoes a rearrangement of its atoms, forming one of two possible ring structures: α-glucose or β-glucose. Although the drawing does not show the complete 3-D structure, the thick, tapered bonds in the lower portion of each ring represent the part of the molecule that would project out of the page toward you. **(b)** The essential differences between α-glucose and β-glucose are more readily apparent in these simplified structures. By convention, a carbon atom is assumed to be present at each angle in the ring unless another atom is shown. Most hydrogen atoms have been omitted.

carbon 1 of one molecule and carbon 4 of the other molecule. The disaccharide maltose (malt sugar) consists of two covalently linked α-glucose units. Sucrose, common table sugar, consists of a glucose unit combined with a fructose unit. Lactose (the sugar present in milk) consists of one molecule of glucose and one of galactose.

As shown in Figure 3-8, a disaccharide can be hydrolyzed, that is, split by the addition of water, into two monosaccharide units. During digestion, maltose is hydrolyzed to form two molecules of glucose:

Maltose + water ⟶ glucose + glucose

Similarly, sucrose is hydrolyzed to form glucose and fructose:

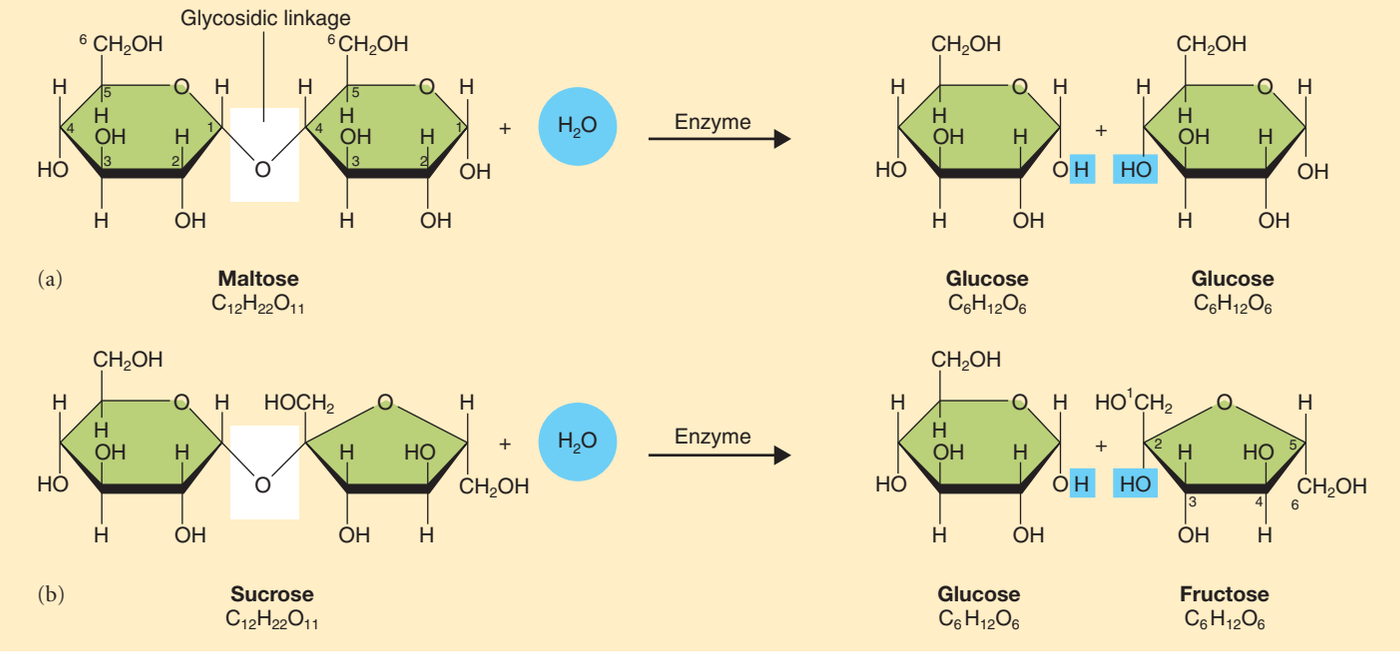
Sucrose + water ⟶ glucose + fructose

Polysaccharides can store energy or provide structure

A **polysaccharide** is a macromolecule consisting of repeating units of simple sugars, usually glucose. The polysaccharides are the most abundant carbohydrates and include starches, glycogen, and cellulose. Although

FIGURE **3-8** **Hydrolysis of disaccharides.**

(a) Maltose may be broken down (as during digestion) to form two molecules of glucose. The glycosidic linkage is broken in a hydrolysis reaction, which requires the addition of water. **(b)** Sucrose can be hydrolyzed to yield a molecule of glucose and a molecule of fructose. Note that an enzyme is needed to promote these reactions.



the precise number of sugar units varies, thousands of units are typically present in a single molecule. A polysaccharide may be a single long chain or a branched chain. Because they are composed of different isomers and because the units may be arranged differently, polysaccharides vary in their properties. Those that can be easily broken down to their subunits are well suited for energy storage, whereas the macromolecular 3-D architecture of others makes them particularly well suited to form stable structures.

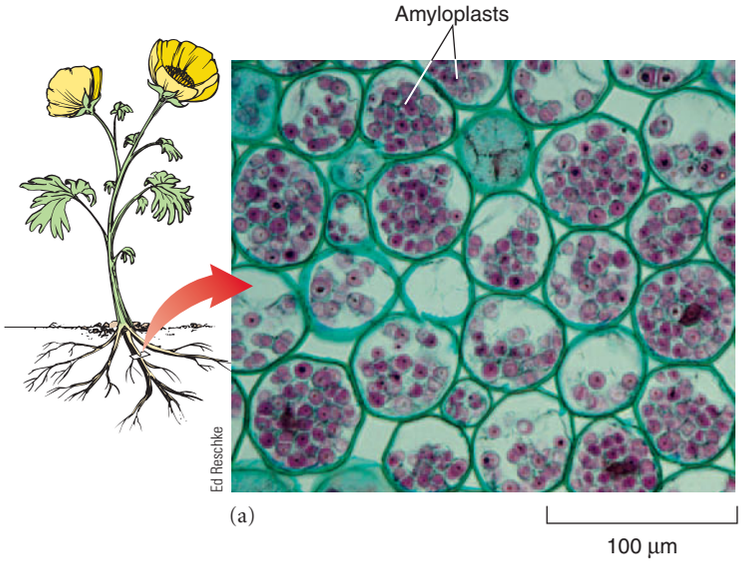
Starch, the typical form of carbohydrate used for energy storage in plants, is a polymer consisting of α-glucose subunits. These monomers are joined by α 1—4 linkages, which means that carbon 1 of one glucose is linked to carbon 4 of the next glucose in the chain (Fig. 3-9). Starch occurs in two forms: amylose and amylopectin. Amylose, the simpler form, is unbranched. Amylopectin, the more common form, usually consists of about 1000 glucose units in a branched chain.

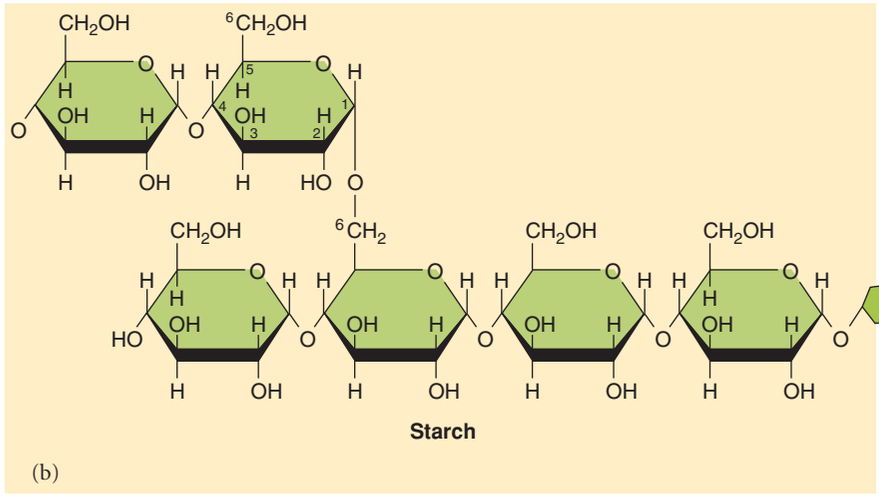
Plant cells store starch mainly as granules within specialized organelles called **amyloplasts** (Fig. 3-9a); some cells, such as those of potatoes, are very rich in amyloplasts. Virtually all organisms have enzymes that can break α 1—4 linkages. When energy is needed for cell work, the plant hydrolyzes the starch, releasing the glucose subunits. Humans and other animals that eat plant foods also have enzymes to hydrolyze starch.

Glycogen (sometimes referred to as *animal starch*) is the form in which glucose subunits, joined by α 1—4 linkages, are stored as an energy source in animal tissues. Glycogen is similar in structure to plant starch but more extensively branched and more water soluble. Glycogen is stored mainly in liver and muscle cells.

Carbohydrates are the most abundant group of organic compounds on Earth, and **cellulose** is the most abundant carbohydrate; it accounts for 50% or more of all the carbon in plants (Fig. 3-10). Cellulose is a structural carbohydrate. Wood is about half cellulose, and cotton is at least 90% cellulose. Plant cells are surrounded by strong supporting cell walls consisting mainly of cellulose.

Cellulose is an insoluble polysaccharide composed of many glucose molecules joined together. The bonds joining these sugar units are different from those in starch. Recall that starch is composed of α-glucose subunits, joined by α 1—4 glycosidic linkages. Cellulose contains β-glucose monomers joined by β 1—4 linkages. These bonds cannot be split by the enzymes that hydrolyze the α linkages in starch. Because humans, like other animals, lack enzymes that digest cellulose, we cannot use it as a nutrient. The cellulose found in whole grains and vegetables remains fibrous and provides bulk that helps keep our digestive tract functioning properly.





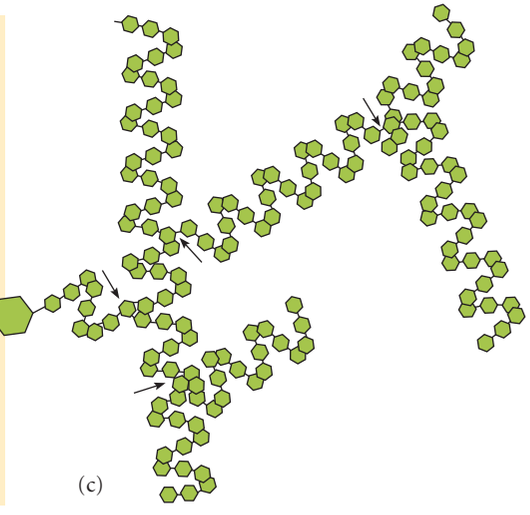


FIGURE **3-9** **Starch, a storage polysaccharide.**

(a) Starch (*stained purple*) is stored in specialized organelles, called *amyloplasts,* in these cells of a buttercup root. **(b)** Starch is composed of α-glucose molecules joined by glycosidic bonds. At the branch points are bonds between carbon 6 of the glucose in the straight chain and carbon 1 of the glucose in the branching chain. **(c)** Starch consists of highly branched chains; the arrows indicate the branch points. Each chain is actually a coil or helix, stabilized by hydrogen bonds between the hydroxyl groups of the glucose subunits.

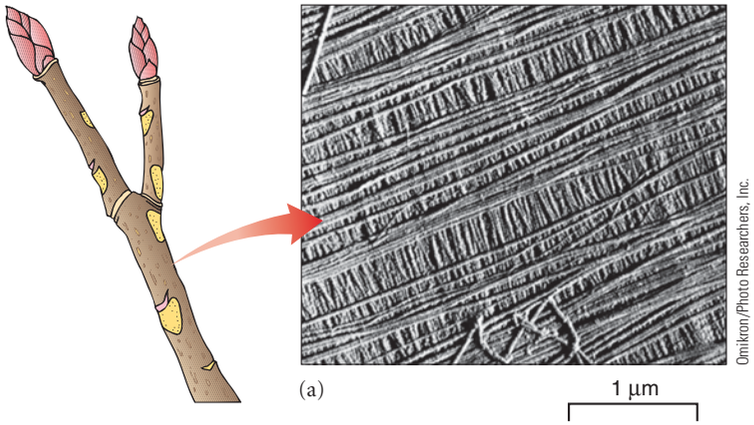

FIGURE 3-10 Cellulose, a structural polysaccharide.
(a) An electron micrograph of cellulose fibers from a cell wall. The fibers consist of bundles of cellulose molecules, interacting through hydrogen bonds. **(b)** The cellulose molecule is an unbranched polysaccharide consisting of about 10,000 β-glucose units joined by glycosidic bonds.

Some microorganisms digest cellulose to glucose. In fact, cellulose-digesting bacteria live in the digestive systems of cows and sheep, enabling these grass-eating animals to obtain nourishment from cellulose. Similarly, the digestive systems of termites contain microorganisms that digest cellulose (see Fig. 24-5b).

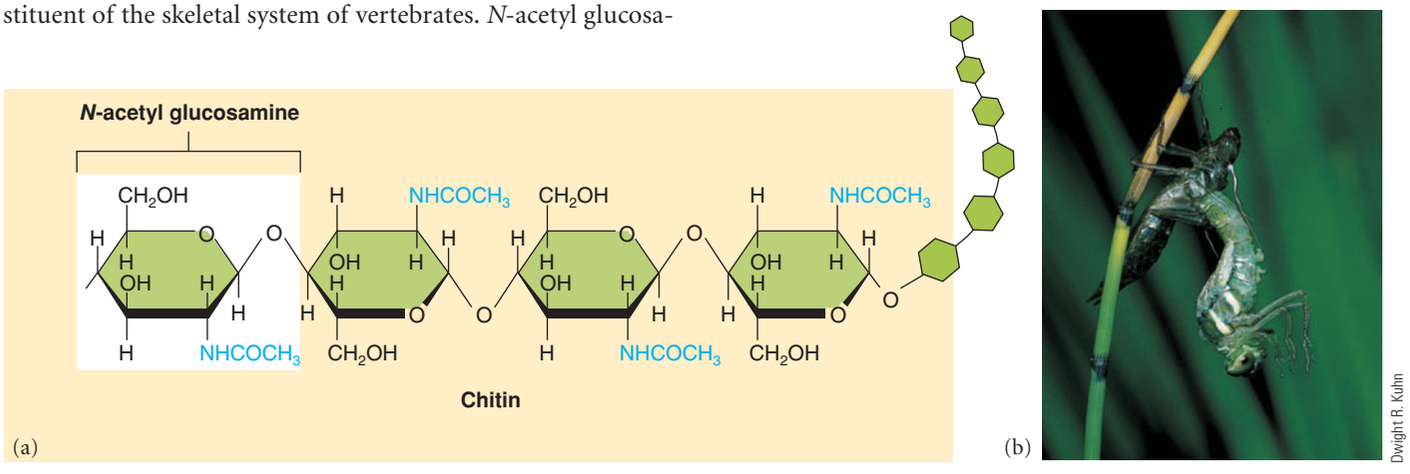
Cellulose molecules are well suited for a structural role. The β-glucose subunits are joined in a way that allows extensive hydrogen bonding among different cellulose molecules, and they aggregate in long bundles of fibers (Fig. 3-10a).

Some modified and complex carbohydrates have special roles

Many derivatives of monosaccharides are important biological molecules. Some form important structural components. The amino sugars galactosamine and glucosamine are compounds in which a hydroxyl group (—OH) is replaced by an amino group (—NH_2). Galactosamine is present in cartilage, a constituent of the skeletal system of vertebrates. *N*-acetyl glucosamine (NAG) subunits, joined by glycosidic bonds, compose **chitin,** a main component of the cell walls of fungi and of the external skeletons of insects, crayfish, and other arthropods (Fig. 3-11). Chitin forms very tough structures because, as in cellulose, its molecules interact through multiple hydrogen bonds. Some chitinous structures, such as the shell of a lobster, are further hardened by the addition of calcium carbonate ($CaCO_3$, an inorganic form of carbon).

Carbohydrates may also combine with proteins to form **glycoproteins,** compounds present on the outer surface of cells other than bacteria. Some of these carbohydrate chains allow

FIGURE 3-11 Chitin, a structural polysaccharide.
(a) Chitin is a polymer composed of *N*-acetyl glucosamine subunits. **(b)** Chitin is an important component of the exoskeleton (outer covering) this dragonfly is shedding.



cells to adhere to one another, whereas others provide protection. Most proteins secreted by cells are glycoproteins. These include the major components of mucus, a complex protective material secreted by the mucous membranes of the respiratory and digestive systems. Carbohydrates combine with lipids to form **glycolipids,** compounds on the surfaces of animal cells that allow cells to recognize and interact with one another.

Review

- What features related to hydrogen bonding give storage polysaccharides, such as starch and glycogen, very different properties from structural polysaccharides, such as cellulose and chitin?
- Why can't humans digest cellulose?

LIPIDS

Learning Objective

6 Distinguish among fats, phospholipids, and steroids, and describe the composition, characteristics, and biological functions of each.

Unlike carbohydrates, which are defined by their structure, **lipids** are a heterogeneous group of compounds that are categorized by the fact that they are soluble in nonpolar solvents (such as ether and chloroform) and are relatively insoluble in water. Lipid molecules have these properties because they consist mainly of carbon and hydrogen, with few oxygen-containing functional groups. Hydrophilic functional groups typically contain oxygen atoms; therefore lipids, with little oxygen, tend to be hydrophobic. Among the biologically important groups of lipids are fats, phospholipids, carotenoids (orange and yellow plant pigments), steroids, and waxes. Some lipids are used for energy storage, others serve as structural components of cellular membranes, and some are important hormones.

Triacylglycerol is formed from glycerol and three fatty acids

The most abundant lipids in living organisms are triacylglycerols. These compounds, commonly known as *fats,* are an economical form of reserve fuel storage because, when metabolized, they yield more than twice as much energy per gram as do carbohydrates. Carbohydrates and proteins can be transformed by enzymes into fats and stored within the cells of adipose (fat) tissue of animals and in some seeds and fruits of plants.

A **triacylglycerol** molecule (also known as a *triglyceride*) consists of glycerol joined to three fatty acids (Fig. 3-12). **Glycerol** is a three-carbon alcohol that contains three hydroxyl (—OH) groups, and a **fatty acid** is a long, unbranched hydrocarbon chain with a carboxyl group (—COOH) at one end. A triacylglycerol molecule is formed by a series of three condensation reactions. In each reaction, the equivalent of a water molecule is removed as one of the glycerol's hydroxyl groups reacts with the carboxyl group of a fatty acid, resulting in the formation of a covalent linkage known as an **ester linkage** (Fig. 3-12b). The first reaction yields a **monoacylglycerol** (*monoglyceride*); the second, a diacylglycerol (*diglyceride*); and the third, a triacylglycerol. During digestion triacylglycerols are hydrolyzed to produce fatty acids and glycerol (see Chapter 45). Diacylglycerol is an important molecule for sending signals within the cell (see Chapter 47).

The space-filling models show the actual shapes of the fatty acids. **(c)** Palmitic acid, a saturated fatty acid, is a straight chain. **(d)** Oleic acid (monounsaturated) and **(e)** linoleic acid (polyunsaturated) are bent or kinked wherever a carbon-to-carbon double bond appears.

Biology Now™ Learn more about **triacylglycerol and other lipids** by clicking on this figure on your BiologyNow CD-ROM.

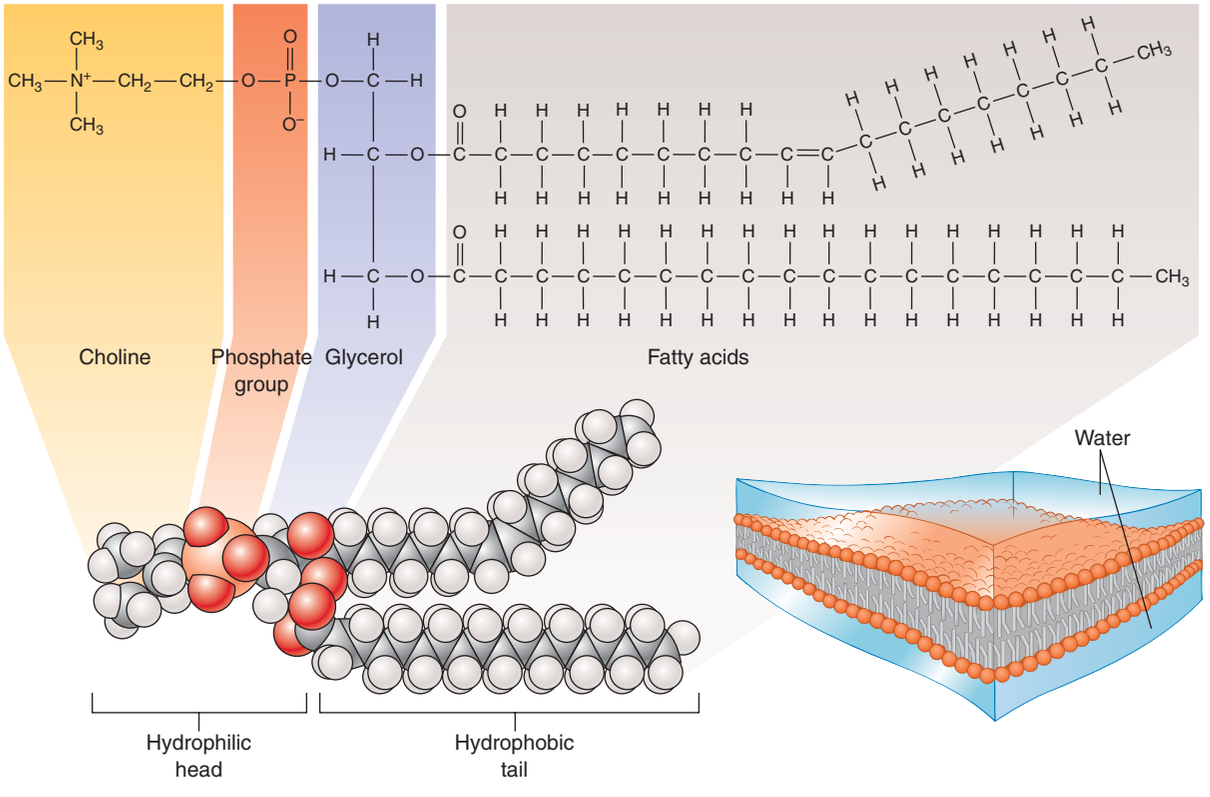
Saturated and unsaturated fatty acids differ in physical properties

About 30 different fatty acids are commonly found in lipids, and they typically have an even number of carbon atoms. For example, butyric acid, present in rancid butter, has four carbon atoms. Oleic acid, with 18 carbons, is the most widely distributed fatty acid in nature and is found in most animal and plant fats.

Saturated fatty acids contain the maximum possible number of hydrogen atoms. Palmitic acid, a 16-carbon fatty acid, is a common saturated fatty acid (Fig. 3-12c). Fats high in saturated fatty acids, such as animal fat and solid vegetable shortening, tend to be solid at room temperature. This is because even electrically neutral, nonpolar molecules can develop transient regions of weak positive charge and weak negative charge. This occurs as the constant motion of their electrons causes some regions to have a temporary excess of electrons, whereas others have a temporary electron deficit. These slight opposite charges result in attractions, known as **van der Waals interactions,** between adjacent molecules. Although van der Waals interactions are individually weak, they can be strong when many occur among long hydrocarbon chains.

Unsaturated fatty acids include one or more adjacent pairs of carbon atoms joined by a double bond. Therefore they are not fully saturated with hydrogen. Fatty acids with one double bond are **monounsaturated fatty acids,** whereas those with more than one double bond are **polyunsaturated fatty acids.** Oleic acid is a monounsaturated fatty acid, and linoleic acid is a common polyunsaturated fatty acid (Fig. 3-12d, e). Fats containing a high proportion of monounsaturated or polyunsaturated fatty acids tend to be liquid at room temperature. This is because each double bond produces a bend in the hydrocarbon chain that prevents it from aligning closely with an adjacent chain, thereby limiting van der Waals interactions.

Food manufacturers commonly hydrogenate or partially hydrogenate cooking oils to make margarine and other foodstuffs, converting unsaturated fatty acids to saturated fatty acids and making the fat more solid at room temperature. This process makes the fat less healthful because saturated fatty acids in the diet are known to increase the risk of cardiovascular disease (see Chapter 42). The hydrogenation process has yet another effect. Note that in the naturally occurring unsaturated fatty acids oleic acid and linoleic acid shown in Figure 3-12, the two hydrogens flanking each double bond are on the same side of



(a) Phospholipid (lecithin)

(b) Phospholipid bilayer

FIGURE **3-13** **A phospholipid and a phospholipid bilayer.**

(a) A phospholipid consists of a hydrophobic tail, made up of two fatty acids, and a hydrophilic head, which includes a glycerol bonded to a phosphate group, which is in turn bonded to an organic group that can vary. Choline is the organic group in lecithin (or phosphatidylcholine), the molecule shown. The fatty acid at the top of the figure is monounsaturated; it contains one double bond that produces a characteristic bend in the chain. **(b)** Phospholipids form lipid bilayers in which the hydrophilic heads interact with water and the hydrophobic tails are in the bilayer interior.

the hydrocarbon chain (the *cis* configuration). When fatty acids are artificially hydrogenated, the double bonds can become rearranged, resulting in a *trans* configuration, analogous to the arrangement shown in Fig. 3-3b. *Trans* fatty acids are technically unsaturated, but they mimic many of the properties of saturated fatty acids. Because the *trans* configuration does not produce a bend at the site of the double bond, *trans* fatty acids are more solid at room temperature and, like saturated fatty acids, they increase the risk of cardiovascular disease.

At least two unsaturated fatty acids (linoleic acid and arachidonic acid) are essential nutrients that must be obtained from food because the human body cannot synthesize them. However, the amounts required are small, and deficiencies are rarely seen. There is no dietary requirement for saturated fatty acids.

Phospholipids are components of cell membranes

Phospholipids belong to a group of lipids, called **amphipathic lipids,** in which one end of each molecule is hydrophilic and the other end is hydrophobic (Fig. 3-13). The two ends of a phospholipid differ both physically and chemically. A **phospholipid** consists of a glycerol molecule attached at one end to two fatty acids, and at the other end to a phosphate group linked to an organic compound such as choline. The organic compound usually contains nitrogen. (Note that phosphorus and nitrogen are absent in triacylglycerols as shown in Fig. 3-12b.) The fatty acid portion of the molecule (containing the two hydrocarbon "tails") is hydrophobic and not soluble in water. However, the portion composed of glycerol, phosphate, and the organic base (the "head" of the molecule) is ionized and readily water soluble. The amphipathic properties of phospholipids cause them to form lipid bilayers in aqueous (watery) solution. Thus they are uniquely suited to function as the fundamental components of cell membranes (see Chapters 4 and 5).

Carotenoids and many other pigments are derived from isoprene units

The orange and yellow plant pigments called **carotenoids** are classified with the lipids because they are insoluble in water and have an oily consistency. These pigments, found in the cells of all plants, play a role in photosynthesis. Carotenoid molecules, such as β-carotene, and many other important pigments, consist of five-carbon hydrocarbon monomers known as **isoprene units** (Fig. 3-14).

Most animals convert carotenoids to vitamin A, which can then be converted to the visual pigment **retinal.** Three different groups of animals—the mollusks, insects, and vertebrates—have eyes and use retinal in the process of light reception.

Notice that carotenoids, vitamin A, and retinal all have a pattern of double bonds alternating with single bonds. The electrons that make up these bonds can move about relatively easily when light strikes the molecule. Such molecules are pigments; they tend to be highly colored because the mobile electrons cause them to strongly absorb light of certain wavelengths and reflect light of other wavelengths.

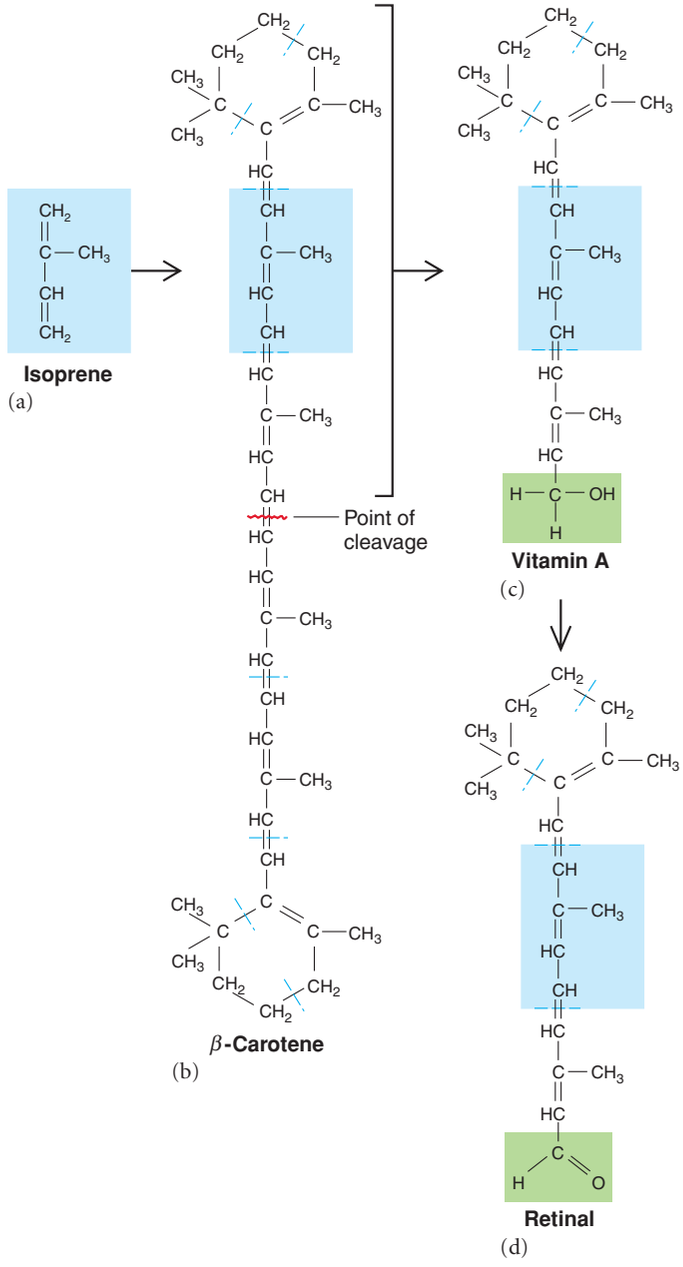


FIGURE **3-14** **Isoprene-derived compounds.**

(a) An isoprene subunit. **(b)** β-carotene, with dashed lines indicating the boundaries of the individual isoprene units within. The wavy line is the point at which most animals cleave the molecule to yield two molecules of **(c)** vitamin A. Vitamin A is converted to the visual pigment **(d)** retinal.

Steroids contain four rings of carbon atoms

A **steroid** consists of carbon atoms arranged in four attached rings; three of the rings contain six carbon atoms, and the fourth contains five (Fig. 3-15). The length and structure of the side chains that extend from these rings distinguish one steroid from another. Like carotenoids, steroids are synthesized from isoprene units.

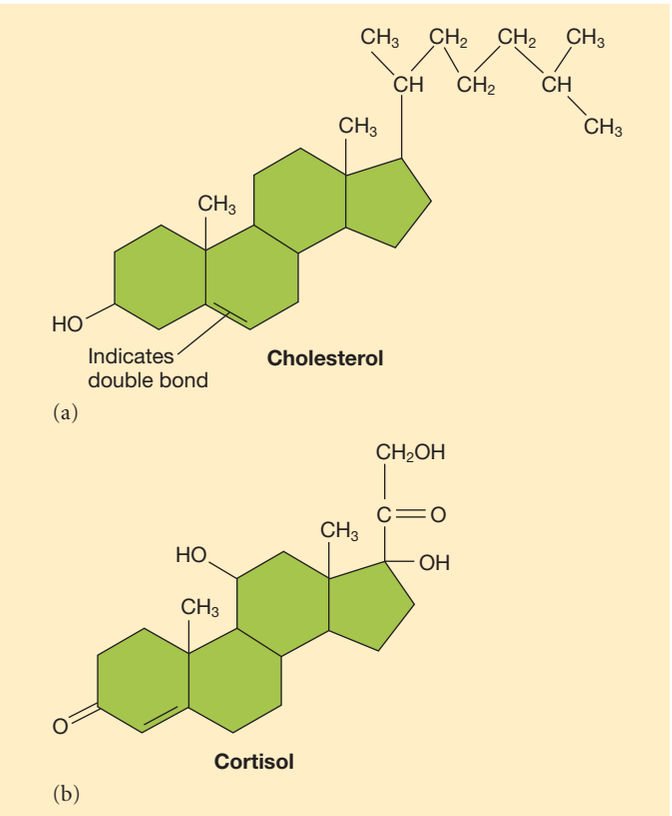

FIGURE **3-15** **Steroids.**

Four attached rings—three six-carbon rings and one with five carbons—make up the fundamental structure of a steroid *(shown in green).* Note that some carbons are shared by two rings. In these simplified structures, a carbon atom is present at each angle of a ring; the hydrogen atoms attached directly to the carbon atoms have not been drawn. **(a)** Cholesterol is an essential component of animal cell membranes. **(b)** Cortisol is a steroid hormone secreted by the adrenal glands. Cortisol differs from cholesterol in its attached functional groups.

Among the steroids of biological importance are cholesterol, bile salts, reproductive hormones, and cortisol and other hormones secreted by the adrenal cortex. Cholesterol is an essential structural component of animal cell membranes, but when excess cholesterol in blood forms plaques on artery walls, it leads to an increased risk of cardiovascular disease (see Chapter 42). Plant cell membranes contain molecules similar to cholesterol. Interestingly, some of these plant steroids are able to block the intestine's absorption of cholesterol. Bile salts emulsify fats in the intestine so they can be enzymatically hydrolyzed. Steroid hormones regulate certain aspects of metabolism in a variety of animals, including vertebrates, insects, and crabs.

Some chemical mediators are lipids

Animal cells secrete chemicals to communicate with each other or to regulate their own activities. Some chemical mediators are produced by the modification of fatty acids that have been removed from membrane phospholipids. These include *prostaglandins,* which have varied roles, including promoting inflammation and smooth muscle contraction. Certain hormones, such as the juvenile hormone of insects, are also fatty acid derivatives (see Chapter 47).

Review

- Why do saturated, unsaturated, and *trans* fatty acids differ in their properties?
- Why do phospholipids form lipid bilayers in aqueous conditions?

PROTEINS

Learning Objectives

7 Give an overall description of the structure and functions of proteins.

8 Describe the features that are shared by all amino acids, and explain how amino acids are grouped into classes based on the characteristics of their side chains.

9 Distinguish among the four levels of organization of protein molecules.

Proteins, macromolecules composed of amino acids, are the most versatile cell components. As discussed in Chapter 15, scientists have succeeded in sequencing virtually all the genetic information in a human cell, and the genetic information of many other organisms is being studied. Some people might think that the sequencing of genes is the end of the story, but it is actually only the beginning. Most genetic information is used to specify the structure of proteins, and it has been predicted that most of the 21st century will be devoted to understanding this extraordinarily multifaceted group of macromolecules that are of central importance in the chemistry of life. In a real sense, proteins are involved in virtually all aspects of metabolism because most **enzymes** (molecules that accelerate the thousands of different chemical reactions that take place in an organism) are proteins. Proteins are assembled into a variety of shapes, allowing them to serve as major structural components of cells and tissues. For this reason, growth and repair, as well as maintenance of the organism, depend on proteins. As shown in Table 3-2, proteins perform many other specialized functions.

The protein constituents of a cell are the clues to its lifestyle. Each cell type contains characteristic forms, distributions, and amounts of protein that largely determine what the cell looks like and how it functions. A muscle cell contains large amounts of the proteins myosin and actin, which are responsible for its appearance as well as its ability to contract. The protein hemoglobin, found in red blood cells, is responsible for the specialized function of oxygen transport.

Amino acids are the subunits of proteins

Amino acids, the constituents of proteins, have an amino group ($—NH_2$) and a carboxyl group (—COOH) bonded to the same asymmetrical carbon atom, known as the **alpha carbon.** Twenty amino acids are commonly found in proteins, each uniquely

TABLE **3-2** **Major Classes of Proteins and Their Functions**

Protein Class	Functions and Examples
Enzymes	Catalyze specific chemical reactions
Structural proteins	Strengthen and protect cells and tissues (e.g., collagen strengthens animal tissues)
Storage proteins	Store nutrients; particularly abundant in eggs (e.g., ovalbumin in egg white) and seeds (e.g., zein in corn kernels)
Transport proteins	Transport specific stubstances between cells (e.g., hemoglobin transports oxygen in red blood cells; move specific substances (e.g., ions, glucose, amino acids) across cell membranes
Regulatory proteins	Some are protein hormones (e.g., insulin); some control the expression of specific genes
Motile proteins	Participate in cellular movements (e.g., actin and myosin are essential for muscle contraction)
Protective proteins	Defend against foreign invaders (e.g., antibodies play a role in the immune system)

identified by the variable side chain (*R* group) bonded to the α carbon (Fig. 3-16). Glycine, the simplest amino acid, has a hydrogen atom as its R group; alanine has a methyl (—CH_3) group.

Amino acids in solution at neutral pH are mainly dipolar ions. This is generally how amino acids exist at cell pH. Each carboxyl group (—COOH) donates a proton and becomes ionized (—COO^-), whereas each amino group (—NH_2) accepts a proton and becomes —NH_3^+ (Fig. 3-17). Because of the ability of their amino and carboxyl groups to accept and release protons, amino acids in solution resist changes in acidity and alkalinity and therefore are important biological buffers.

The amino acids are grouped in Figure 3-16 by the properties of their side chains. These broad groupings actually include amino acids with a fairly wide range of properties. Amino acids classified as having *nonpolar* side chains tend to have hydrophobic properties, whereas those classified as *polar* are more hydrophilic. An acidic amino acid has a side chain that contains a carboxyl group. At cell pH the carboxyl group is dissociated, giving the R group a negative charge. A basic amino acid becomes positively charged when the amino group in its side chain accepts a hydrogen ion. Acidic and basic side chains are ionic at cell pH and therefore hydrophilic.

In addition to the 20 common amino acids, some proteins have unusual ones. These rare amino acids are produced by the modification of common ones after they have become part of a protein. For example, after they have been incorporated into collagen, lysine and proline may be converted to hydroxylysine and hydroxyproline. These amino acids can form cross links between the peptide chains that make up collagen. Such cross links produce the firmness and great strength of the collagen molecule, which is a major component of cartilage, bone, and other connective tissues.

With some exceptions, bacteria and plants synthesize all their needed amino acids from simpler substances. If the proper raw materials are available, the cells of animals can manufacture some, but not all, of the biologically significant amino acids. **Essential amino acids** are those an animal cannot synthesize in amounts sufficient to meet its needs and must obtain from the diet. Animals differ in their biosynthetic capacities; what is an essential amino acid for one species may not be for another. The essential amino acids for humans are isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, valine, and histidine. For children arginine is added to the list because they do not synthesize enough to support growth.

Peptide bonds join amino acids

Amino acids combine chemically with one another by a condensation reaction that bonds the carboxyl carbon of one molecule to the amino nitrogen of another (Fig. 3-18). The covalent carbon-to-nitrogen bond linking two amino acids together is a **peptide bond.** When two amino acids combine, a **dipeptide** is formed; a longer chain of amino acids is a **polypeptide.** A protein consists of one or more polypeptide chains. Each polypeptide has a free amino group at one end and a free carboxyl group (belonging to the last amino acid added to the chain) at the opposite end. The other amino and carboxyl groups of the amino acid monomers (except those in side chains) are part of the peptide bonds. The complex process by which polypeptides are synthesized is discussed in Chapter 12.

A polypeptide may contain hundreds of amino acids joined in a specific linear order. The backbone of the polypeptide chain includes the repeating sequence

N—C—C—N—C—C—N—C—C

plus all other atoms *except those in the* R *groups.* The *R* groups of the amino acids extend from this backbone.

An almost infinite variety of protein molecules is possible, differing from one another in the number, types, and sequences of amino acids they contain. The 20 types of amino acids found in proteins may be thought of as letters of a protein alphabet; each protein is a very long sentence made up of amino acid letters.

Proteins have four levels of organization

The polypeptide chains making up a protein are twisted or folded to form a macromolecule with a specific *conformation,* or 3-D shape. Some polypeptide chains form long fibers. **Globular** proteins are tightly folded into compact, roughly spherical shapes. There is a close relationship between a protein's conformation and its function. For example, a typical enzyme is a globular protein with a unique shape that allows it to catalyze a specific chemical reaction. Similarly, the shape of a protein hormone enables it to combine with receptors on its target cell (the cell the hormone acts on). Scientists recognize four main levels of protein organization: primary, secondary, tertiary, and quaternary.

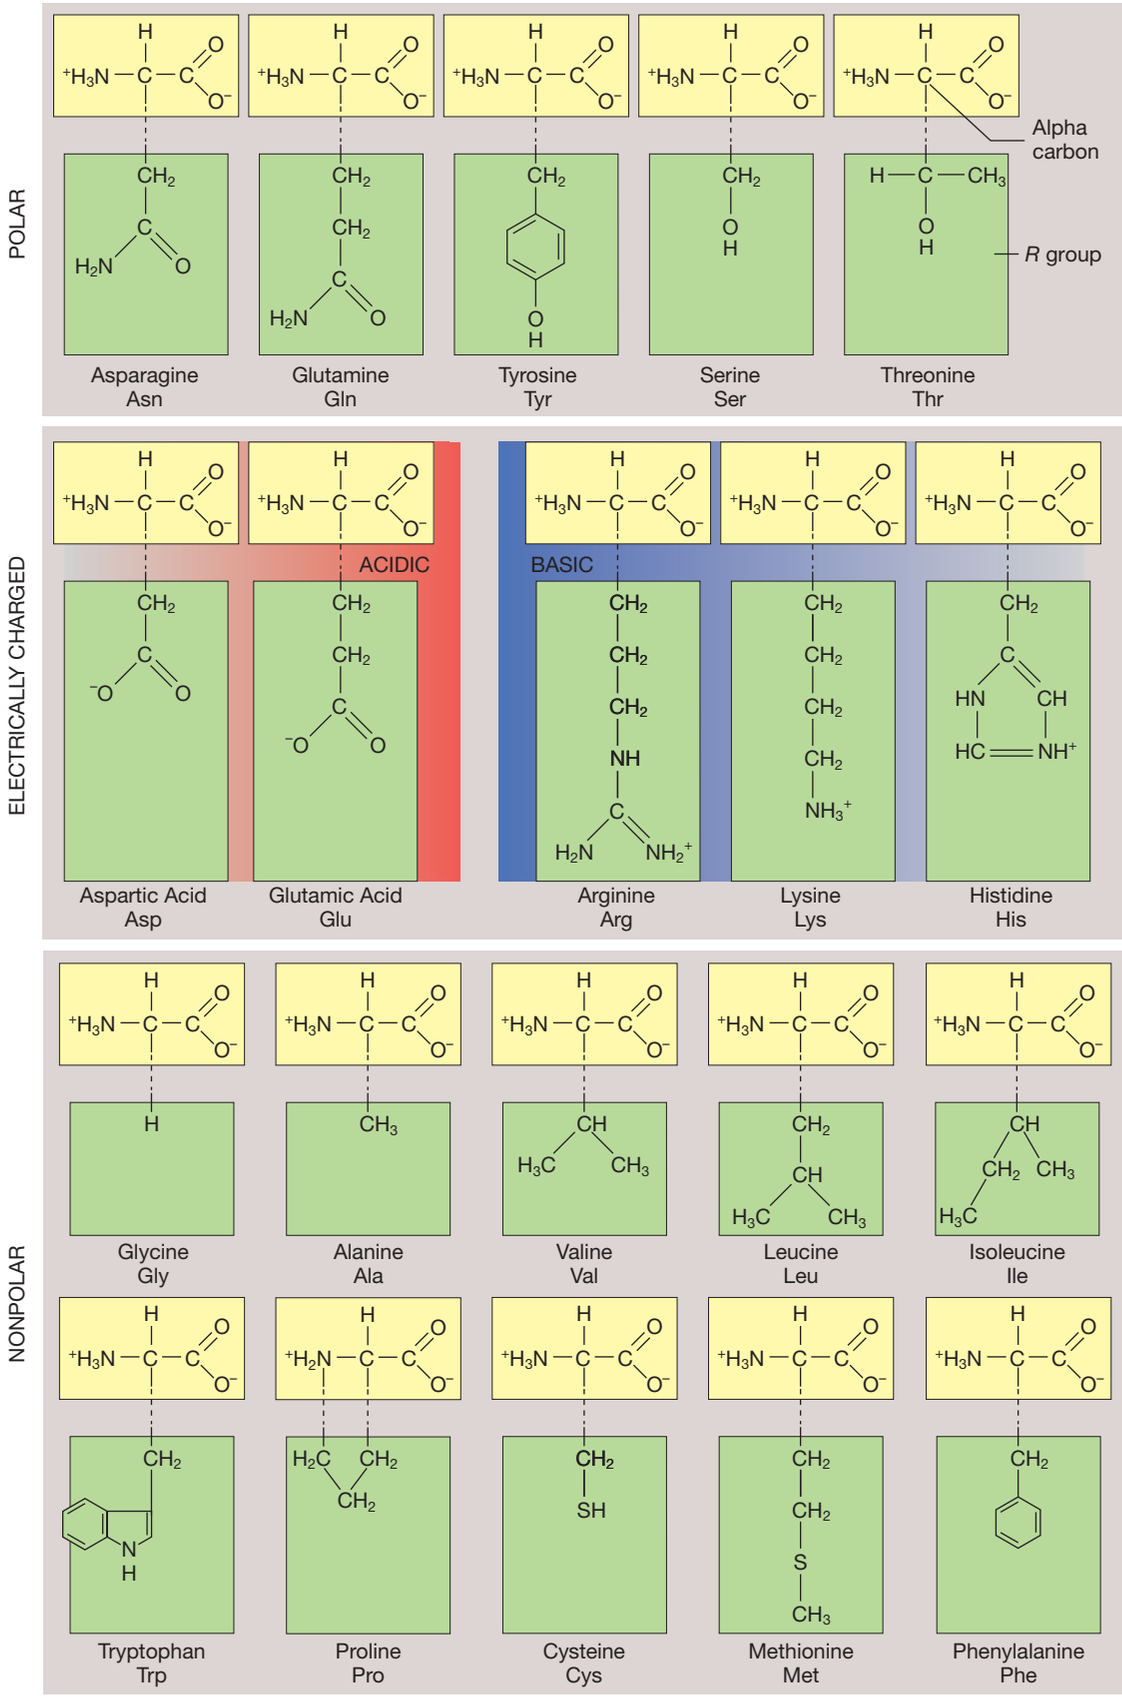
Primary structure is the amino acid sequence

The sequence of amino acids, joined by peptide bonds, is the **primary structure** of a polypeptide chain. As discussed in Chap-

FIGURE **3-16**

The 20 common amino acids.

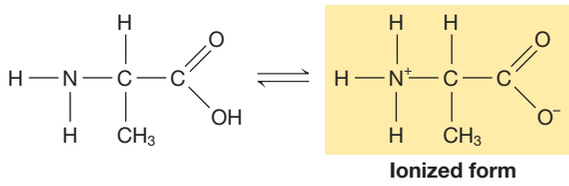
Polar amino acids have relatively hydrophilic side chains, whereas nonpolar amino acids have side chains that are relatively hydrophobic. Carboxyl groups and amino groups are electrically charged at cell pH; therefore, acidic and basic amino acids are hydrophilic. The three-letter abbreviations appear below the amino acid names.



ter 12, this sequence is specified by the instructions in a gene. Using analytical methods investigators can determine the exact sequence of amino acids in a protein molecule. The primary structures of thousands of proteins are known. For example, glucagon, a hormone secreted by the pancreas, is a small polypeptide, consisting of only 29 amino acid units (Fig. 3-19).

FIGURE **3-17** **An amino acid at pH 7.**

In living cells, amino acids exist mainly in their ionized form, as dipolar ions.



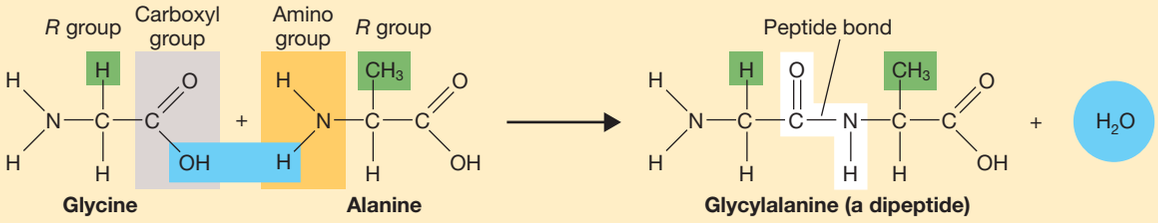


FIGURE **3-18** **Peptide bonds.**

(a) A dipeptide is formed by a condensation reaction, that is, by the removal of the equivalent of a water molecule from the carboxyl group of one amino acid and the amino group of another amino acid. The resulting peptide bond is a covalent, carbon-to-nitrogen bond. Note that the carbon is also part of a carbonyl group, and that the nitrogen is also covalently bonded to a hydrogen. Additional amino acids can be added to form a long polypeptide chain with a free amino group at one end and a free carboxyl group at the other.

Primary structure is always represented in a simple, linear, "beads-on-a-string" form. However, the overall conformation of a protein is far more complex, involving interactions among the various amino acids that comprise the primary structure of the molecule. Therefore, the higher orders of structure—secondary, tertiary, and quaternary—ultimately derive from the specific amino acid sequence (the primary structure).

Secondary structure results from hydrogen bonding involving the backbone

Some regions of a polypeptide exhibit **secondary structure,** which is highly regular. The two most common types of secondary structure are the α-helix and the β-pleated sheet; the designations α and β refer simply to the order in which these two types of secondary structure were discovered. An **α-helix** is a region where a polypeptide chain forms a uniform helical coil (Fig. 3-20a). The helical structure is determined and maintained by the formation of hydrogen bonds between the backbones of the amino acids in successive turns of the spiral coil. Each hydrogen bond forms between an oxygen with a partial negative charge and a hydrogen with a partial positive charge. The oxygen is part of the remnant of the carboxyl group of one amino acid; the hydrogen is part of the remnant of the amino group of the fourth amino acid down the chain. Thus 3.6 amino acids are included in each complete turn of the helix. Every amino acid in an α-helix is hydrogen bonded in this way.

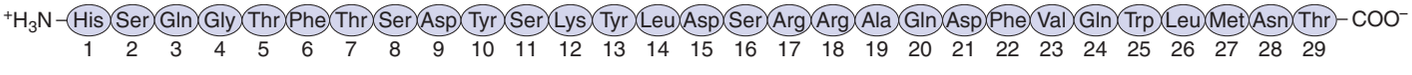
The α-helix is the basic structural unit of some fibrous proteins that make up wool, hair, skin, and nails. The elasticity of these fibers is due to a combination of physical factors (the helical shape) and chemical factors (hydrogen bonding). Although hydrogen bonds maintain the helical structure, these bonds can be broken, allowing the fibers to stretch under tension (like a telephone cord). When the tension is released, the fibers recoil and hydrogen bonds reform. This is why you can stretch the hairs on your head to some extent and they will snap back to their original length.

The hydrogen bonding in a **β-pleated sheet** takes place between different polypeptide chains, or different regions of a polypeptide chain that has turned back on itself (Fig. 3-20b). Each chain is fully extended, but because each has a zigzag structure the resulting "sheet" has an overall pleated conformation (much like a sheet of paper that has been folded to make a fan). Although the pleated sheet is strong and flexible, it is not elastic. This is because the distance between the pleats is fixed, determined by the strong covalent bonds of the polypeptide backbones. Fibroin, the protein of silk, is characterized by a β-pleated sheet structure, as are the cores of many globular proteins.

It is not uncommon for a single polypeptide chain to include both α-helical regions and regions with β-pleated sheet conformations. The properties of some complex biological materials result from such combinations. A spider's web is composed of a material that is extremely strong, flexible, and elastic. Once again we see function and structure working together, as these properties derive from the fact that spider silk is a com-

FIGURE **3-19** **Primary structure of a polypeptide.**

Glucagon is a very small polypeptide made up of 29 amino acids. The linear sequence of amino acids is indicated by ovals containing their abbreviated names (see Fig. 3-16).



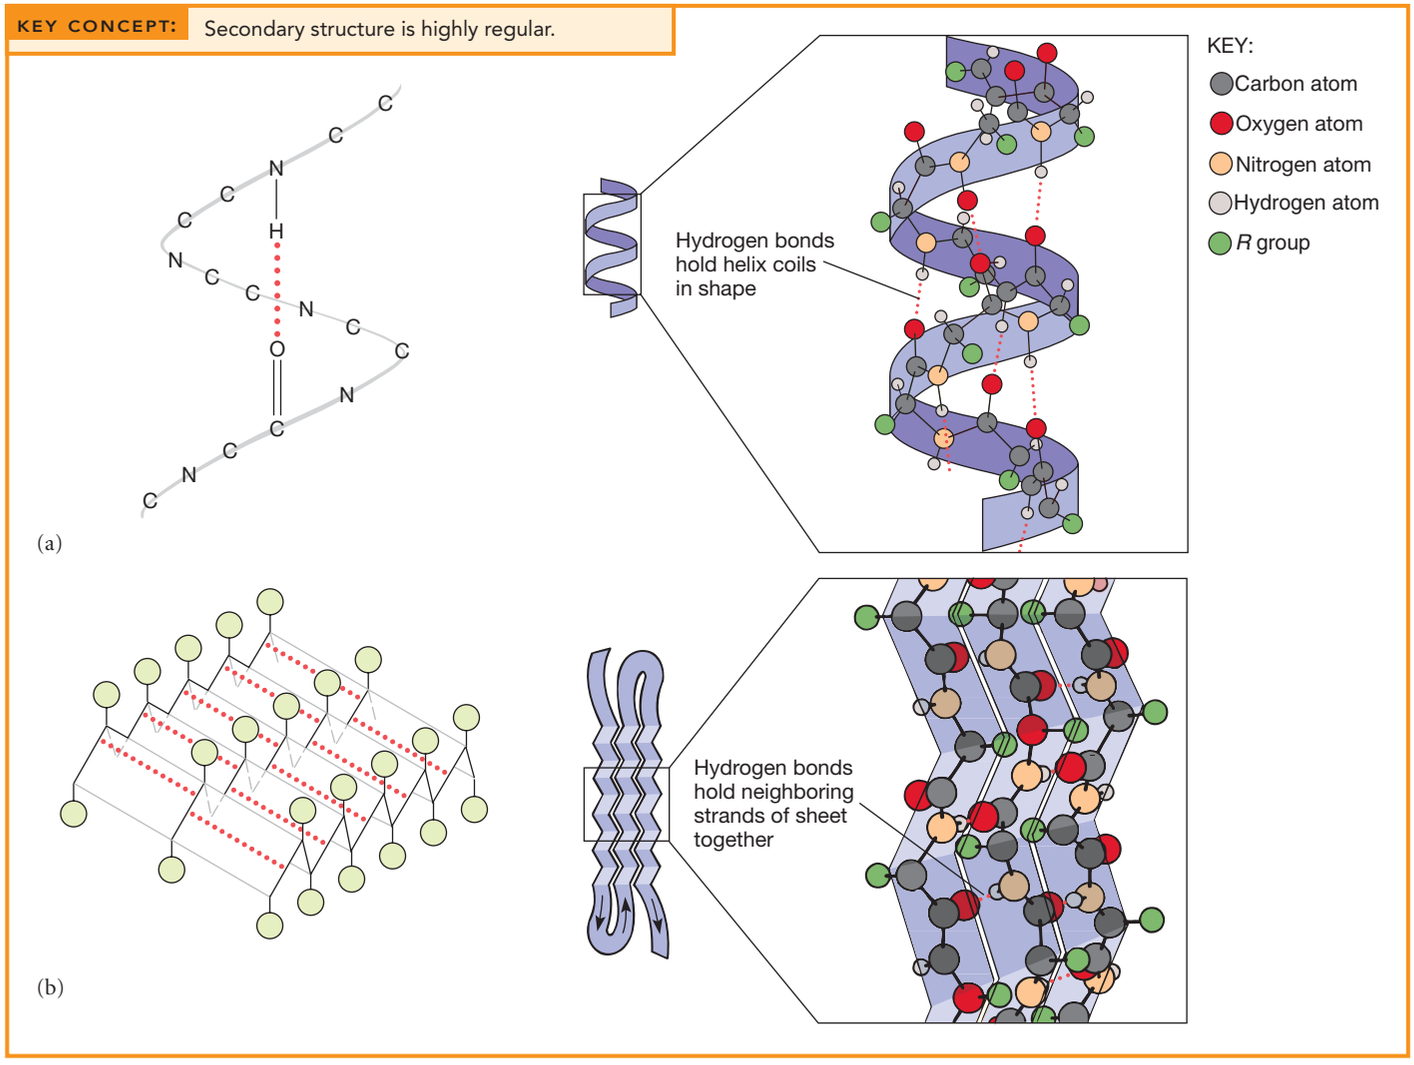


FIGURE **3-20** **Secondary structure of a protein.**

(a) In an α-helix the *R* groups project out from the sides. (The *R* groups have been omitted in the simplified diagram at left.) **(b)** A β-pleated sheet forms when a polypeptide chain folds back on itself *(arrows);* half the *R* groups project above the sheet, and the other half project below it.

posite of proteins with α-helical conformations (providing elasticity) and others with β-pleated sheet conformations (providing strength).

Tertiary structure depends on interactions among side chains

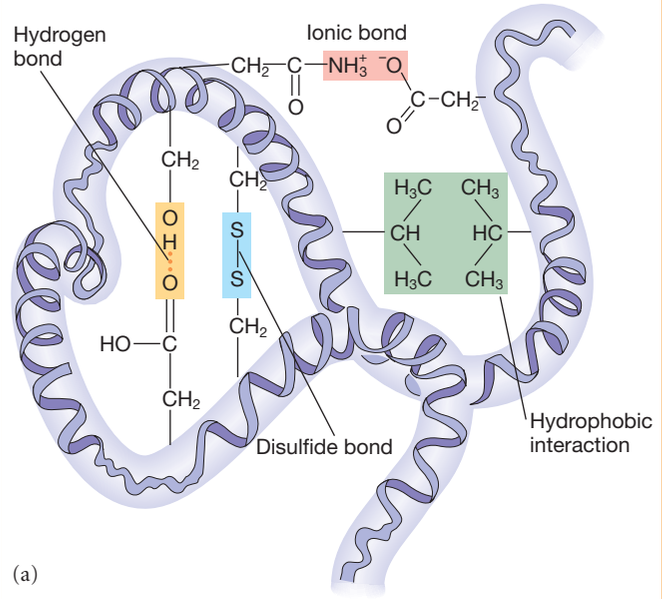
The **tertiary structure** of a protein molecule is the overall shape assumed by each individual polypeptide chain (Fig. 3-21). This 3-D structure is determined by four main factors that involve interactions among *R* groups (side chains) belonging to the same polypeptide chain. These include both weak interactions (hydrogen bonds, ionic bonds, and hydrophobic interactions) and strong covalent bonds.

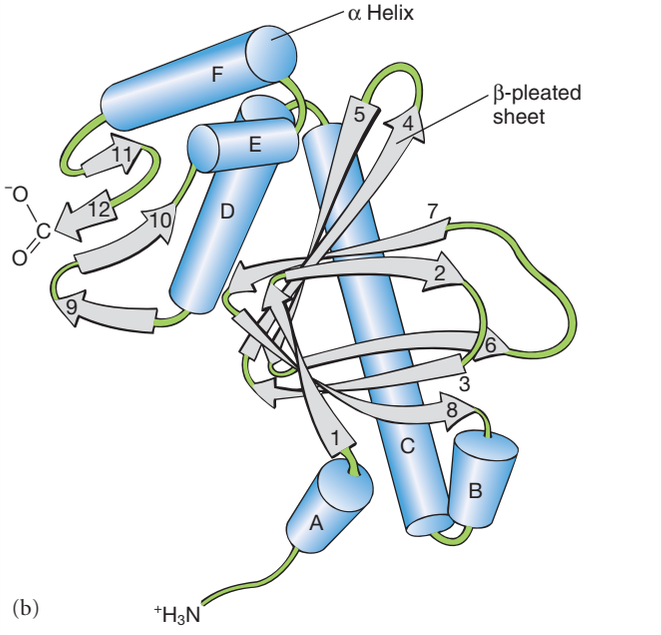
1. Hydrogen bonds form between *R* groups of certain amino acid subunits.
2. An ionic bond can occur between an *R* group with a unit of positive charge and one with a unit of negative charge.
3. Hydrophobic interactions result from the tendency of nonpolar *R* groups to be excluded by the surrounding water and therefore to associate in the interior of the globular structure.
4. Covalent bonds known as *disulfide bonds* or *disulfide bridges* (—S—S—) may link the sulfur atoms of two cysteine subunits belonging to the same chain. A disulfide bridge forms when the sulfhydryl groups of two cysteines react; the two hydrogens are removed, and the two sulfur atoms that remain become covalently linked.

Quaternary structure results from interactions among polypeptides

Many functional proteins are composed of two or more polypeptide chains, interacting in specific ways to form the biologically active molecule. **Quaternary structure** is the resulting 3-D

KEY CONCEPT: Tertiary structure depends on side chain interactions.





ACTIVE FIGURE 3-21 **Tertiary structure of a protein.**

(a) Hydrogen bonds, ionic bonds, hydrophobic interactions, and disulfide bridges between *R* groups hold the parts of the molecule in the designated shape. **(b)** In this drawing, α-helical regions are represented as blue tubes lettered A through F; β-pleated sheets are the gray arrows numbered 1 through 12. Green lines represent connecting regions. Although the molecule seems very complicated, it is a single polypeptide chain, starting at the amino end *(bottom left)* and terminating at the carboxyl end *(upper left)*. Most of the bends and foldbacks that give the molecule its overall conformation (tertiary structure) are stabilized by *R*-group interactions. This polypeptide is a subunit of a DNA-binding protein (known as CAP) from the bacterium *Escherichia coli*.

BiologyNow™ Learn more about the **structure of a protein** by clicking on this figure on your BiologyNow CD-ROM.

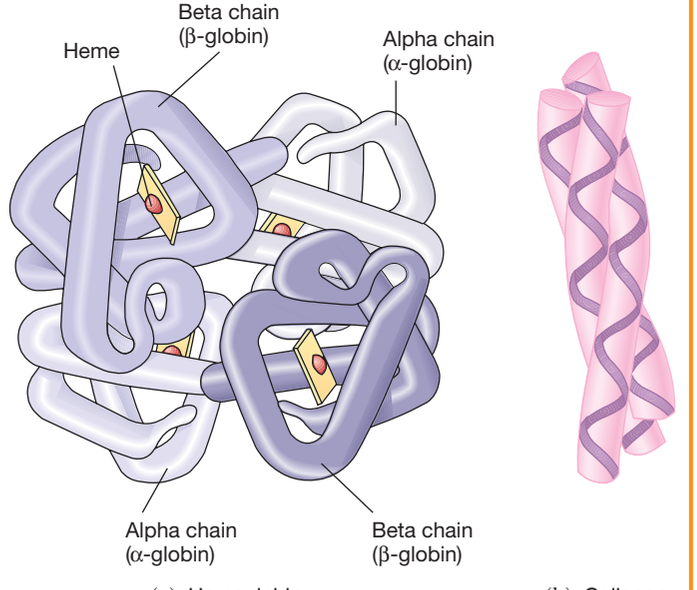
Hemoglobin, the protein in red blood cells responsible for oxygen transport, is an example of a globular protein with a quaternary structure (Fig. 3-22a). Hemoglobin consists of 574 amino acids arranged in four polypeptide chains: two identical chains called *alpha chains* and two identical chains called *beta chains*.

Collagen, mentioned previously, has a fibrous type of quaternary structure that allows it to function as the major strengthener of animal tissues. It consists of three polypeptide chains,

FIGURE 3-22 **Quaternary structure of a protein.**

(a) Hemoglobin, a globular protein, consists of four polypeptide chains, each joined to an iron-containing molecule, a heme. **(b)** Collagen, a fibrous protein, is a triple helix consisting of three long polypeptide chains.

KEY CONCEPT: Proteins with two or more polypeptide chains have quaternary structure.



architecture of these polypeptide chains, each with its own primary, secondary, and tertiary structure. The same types of interactions that produce secondary and tertiary structure also contribute to quaternary structure; these include hydrogen bonding, ionic bonding, hydrophobic interactions, and disulfide bridges.

A functional antibody molecule, for example, consists of four polypeptide chains joined by disulfide bridges (see Chapter 43). Disulfide bridges are a common feature of proteins secreted from cells, such as antibodies. These strong bonds stabilize the molecules in the extracellular environment.

wound about each other and bound by cross links between their amino acids (Fig. 3-22b).

The amino acid sequence of a protein determines its conformation

PROCESS OF SCIENCE

In 1996, researchers at the University of Illinois at Champaign-Urbana devised a test of the hypothesis that the conformation of a protein is dictated by its amino acid sequence. They conducted an experiment in which they completely unfolded myoglobin, a polypeptide that stores oxygen in muscle cells, and then used sophisticated technology to track the refolding process. They found that within a few fractions of a microsecond the molecule had coiled up to form α-helices, and within 4 microseconds formation of the tertiary structure was completed. Thus these researchers demonstrated that, at least under defined experimental conditions in vitro (outside a living cell), a polypeptide can spontaneously undergo folding processes that yield its normal, functional conformation.

This and other types of evidence support the widely held conclusion that amino acid sequence is the ultimate determinant of protein conformation. However, because conditions in vivo (in the cell) are quite different from defined laboratory conditions, proteins do not necessarily always fold spontaneously. On the contrary, scientists have learned that proteins known as **molecular chaperones** mediate the folding of other protein molecules. Molecular chaperones are thought to make the folding process more orderly and efficient and to prevent partially folded proteins from becoming inappropriately aggregated. However, there is no evidence that molecular chaperones actually dictate the folding pattern. For this reason, the existence of chaperones is not an argument against the idea that amino acid sequence determines conformation.

Protein conformation determines function

The overall structure of a protein helps determine its biological activity. A single protein may have more than one distinct structural region, each with its own function. Many proteins are modular, consisting of two or more globular regions, called *domains,* connected by less compact regions of the polypeptide chain. Each domain may have a different function. For example, a protein may have one domain that attaches it to a membrane and another that allows it to act as an enzyme.

The biological activity of a protein can be disrupted by a change in amino acid sequence that results in a change in conformation. For example, the genetic disease known as *sickle cell anemia* is due to a mutation that causes the substitution of the amino acid valine for glutamic acid at position 6 (the sixth amino acid from the amino end) in the beta chain of hemoglobin. The substitution of valine (which has a nonpolar side chain) for glutamic acid (which has a charged side chain) makes the hemoglobin less soluble and more likely to form crystal-like structures. This alteration of the hemoglobin affects the red blood cells, changing them to the crescent or sickle shapes that characterize this disease (see Fig. 15-8).

The biological activity of a protein may be affected by changes in its 3-D structure. When a protein is heated, subjected to significant pH changes, or treated with any of a number of chemicals, its structure becomes disordered and the coiled peptide chains unfold, yielding a more random conformation. This unfolding, which is mainly due to the disruption of hydrogen bonds and ionic bonds, is typically accompanied by a loss of normal function. Such changes in shape and the accompanying loss of biological activity are termed **denaturation** of the protein. For example, a denatured enzyme would lose its ability to catalyze a chemical reaction. An everyday example of denaturation occurs when we fry an egg. The consistency of the egg white protein, known as *albumin,* changes to a solid. Denaturation generally cannot be reversed (you can't "unfry" an egg). However, under certain conditions, some proteins have been denatured and have returned to their original shape and biological activity when normal environmental conditions have been restored.

Protein conformation is studied through a variety of methods

PROCESS OF SCIENCE

The architecture of a protein can be ascertained directly through sophisticated types of analysis, such as the x-ray diffraction studies discussed in Chapter 11. Because these studies are tedious and costly, researchers are developing alternative approaches, which rely heavily on the enormous databases generated by the Human Genome Project and related initiatives. Today a protein's primary structure can be determined rapidly through the application of genetic engineering techniques (see Chapter 14), or by the use of sophisticated technology such as mass spectrometry. Researchers use a variety of techniques to effectively use these amino acid sequence data to predict a protein's higher levels of structure. As you have seen, side chains interact in relatively predictable ways, such as through ionic and hydrogen bonds. In addition, regions with certain types of side chains appear more likely to form α-helices or β-pleated sheets. Complex computer programs make such predictions, but these are imprecise because of the many possible combinations of folding patterns.

Computers are an essential part of yet another strategy. Once the amino acid sequence of a polypeptide has been determined, researchers use computers to search databases to find polypeptides with similar sequences. If the conformations of any of those polypeptides or portions have already been determined directly by x-ray diffraction or other techniques, this information can be extrapolated to make similar correlations between amino acid sequence and 3-D structure for the protein under investigation. These predictions are increasingly reliable, as more information is added to the databases every day.

Review

- Draw the structural formula of a simple amino acid. What is the importance of the carboxyl group, amino group, and *R* group?
- How does the primary structure of a polypeptide influence its secondary and tertiary structures?

■ How can the conformation of a protein be disrupted?

BiologyNow™ Assess your understanding of **proteins** by taking the pretest on your BiologyNow CD-ROM.

NUCLEIC ACIDS

Learning Objective

10 Describe the components of a nucleotide. Name some nucleic acids, and discuss the importance of these compounds in living organisms.

Nucleic acids transmit hereditary information and determine what proteins a cell manufactures. Two classes of nucleic acids are found in cells: ribonucleic acid and deoxyribonucleic acid. **Deoxyribonucleic acid (DNA)** comprises the genes, the hereditary material of the cell, and contains instructions for making all the proteins, as well as all the RNA the organism needs. **Ribonucleic acid (RNA)** participates in the complex process in which amino acids are linked to form polypeptides. Some types of RNA, known as **ribozymes,** can even act as specific biological catalysts. Like proteins, nucleic acids are large, complex molecules. The name *nucleic acid* reflects the fact that they are acidic and were first identified, by Friedrich Miescher in 1870, in the nuclei of pus cells.

Nucleic acids are polymers of **nucleotides,** molecular units that consist of (1) a five-carbon sugar, either **deoxyribose** (in DNA) or **ribose** (in RNA); (2) one or more phosphate groups, which make the molecule acidic; and (3) a nitrogenous base, a ring compound that contains nitrogen. The nitrogenous base may be either a double-ring **purine** or a single-ring **pyrimidine** (Fig. 3-23).

DNA commonly contains the purines adenine (A) and guanine (G), the pyrimidines cytosine (C) and thymine (T), the sugar deoxyribose, and phosphate. RNA contains the purines adenine and guanine, and the pyrimidines cytosine and uracil (U), together with the sugar ribose, and phosphate.

The molecules of nucleic acids are made of linear chains of nucleotides, which are joined by **phosphodiester linkages,** each consisting of a phosphate group and the covalent bonds that attach it to the sugars of adjacent nucleotides (Fig. 3-24). Note that each nucleotide is defined by its particular base and that nucleotides can be joined in any sequence. A nucleic acid molecule

(b) Purines

FIGURE **3-23** **Components of nucleotides.**

(a) The three major pyrimidine bases found in nucleotides are cytosine, thymine (in DNA only), and uracil (in RNA only). **(b)** The two major purine bases found in nucleotides are adenine and guanine. The hydrogens indicated by the boxes are removed when the base is attached to a sugar.

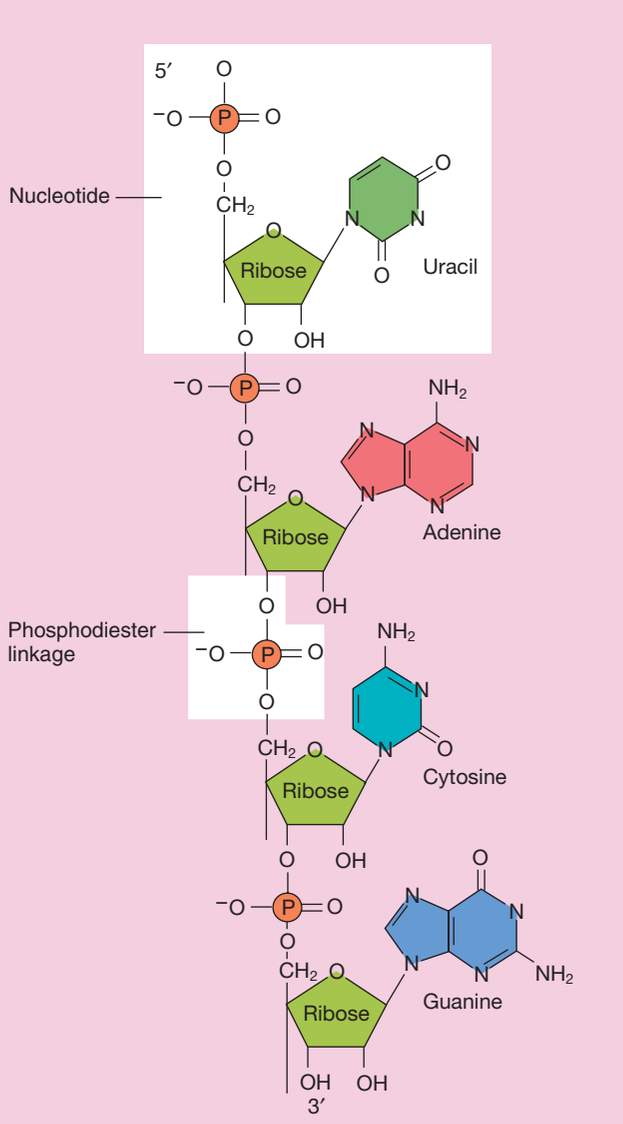

FIGURE **3-24** **RNA, a nucleic acid.**

Nucleotides, each with a specific base, are joined by phosphodiester linkages.

TABLE 3-3 Classes of Biologically Important Organic Compounds

Class and Component Elements	Description	How to Recognize	Principal Function in Living Systems
Carbohydrates C, H, O	Contain approximately 1 C:2 H:1 O (but make allowance for loss of oxygen when sugar units as nucleic acids and glycoproteins are linked)	Count the carbons, hydrogens, and oxygens.	Cell fuel; energy storage; structural component of plant cell walls; component of other compounds such as nucleic acids and glycoproteins
	1. Monosaccharides (simple sugars). Mainly five-carbon (pentose) molecules such as ribose or six-carbon (hexose) molecules such as glucose and fructose	Look for the ring shapes: 	Cell fuel; components of other compounds
	2. Disaccharides. Two sugar units linked by a glycosidic bond, e.g., maltose, sucrose	Count sugar units	Components of other compounds; form of sugar transported in plants
	3. Polysaccharides. Many sugar units linked by glycosidic bonds, e.g., glycogen, cellulose	Count sugar units	Energy storage; structural components of plant cell walls
Lipids C, H, O (sometimes N, P)	Contain much less oxygen relative to carbon and hydrogen than do carbohydrates		Energy storage; cellular fuel, components of cells; thermal insulation
	1. *Fats.* Combination of glycerol with one to three fatty acids. Monoacylglycerol contains one fatty acid; diacylglycerol contains two fatty acids; triacylglycerol contains three fatty acids. If fatty acids contain double carbon-to-carbon linkages (C = C), they are unsaturated; otherwise they are saturated	Look for glycerol at one end of molecule: 	Cell fuel; energy storage
	2. *Phospholipids.* Composed of glycerol attached to one or two fatty acids and to an organic base containing phosphorus	Look for glycerol and side chain containing phosphorus and nitrogen.	Components of cell membranes
	3. *Steroids.* Complex molecules containing carbon atoms arranged in four attached rings (Three rings contain six carbon atoms each, and the fourth ring contains five.)	Look for four attached rings: 	Some are hormones, others include cholesterol, bile salts, vitamin D, components of cell membranes
	4. *Carotenoids.* Orange and yellow pigments; consist of isoprene units	Look for isoprene units. 	Retinal (important in photoreception) and vitamin A are formed from carotenoids
Proteins C, H, O, N (usually S)	One or more polypeptides (chains of amino acids) coiled or folded in characteristic shapes	Look for amino acid units joined by C—N bonds.	Serve as enzymes; structural components; muscle proteins; hemoglobin.
Nucleic acids C, H, O, N, P	Backbone composed of alternating pentose and phosphate groups, from which nitrogenous bases project. DNA contains the sugar deoxyribose and the bases guanine, cytosine, adenine, and thymine. RNA contains the sugar ribose and the bases guanine, cytosine, adenine, and uracil. Each molecular subunit, called a nucleotide, consists of a pentose, a phosphate, and a nitrogenous base.	Look for a pentose-phosphate backbone. DNA forms a double helix.	Storage, transmission, and expression of genetic information

is uniquely defined by its specific sequence of nucleotides, which constitutes a kind of code (see Chapter 12). Whereas RNA is usually composed of one nucleotide chain, DNA consists of two nucleotide chains held together by hydrogen bonds and entwined around each other in a double helix (see Fig. 1-7).

Some nucleotides are important in energy transfers and other cell functions

In addition to their importance as subunits of DNA and RNA, nucleotides perform other vital functions in living cells. **Adeno-**

sine triphosphate (ATP), composed of adenine, ribose, and three phosphates (see Fig. 6-5), is of major importance as the primary energy currency of all cells (see Chapter 6). The two terminal phosphate groups are joined to the nucleotide by covalent bonds. These are traditionally indicated by wavy lines, which indicate that ATP can transfer a phosphate group to another molecule, making that molecule more reactive. In this way ATP is able to donate some of its chemical energy. Most of the readily available chemical energy of the cell is associated with the phosphate groups of ATP. Like ATP, **guanosine triphosphate (GTP),** a nucleotide that contains the base guanine, can transfer energy by transferring a phosphate group and also has a role in cell signaling (see Chapter 5).

A nucleotide may be converted to an alternative form with specific cellular functions. ATP, for example, is converted to **cyclic adenosine monophosphate (cyclic cAMP)** by the enzyme adenylyl cyclase (Fig. 3-25). Cyclic AMP regulates certain cell functions and is important in the mechanism by which some hormones act (see Chapters 13, 39, and 47). A related molecule, **cyclic guanosine monophosphate (cGMP),** also plays a role in certain cell signaling processes.

Cells contain several dinucleotides, which are of great importance in metabolic processes. For example, as discussed in Chapter 6, **nicotinamide adenine dinucleotide** has a primary role in biological oxidation and reduction reactions in cells. It can exist in an oxidized form (NAD^+) that is converted to a reduced form (**NADH**) when it accepts electrons (in association with hydrogen; see Fig. 6-7). These electrons, along with their energy, are transferred to other molecules.

Review

- Compare the functions of proteins and nucleic acids. How are their structures related to these functions?

BiologyNow™ Assess your understanding of **nucleic acids** by taking the pretest on your BiologyNow CD-ROM.

IDENTIFYING BIOLOGICAL MOLECULES

Learning Objective

11 Compare the functions and chemical compositions of the major groups of organic compounds: carbohydrates, lipids, proteins, and nucleic acids.

Although the fundamental classes of biological molecules may seem overwhelming at first, you will learn to distinguish them readily by understanding their chief attributes. These are summarized in Table 3-3.

Review

- How can you distinguish a pentose sugar from a hexose sugar? A disaccharide from a sterol? An amino acid from a monosaccharide? A phospholipid from a triacylglycerol? A protein from a polysaccharide? A nucleic acid from a protein?

BiologyNow™ Assess your understanding of **biological molecules** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Describe the properties of carbon that make it the central component of organic compounds.

- Each carbon atom forms four covalent bonds with up to four other atoms; these bonds are single, double, or triple bonds.
- Carbon atoms form straight or branched chains or join into rings.
- Carbon forms covalent bonds with a greater number of different elements than does any other type of atom.

2 Define the term *isomer,* and distinguish among the three principal isomer types.

- **Isomers** are compounds with the same molecular formula but different structures.
- **Structural isomers** differ in the covalent arrangements of their atoms. **Geometric isomers,** or *cis–trans* isomers, differ in the spatial arrangements of their atoms. **Enantiomers** are isomers that are mirror images of each other. Cells can distinguish between these configurations.

3 Identify the major functional groups present in organic compounds, and describe their properties.

- Hydrocarbons, organic compounds consisting of only carbon and hydrogen, are nonpolar and hydrophobic. The **methyl group** is a hydrocarbon group.
- Polar and ionic functional groups interact with each other and are hydrophilic.
- Partial charges on atoms at opposite ends of a bond are responsible for the polar property of a functional group. **Hydroxyl** and **carbonyl groups** are polar.
- **Carboxyl** and **phosphate groups** are acidic, becoming negatively charged when they release hydrogen ions. The **amino group** is basic, becoming positively charged when it accepts a hydrogen ion.

4 Explain the relationship between polymers and macromolecules.

- Long chains of **monomers** (similar organic compounds) linked together through **condensation reactions** are called **polymers.**
- Large polymers such as polysaccharides, proteins, and DNA are referred to as **macromolecules.** They can be broken down by **hydrolysis reactions.**

SUMMARY WITH KEY TERMS *(continued)*

5 Distinguish among monosaccharides, disaccharides, and polysaccharides; compare storage polysaccharides with structural polysaccharides.

- **Carbohydrates** contain carbon, hydrogen, and oxygen in a ratio of approximately one carbon to two hydrogens to one oxygen.
- **Monosaccharides** are simple sugars such as glucose, fructose, and ribose.
- Two monosaccharides join by a **glycosidic linkage** to form a **disaccharide** such as maltose or sucrose.
- Most carbohydrates are **polysaccharides,** long chains of repeating units of a simple sugar. Carbohydrates are typically stored in plants as the polysaccharide **starch** and in animals as the polysaccharide **glycogen.** The cell walls of plants are composed mainly of the structural polysaccharide **cellulose.**

6 Distinguish among fats, phospholipids, and steroids, and describe the composition, characteristics, and biological functions of each.

- **Lipids** are composed mainly of hydrocarbon-containing regions, with few oxygen-containing (polar or ionic) functional groups. Lipids have a greasy or oily consistency and are relatively insoluble in water.
- **Triacylglycerol,** the main storage form of fat in organisms, consists of a molecule of **glycerol** combined with three **fatty acids. Monoacylglycerols** and **diacylglycerols** contain one and two fatty acids, respectively. A fatty acid can be either **saturated** with hydrogen, or **unsaturated.**
- **Phospholipids** are structural components of cell membranes. A phospholipid consists of a glycerol molecule attached at one end to two fatty acids and at the other end to a phosphate group linked to an organic compound such as choline.
- **Steroid** molecules contain carbon atoms arranged in four attached rings. Cholesterol, bile salts, and certain hormones are important steroids.

7 Give an overall description of the structure and functions of proteins.

- **Proteins** are large, complex molecules made of simpler subunits, called **amino acids,** joined by **peptide bonds.**
- Proteins are the most versatile class of biological molecules, serving a variety of functions, such as **enzymes,** structural components, and cell regulators.
- Proteins are composed of various linear sequences of 20 different amino acids. Two amino acids combine to form a **dipeptide.** A longer chain of amino acids is a **polypeptide.**

8 Describe the features that are shared by all amino acids, and explain how amino acids are grouped into classes based on the characteristics of their side chains.

- All amino acids contain an amino group and a carboxyl group.
- Amino acids vary in their side chains, which dictate their chemical properties—nonpolar, polar, acidic or basic.
- Amino acids generally exist as dipolar ions at cell pH and serve as important biological buffers.

9 Distinguish among the four levels of organization of protein molecules.

- **Primary structure** is the linear sequence of amino acids in the polypeptide chain.
- **Secondary structure** is a regular conformation, such as an **α-helix** or a **β-pleated sheet;** it is due to hydrogen bonding between elements of the backbones of the amino acids.
- **Tertiary structure** is the overall shape of the polypeptide chains, as dictated by chemical properties and interactions of the side chains of specific amino acids. Hydrogen bonds, ionic bonds, hydrophobic interactions, and disulfide bridges contribute to tertiary structure.
- **Quaternary structure** is determined by the association of two or more polypeptide chains.

10 Describe the components of a nucleotide. Name some nucleic acids and nucleotides, and discuss the importance of these compounds in living organisms.

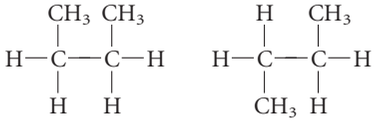
- **Nucleotides** are composed of a two-ring **purine** or one-ring **pyrimidine** nitrogenous base, a five-carbon sugar (**ribose** or **deoxyribose**), and one or more phosphate groups.
- The **nucleic acids DNA** and **RNA,** composed of long chains of nucleotide subunits, store and transfer information that governs the sequence of amino acids in proteins and ultimately the structure and function of the organism.
- **ATP** (**adenosine triphosphate**) is a nucleotide of special significance in energy metabolism. **NAD^+** is also involved in energy metabolism through its role as an electron (hydrogen) acceptor in biological oxidation and reduction reactions.

11 Compare the functions and chemical compositions of the major groups of organic compounds: carbohydrates, lipids, proteins, and nucleic acids.

- Review Table 3-3.

POST-TEST

1. Which of the following is generally considered an inorganic form of carbon? (a) CO_2 (b) C_2H_4 (c) CH_3COOH (d) b and c (e) all of the preceding are inorganic
2. Carbon is particularly well suited to be the backbone of organic molecules because (a) it can form both covalent bonds and ionic bonds (b) its covalent bonds are very irregularly arranged in three-dimensional space (c) its covalent bonds are the strongest chemical bonds known (d) it can bond to atoms of a large number of other elements (e) all the bonds it forms are polar
3. The structures depicted are



(a) enantiomers (b) different views of the same molecule (c) geometric (*cis–trans*) isomers (d) both geometric isomers and enantiomers (e) structural isomers

POST-TEST *(continued)*

4. Which of the following are generally hydrophobic? (a) polar molecules and hydrocarbons (b) ions and hydrocarbons (c) nonpolar molecules and ions (d) polar molecules and ions (e) none of the above
5. Which of the following is a nonpolar molecule? (a) water, H_2O (b) ammonia, NH_3 (c) methane, CH_4 (d) ethane, C_2H_6 (e) more than one of the preceding
6. Which of the following functional groups normally acts as an acid? (a) hydroxyl (b) carbonyl (c) sulfhydryl (d) phosphate (e) amino
7. The synthetic process by which monomers are covalently linked is (a) hydrolysis (b) isomerization (c) condensation (d) glycosidic linkage (e) ester linkage
8. A monosaccharide designated as an aldehyde sugar contains (a) a terminal carboxyl group (b) an internal carboxyl group (c) a terminal carbonyl group (d) an internal carbonyl group (e) a terminal carboxyl group and an internal carbonyl group
9. Structural polysaccharides typically (a) have extensive hydrogen bonding between adjacent molecules (b) are much more hydrophilic than storage polysaccharides (c) have much stronger covalent bonds than do storage polysaccharides (d) consist of alternating α-glucose and β-glucose subunits (e) form helical structures in the cell
10. A carboxyl group is always found in (a) organic acids and sugars (b) sugars and fatty acids (c) fatty acids and amino acids (d) alcohols (e) glycerol
11. Fatty acids are components of (a) phospholipids and carotenoids (b) carotenoids and triacylglycerol (c) steroids and triacylglycerol (d) phospholipids and triacylglycerol (e) carotenoids and steroids
12. Saturated fatty acids are so named because they are saturated with (a) hydrogen (b) water (c) hydroxyl groups (d) glycerol (e) double bonds
13. Fatty acids in phospholipids and triacylglycerols interact with each other by (a) disulfide bridges (b) van der Waals interactions (c) covalent bonds (d) hydrogen bonds (e) actually, fatty acids do not interact with each other
14. Which pair of amino acid side groups would be most likely to associate with each other by an ionic bond?
    1. $—CH_3$
    2. $—CH_2—COO^-$
    3. $—CH_2—CH_2—NH_3^+$
    4. $—CH_2—CH_2—COO^-$
    5. $—CH_2—OH$

    (a) 1 and 2 (b) 2 and 4 (c) 1 and 5 (d) 2 and 5 (e) 3 and 4
15. Which of the following levels of protein structure may be affected by hydrogen bonding? (a) primary and secondary (b) primary and tertiary (c) secondary, tertiary, and quaternary (d) primary, secondary, and tertiary (e) primary, secondary, tertiary, and quaternary
16. Which of the following associations between *R* groups are the strongest? (a) hydrophobic interactions (b) hydrogen bonds (c) ionic bonds (d) peptide bonds (e) disulfide bridges
17. Each phosphodiester linkage in DNA or RNA includes a phosphate joined by covalent bonds to (a) two bases (b) two sugars (c) two additional phosphates (d) a sugar, a base, and a phosphate (e) a sugar and a base

CRITICAL THINKING

1. Like oxygen, sulfur forms two covalent bonds. However, sulfur is far less electronegative. In fact, it is approximately as electronegative as carbon. How would the properties of the various classes of biological molecules be altered if you were to replace all the oxygen atoms with sulfur atoms?
2. In what ways are all species alike biochemically? How do species differ from one another biochemically?
3. Hydrogen bonds and van der Waals interactions are much weaker than covalent bonds, yet they are vital to organisms. Why?

Organization of the Cell

CHAPTER OUTLINE

- Cell Organization and Size
- Methods for Studying Cells
- Prokaryotic and Eukaryotic Cells
- Cell Membranes
- The Cell Nucleus
- Organelles in the Cytoplasm
- The Cytoskeleton
- Cell Coverings

Cells are dramatic examples of the underlying unity of all living things. This idea was first expressed by two German scientists, botanist Matthias Schleiden in 1838 and zoologist Theodor Schwann in 1839. Using their own observations and those of other scientists, these early investigators used inductive reasoning to conclude that all plants and animals consist of cells. Later, Rudolf Virchow, another German scientist, observed cells dividing and giving rise to daughter cells. In 1855, Virchow proposed that new cells form only by the division of previously existing cells.

The work of Schleiden, Schwann, and Virchow contributed greatly to the development of the **cell theory,** the unifying concept that (1) cells are the basic living units of organization and function in all organisms and (2) that all cells come from other cells. About 1880 another German biologist, August Weismann, added an important corollary to Virchow's concept by pointing out that the ancestry of all the cells alive today can be traced back to ancient times. Evidence that all living cells have a common origin is provided by the basic similarities in their structures and in the molecules of which they are made. When we examine a variety of diverse organisms, ranging from simple bacteria to the most complex plants and animals, we find striking similarities at the cell level. Careful studies of shared cell characteristics help us trace the evolutionary history of various groups of organisms and furnish powerful evidence that all organisms alive today had a common origin.

Each cell is a microcosm of life. It is the smallest unit that can carry out all activities we associate with life. When provided with essential nutrients and an appropriate environment, some cells can be kept alive and growing in the laboratory for many years. By contrast, no isolated part of a cell is capable of sustained survival. Composed of a vast array of inorganic and organic ions and molecules, including water, salts, carbohydrates, lipids, proteins, and nucleic acids, most cells have all the physical and chemical components needed for their own maintenance, growth, and division. Genetic information is stored in DNA molecules and is faithfully replicated and passed to each

new generation of cells during cell division. Information in DNA codes for specific proteins that in turn determine cell structure and function. In this chapter and those that follow, we discuss how cells use many of the chemical materials we introduced in Chapters 2 and 3.

Cells exchange materials and energy with the environment. All living cells need one or more sources of energy, but a cell rarely obtains energy in a form that is immediately usable. Cells convert energy from one form to another, and that energy is used to carry out various activities, ranging from mechanical work to chemical synthesis. Cells convert energy to a convenient form, usually chemical energy stored in adenosine triphosphate, or ATP (see Chapter 3). Although the specifics vary, the basic strategies cells use for energy conversion are very similar. The chemical reactions that convert energy from one form to another are essentially the same in all cells, from bacteria to those of complex plants and animals.

Cells are the building blocks of complex multicellular organisms. Although they are basically similar, cells are also extraordinarily diverse and versatile. They can be modified in a variety of ways to carry out specialized functions.

Thanks to advances in technology, cell biologists use increasingly sophisticated tools in their search to better understand the structure and function of cells. For example, investigation of the cytoskeleton (cell skeleton), currently an active and exciting area of research, has been greatly enhanced by advances in microscopy. In the photograph, we see the extensive distribution of microtubules in cells. Microtubules are key components of the cytoskeleton. They help maintain cell shape, function in cell movement, and facilitate transport of materials within the cell. Proteins associated with DNA are also stained in the photomicrograph, and chromosomes are visible in the upper cell. As biologists continue to unlock the secrets of DNA, many new doors are opening to development of medical treatments as well as to better understanding of the organisms that share our planet. ■

CELL ORGANIZATION AND SIZE

Learning Objectives

1. Summarize the relationship between cell organization and homeostasis.
2. Explain the relationship between cell size and maintaining homeostasis.

The organization of cells and their small size allow them to maintain **homeostasis,** an appropriate internal environment. Cells experience constant changes in their environments, such as deviations in salt concentration, pH, and temperature. They must work continuously to restore and maintain the internal conditions that enable their biochemical mechanisms to function.

The organization of all cells is basically similar

To maintain homeostasis, the contents of the cell must be separated from the external environment. The **plasma membrane** is a structurally distinctive surface membrane that surrounds all cells. By making the interior of the cell an enclosed compartment, the plasma membrane allows the chemical composition of the cell to be quite different from that outside the cell. The plasma membrane serves as an extremely selective barrier between the cell contents and the outer environment. Cells exchange materials with the environment and can accumulate needed substances and energy stores.

Typically, cells have internal structures, called **organelles,** that are specialized to carry out metabolic activities such as converting energy to usable forms, synthesizing needed compounds, and manufacturing structures necessary for functioning and reproduction. Each cell has genetic instructions coded in its DNA, which is concentrated in a limited region of the cell.

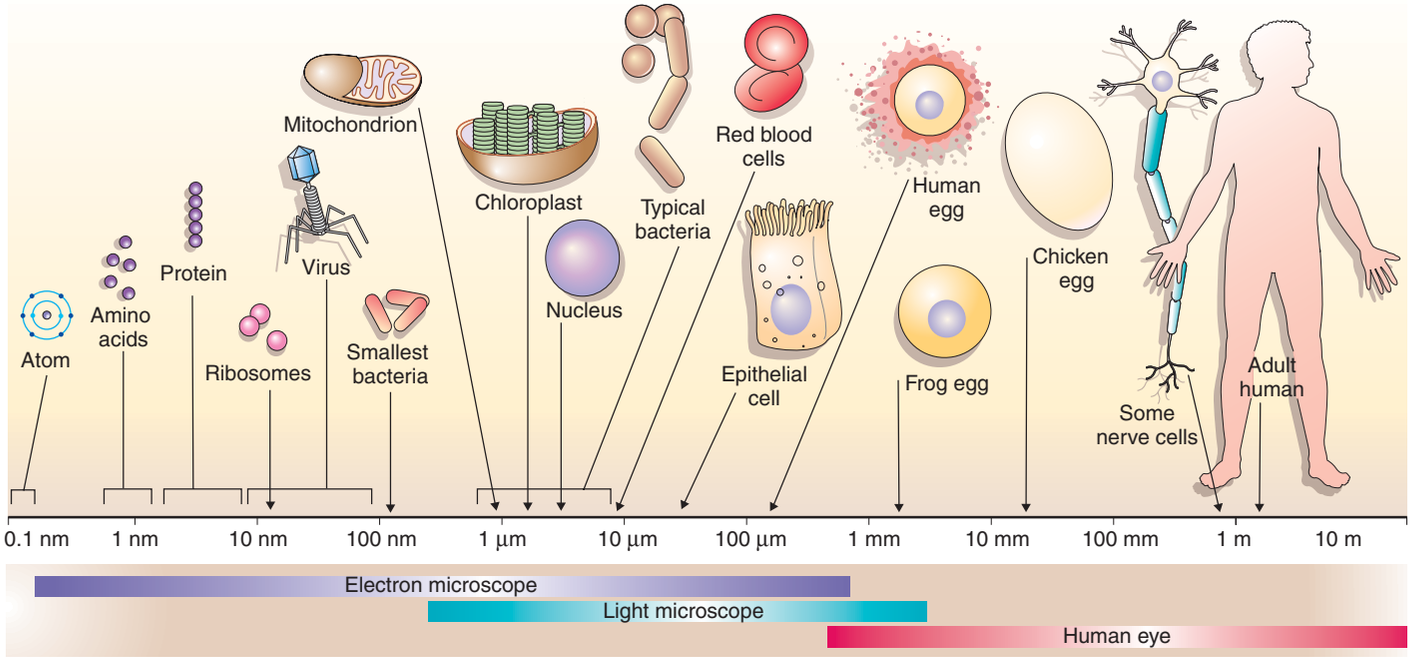
Cell size is limited

Although their sizes vary over a wide range (Fig. 4-1), most cells are microscopic, and must be measured by very small units. The basic unit of linear measurement in the metric system (see inside back cover) is the meter (m), which is just a little longer than a yard. A millimeter (mm) is 1/1000 of a meter and is about as long as the bar enclosed in parentheses (-). The micrometer (μm) is the most convenient unit for measuring cells. A bar 1 μm long is 1/1,000,000 (one millionth) of a meter, or 1/1000 of a millimeter—far too short to be seen with the unaided eye. Most of us have difficulty thinking about units that are too small to see, but it is helpful to remember that a micrometer has the same relationship to a millimeter that a millimeter has to a meter (1/1000).

As small as it is, the micrometer is actually too large to measure most cell components. For this purpose biologists use the nanometer (nm), which is 1/1,000,000,000 (one billionth) of a meter, or 1/1000 of a micrometer. To mentally move down to the world of the nanometer, recall that a millimeter is 1/1000 of a meter, a micrometer is 1/1000 of a millimeter, and a nanometer is 1/1000 of a micrometer.

A few specialized algae and animal cells are large enough to be seen with the naked eye. A human egg cell, for example, is about 130 μm in diameter, or approximately the size of the period at the end of this sentence. The largest cells are birds' eggs, but they are atypical because both the yolk and the egg white consist of food reserves. The functioning part of the cell is a small mass on the surface of the yolk. Most cells are small and can only be seen with a microscope.

Why are most cells so small? If you consider what a cell must do to maintain homeostasis and to grow, it may be easier to understand the reasons for its small size. A cell must take in food and other materials and must rid itself of waste products generated by metabolic reactions. Everything that enters or leaves a cell must pass through its plasma membrane. The plasma membrane contains specialized "pumps" and channels with "gates"



Measurements		
1 meter	=	1000 millimeters (mm)
1 millimeter	=	1000 micrometers (µm)
1 micrometer	=	1000 nanometers (nm)

FIGURE 4-1 Biological size and cell diversity.

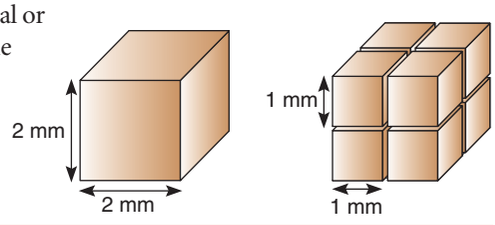
We can compare relative size from the chemical level to the organismic level, using a logarithmic scale (multiples of 10). The prokaryotic cells of bacteria typically range in size from less than 1 to 10 µm long; their small size enables them to grow and divide rapidly. Eukaryotic cells are typically 10 to 100 µm in diameter; most are between 10 and 30 µm. The nuclei of animal and plant cells range from about 3 to 10 µm in diameter. Mitochondria are about the size of small bacteria, whereas chloroplasts are usually larger, about 5 µm long. Ova (egg cells) are among the largest cells. Although microscopic, some nerve cells are very long. The cells shown here are not drawn to scale.

that selectively regulate the passage of materials into and out of the cell. The plasma membrane must be large enough relative to the cell volume to keep up with the demands of regulating the passage of materials. Thus a critical factor in determining cell size is the ratio of its surface area (the plasma membrane) to its volume (Fig. 4-2).

As a cell becomes larger, its volume increases at a greater rate than its surface area (its plasma membrane), which effectively places an upper limit on cell size. Above some critical size, the number of molecules required by the cell could not be transported into the cell fast enough to sustain its needs. In addition, the cell would not be able to regulate its concentration of various ions or efficiently export its wastes.

Of course, not all cells are spherical or cuboid. Because of their shapes, some very large cells have relatively favorable ratios of surface area to volume. In fact, some variations in cell shape represent a strategy for increasing the ratio of surface area to volume. For example, many large plant cells are long and thin, which increases their surface-to-volume ratio. Some cells, such as epithelial cells lining the small intestine, have finger-like projections of the plasma membrane, called **microvilli,** that significantly increase the surface area for absorbing nutrients and other materials (see Fig. 45-10c).

Another reason for the small size of cells is that, once inside, molecules must be trans-



Surface Area (mm)	Surface area = height × width × number of sides × number of cubes	24 (2 × 2 × 6 × 1)	48 (1 × 1 × 6 × 8)
Volume (mm)	Volume = height × width × length × number of cubes	8 (2 × 2 × 2 × 1)	8 (1 × 1 × 1 × 8)
Surface Area/ Volume Ratio	Surface area/ volume	3 (24:8)	6 (48:8)

FIGURE 4-2 Surface area-to-volume ratio.

The surface area of a cell must be large enough relative to its volume to allow adequate exchange of materials with the environment. Although their volumes are the same, eight small cells have a much greater surface area (plasma membrane) in relation to their total volume than one large cell. In the example shown, the ratio of the total surface area to total volume of eight 1-mm cubes is double the surface-to-volume ratio of the single large cube.

ported to the locations where they are converted into other forms. Because cells are small, the distances molecules travel within them are relatively short, which speeds up many cell activities.

Cell size and shape are related to function

The sizes and shapes of cells are related to the functions they perform. Some cells, such as the amoeba and the white blood cell, change their shape as they move about. Sperm cells have long, whiplike tails, called *flagella,* for locomotion. Nerve cells have long, thin extensions that enable them to transmit messages over great distances. The extensions of some nerve cells in the human body may be as long as 1 m. Other cells, such as certain epithelial cells, are almost rectangular and are stacked much like building blocks to form sheetlike structures.

Review

METHODS FOR STUDYING CELLS

Learning Objective

3 Describe methods that biologists use to study cells, including microscopy and cell fractionation.

PROCESS OF SCIENCE

One of the most important tools biologists use for studying cell structures is the microscope. Cells were first described in 1665 by the English scientist Robert Hooke in his book *Micrographica.* Using a microscope he had made, Hooke examined a piece of cork, and drew and described what he saw. Hooke chose the term *cell* because the tissue reminded him of the small rooms monks lived in. Interestingly, what Hooke saw were not actually living cells, but the walls of dead cork cells (Fig. 4-3a). Much later, scientists recognized that the interior enclosed by the walls is the important part of living cells.

A few years later, inspired by Hooke's work, the Dutch naturalist Anton van Leeuwenhoek viewed living cells with small lenses that he made. Leeuwenhoek was highly skilled at grinding lenses and was able to magnify images more than 200 times. Among his important discoveries were bacteria, protists, blood cells, and sperm cells. Leeuwenhoek was among the first scientists to report cells in animals. Leeuwenhoek was a merchant, and not formally trained as a scientist. However, his skill, curiosity, and diligence in sharing his discoveries with scientists at the Royal Society of London brought an awareness of microscopic life to the scientific world. Unfortunately, Leeuwenhoek did not share his techniques, and not until more than 100 years later, in the late 19th century, were microscopes sufficiently developed for biologists to seriously focus their attention on the study of cells.

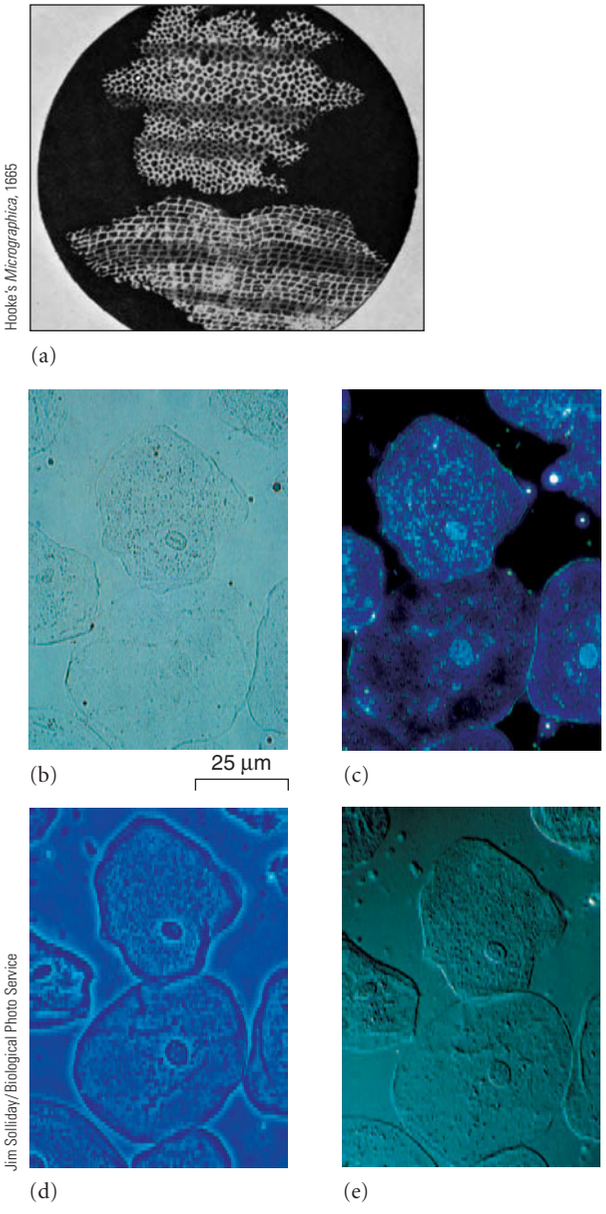

FIGURE **4-3** **Viewing cells with various types of microscopes.**

(a) Using a crude microscope that he constructed, Robert Hooke looked at a thin slice of cork and drew what he saw. More sophisticated microscopes and techniques enable biologists to view cells in more detail. Unstained epithelial cells from the skin of a human cheek are compared using **(b)** bright-field (transmitted light), **(c)** dark-field, **(d)** phase-contrast, and **(e)** Nomarski differential interference microscopy. Bright-field can be enhanced by staining. The phase-contrast and differential interference microscopes enhance detail by increasing the differences in optical density in different regions of the cells.

Light microscopes are used to study stained or living cells

The **light microscope (LM),** the type used by most students, consists of a tube with glass lenses at each end. Because it contains several lenses, the modern light microscope is referred to as a *compound microscope.* Visible light passes through the spec-

imen being observed and through the lenses. Light is refracted (bent) by the lenses, magnifying the image.

Two features of a microscope determine how clearly a small object can be viewed: magnification and resolving power. **Magnification** is the ratio of the size of the image seen with the microscope to the actual size of the object. The best light microscopes usually magnify an object no more than 1000 times. **Resolution,** or **resolving power,** is the capacity to distinguish fine detail in an image; it is defined as the minimum distance between two points at which they can both be seen separately rather than as a single, blurred point. Resolving power depends on the quality of the lenses and the wavelength of the illuminating light. As the wavelength decreases, the resolution increases. The visible light used by light microscopes has wavelengths ranging from about 400 nm (violet) to 700 nm (red); this limits the resolution of the light microscope to details no smaller than the diameter of a small bacterial cell (about 1 μm).

By the early 20th century, refined versions of the light microscope, as well as certain organic compounds that specifically stain different cell structures, became available. Using these tools, biologists discovered that cells contain many different internal structures, the organelles. The contribution of organic chemists in developing biological stains was essential to this understanding, because the interior of many cells is transparent. Most methods used to prepare and stain cells for observation, however, also kill them in the process.

Living cells can now be studied using light microscopes with special optical systems. In *bright-field microscopy,* an image is formed by transmitting light through a cell in culture (Fig. 4-3b). Because there is little contrast, the details of cell structure are not visible. In *dark-field microscopy,* rays of light are directed from the side and only scattered light enters the lenses. The cell is visible as a bright object against a dark background (Fig. 4-3c). *Phase contrast microscopy* and *differential-interference-contrast microscopy (Nomarski)* take advantage of variations in density within the cell (Fig. 4-3d and e). (These variations in density cause differences in the way various regions of the cytoplasm refract (bend light). Using these microscopes, scientists can observe living cells in action, with numerous internal structures that are constantly changing shape and location.

Cell biologists use a *fluorescence microscope* to detect the locations of specific molecules in cells. Fluorescent stains (like paints that glow under black light) are molecules that absorb light energy of one wavelength and then release some of that energy as light of a longer wavelength. One such stain binds specifically to DNA molecules and emits green light after absorbing ultraviolet light. Cells can be stained, and the location of the DNA can be determined, by observing the source of the green fluorescent light within the cell.

Some fluorescent stains are chemically bonded to *antibodies,* protein molecules important in internal defense. The antibody then binds to a highly specific region of a molecule in the cell. A single type of antibody molecule binds to only one type of structure, such as a part of a specific protein or some of the sugars in a specific polysaccharide. Purified fluorescent antibodies known to bind to a specific protein isolated from a cell are used to determine where that protein is located. Powerful computer imaging methods have allowed the development of the *confocal fluorescence microscope,* which greatly improves the resolution of structures labeled by fluorescent dyes (see the micrograph in the chapter introduction).

Cell biologists are developing new techniques for viewing cells using computers, lasers, and photodetectors. Computer-based image processing combines multiple images to produce 3-D views.

Electron microscopes provide a high-resolution image that can be greatly magnified

Even with improved microscopes and techniques for staining cells, ordinary light microscopes can distinguish only the gross details of many cell parts (Fig. 4-4a). In most cases, you can clearly see only the outline of an organelle and its ability to be stained by some dyes and not by others. With the development of the **electron microscope (EM),** which came into wide use in the 1950s, researchers began to study the fine details, or **ultrastructure,** of cells.

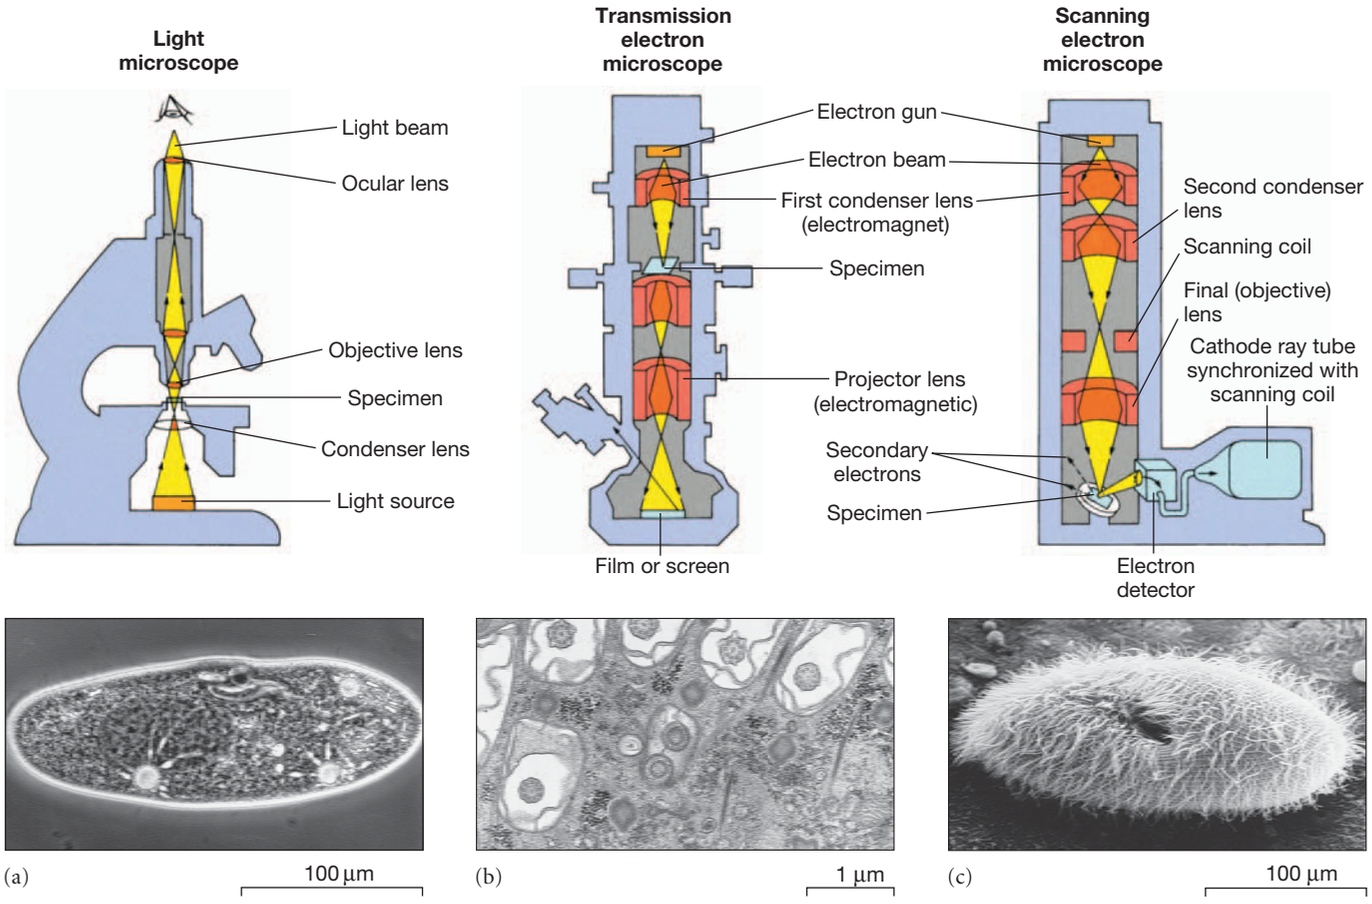
Whereas the best light microscopes have about 500 times more resolution than the human eye, the electron microscope multiplies the resolving power by more than 10,000. This is because electrons have very short wavelengths, on the order of about 0.1 to 0.2 nm. Although such resolution is difficult to achieve with biological material, researchers can approach that resolution when examining isolated molecules such as proteins and DNA. This high degree of resolution permits very high magnifications of 250,000 times or more as compared to typical magnifications of no more than 1000 times in light microscopy.

The image formed by the electron microscope is not directly visible. The electron beam itself consists of energized electrons, which, because of their negative charge, can be focused by electromagnets just as images are focused by glass lenses in a light microscope (see Fig. 4-4b). For **transmission electron microscopy (TEM),** the specimen is embedded in plastic and then cut into extraordinarily thin sections (50 to 100 nm thick) with a glass or diamond knife. A section is then placed on a small metal grid. The electron beam passes through the specimen and then falls onto a photographic plate or a fluorescent screen.

When you look at TEMs in this chapter (and elsewhere), keep in mind that each represents only a thin cross section of a cell. To reconstruct a 3-D view of the cell interior, the cell biologist studies many consecutive sectional views (called *serial sections*) through the object. (To understand the enormity of such a task, imagine trying to reconstruct an image of the contents of your home from a set of hundreds of consecutive 5-cm sections.)

Researchers detect certain specific molecules in electron microscope images by using antibody molecules to which very tiny gold particles are bound. The dense gold particles block the electron beam and identify the location of the proteins recognized by the antibodies as precise black spots on the electron micrograph.

In another type of electron microscope, the **scanning electron microscope (SEM),** the electron beam does not pass through



Photos courtesy of T.K. Maugel/ University of Maryland

FIGURE **4-4** **Comparing light and electron microscopy.**
Distinctive images of cells, such as the protist *Paramecium* shown in these photomicrographs, are provided by three types of microscopes. **(a)** A phase contrast light microscope can be used to view stained or living cells, but at relatively low resolution. **(b)** The transmission electron microscope (TEM) produces a high-resolution image that can be greatly magnified. A small part of a thin slice through the *Paramecium* is shown. **(c)** The scanning electron microscope (SEM) is used to provide a clear view of surface features.

the specimen. Instead, the specimen is coated with a thin film of gold or some other metal. When the electron beam strikes various points on the surface of the specimen, secondary electrons are emitted whose intensity varies with the contour of the surface. The recorded emission patterns of the secondary electrons give a 3-D picture of the surface (see Fig. 4-4c). The SEM provides information about the shape and external features of the specimen that cannot be obtained with the TEM.

Note that the LM, TEM, and SEM are focused by similar principles. A beam of light or an electron beam is directed by the condenser lens onto the specimen and is magnified by the objective lens and the eyepiece in the light microscope or by the objective lens and the projector lens in the TEM. The TEM image is focused onto a fluorescent screen, and the SEM image is viewed on a type of television screen. Lenses in electron microscopes are actually magnets that bend the beam of electrons.

Cell fractionation enables the study of cell components

PROCESS OF SCIENCE

The EM is a powerful tool for studying cell structure, but it has limitations. The methods used to prepare cells for electron microscopy kill them and may alter their structure. Furthermore, electron microscopy provides few clues about the functions of organelles and other cell components. To determine what organelles actually do, researchers purify different parts of cells so that they can be studied by physical and chemical methods.

Cell fractionation is a technique for purifying organelles. Generally, cells are broken apart as gently as possible, and the mixture, referred to as the *cell extract,* is subjected to centrifugal force by spinning in a device called a **centrifuge** (Fig. 4-5 top). An ultracentrifuge, a very powerful centrifuge, can spin at speeds exceeding 100,000 revolutions per minute (rpm), generating a centrifugal force of 500,000 × G (a G is equal to the force of gravity). Centrifugal force separates the extract into two fractions: a pellet and a supernatant. The *pellet* that forms at the bottom of the tube contains heavier materials, such as nuclei, packed together. The *supernatant,* the liquid above the pellet, contains lighter particles, dissolved molecules, and ions.

The supernatant can be centrifuged again at a higher speed to obtain a pellet that contains the next heaviest cell components, for example, mitochondria and chloroplasts. In **differential centrifugation,** the supernatant is spun at successively higher

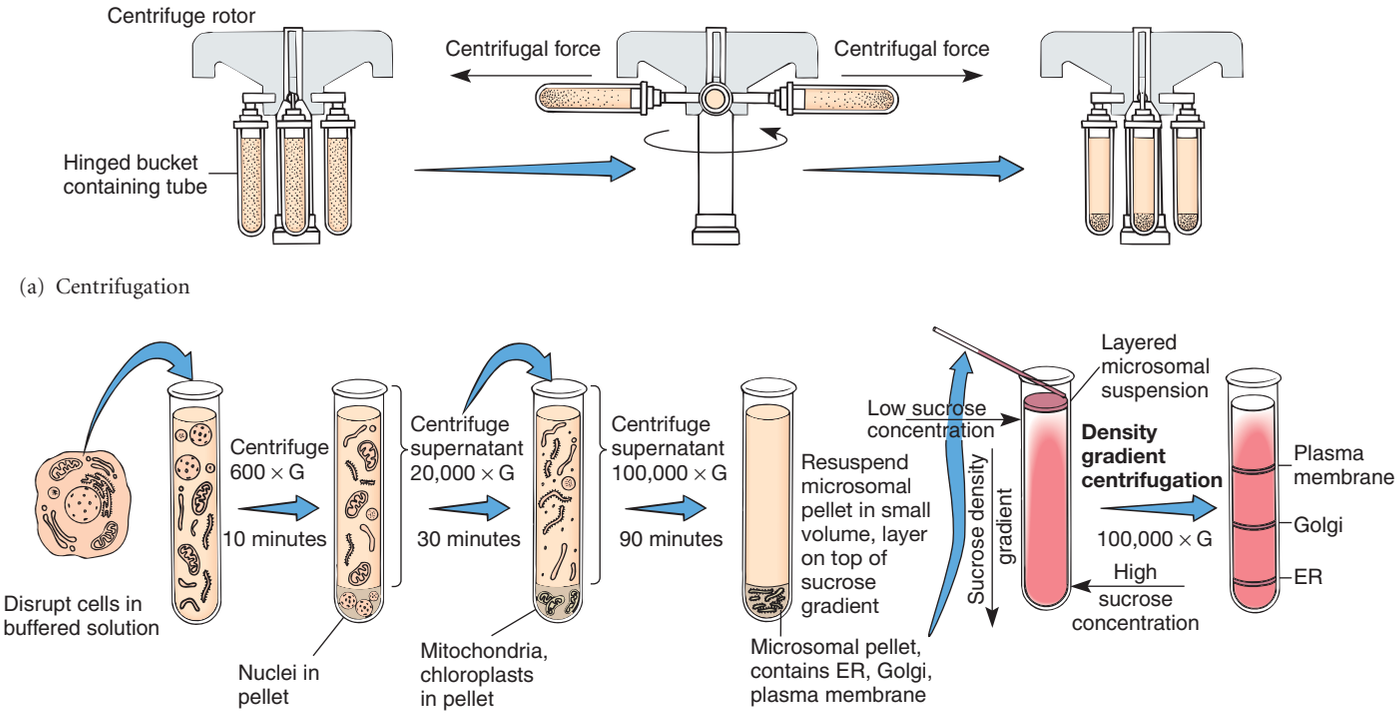


FIGURE **4-5** **Cell fractionation.**

(a) (Top) In centrifugation, large or very dense particles move toward the bottom of a tube. **(b)** (Bottom) Differential centrifugation enables cell biologists to separate cell structures into various fractions by spinning the suspension at increasing revolutions per minute. Membranes and organelles from the resuspended pellets can then be further purified by density gradient centrifugation, shown as the last step in the figure. G is the force of gravity. ER is the endoplasmic reticulum.

speeds, permitting various cell components to be separated on the basis of their different sizes and densities (Fig. 4-5 bottom).

Cell components in the resuspended pellets are further purified by **density gradient centrifugation.** In this procedure, the resuspended pellet is placed in a layer on top of a density gradient, usually made up of a solution of sucrose (table sugar) and water. The concentration of sucrose is highest at the bottom of the tube and decreases gradually so that it is lowest at the top. Because the densities of organelles differ, each will migrate during centrifugation and form a band at the position in the gradient where its own density equals that of the sucrose solution.

Purified organelles are examined to determine what kinds of proteins and other molecules they might contain, as well as the nature of the chemical reactions that take place within them. Cell biologists typically use a combination of experimental approaches to study the functions of cell structures.

PROKARYOTIC AND EUKARYOTIC CELLS

Learning Objective

4 Compare and contrast the general characteristics of prokaryotic and eukaryotic cells, and contrast plant and animal cells.

Recall from Chapter 1 that two basic types of cells are known: prokaryotic and eukaryotic. Bacteria and archaea are prokaryotic cells. All other known organisms consist of eukaryotic cells. Prokaryotic cells are typically smaller than eukaryotic cells. In fact, the average prokaryotic cell is only about one 10th the diameter of the average eukaryotic cell. In prokaryotic cells, the DNA is not enclosed in a nucleus. Instead, the DNA is located in a limited region of the cell called a **nuclear area,** or **nucleoid,** which is not enclosed by a membrane (Fig. 4-6). The term *prokaryotic,* meaning "before the nucleus" refers to this major difference between prokaryotic and eukaryotic cells. Other types of internal membrane–enclosed organelles are also absent in prokaryotic cells.

Like eukaryotic cells, prokaryotic cells have a plasma membrane that confines the contents of the cell to an internal compartment. In some prokaryotic cells the plasma membrane may be folded inward to form a complex of membranes along which many of the cell's metabolic reactions take place. Most prokaryotic cells have **cell walls,** which are extracellular structures that enclose the entire cell, including the plasma membrane. Many prokaryotes have **flagella** (sing., *flagellum*), long fibers that project from the surface of the cell. Prokaryotic flagella, which operate like propellers, are important in locomotion.

The dense internal material of the bacterial cell contains **ribosomes,** small complexes of ribonucleic acid (RNA) and protein that synthesize polypeptides. The ribosomes of prokaryotic

FIGURE **4-6** **TEM of a prokaryotic cell.**

This bacterium *(E. coli),* has two nuclear areas (blue areas) because it is preparing to divide. The nucelar material (DNA) appears as pale fibrils within the blue patches.

cells are smaller than those found in eukaryotic cells. Prokaryotic cells also contain storage granules that hold glycogen, lipid, or phosphate compounds. This chapter focuses primarily on eukaryotic cells. Prokaryotes are discussed in more detail in Chapter 23.

Eukaryotic cells are characterized by highly organized membrane-enclosed organelles, including a prominent *nucleus,* which contains the hereditary material, DNA. The term *eukaryotic* means "true nucleus." Early biologists thought cells consisted of a homogeneous jelly, which they called *protoplasm.* With the electron microscope and other modern research tools, perception of the environment within the cell has been greatly expanded. We now know the cell is highly organized and complex (Figs. 4-7 and 4-8). The eukaryotic cell has its own control center, internal transportation system, power plants, factories for making needed materials, packaging plants, and even a "self-destruct" system. Biologists refer to the part of the cell outside the nucleus as **cytoplasm** and the part of the cell within the nucleus as **nucleoplasm.** Various organelles are suspended within the fluid component of the cytoplasm, which is called the **cytosol.** Therefore, the term *cytoplasm* includes both the cytosol and all the organelles other than the nucleus.

The many specialized organelles of eukaryotic cells solve some of the problems associated with large size, so eukaryotic cells can be much larger than prokaryotic cells. Eukaryotic cells also differ from prokaryotic cells in having a supporting framework, or cytoskeleton, important in maintaining shape and transporting materials within the cell.

Some organelles are only in specific cells. For example, *chloroplasts,* structures that trap sunlight for energy conversion, are only in cells that carry on photosynthesis, such as certain plant or algal cells. Most bacteria, fungi, and plant cells are surrounded by a *cell wall* external to the plasma membrane. Plant cells also contain a large, membrane-enclosed *vacuole.* We discuss these and other differences among major types of cells throughout this chapter. Plant and animal cells are compared in Figures 4-7 and 4-8 and also in Figures 4-9 and 4-10.

Review

CELL MEMBRANES

Learning Objective

5 Describe three functions of cell membranes.

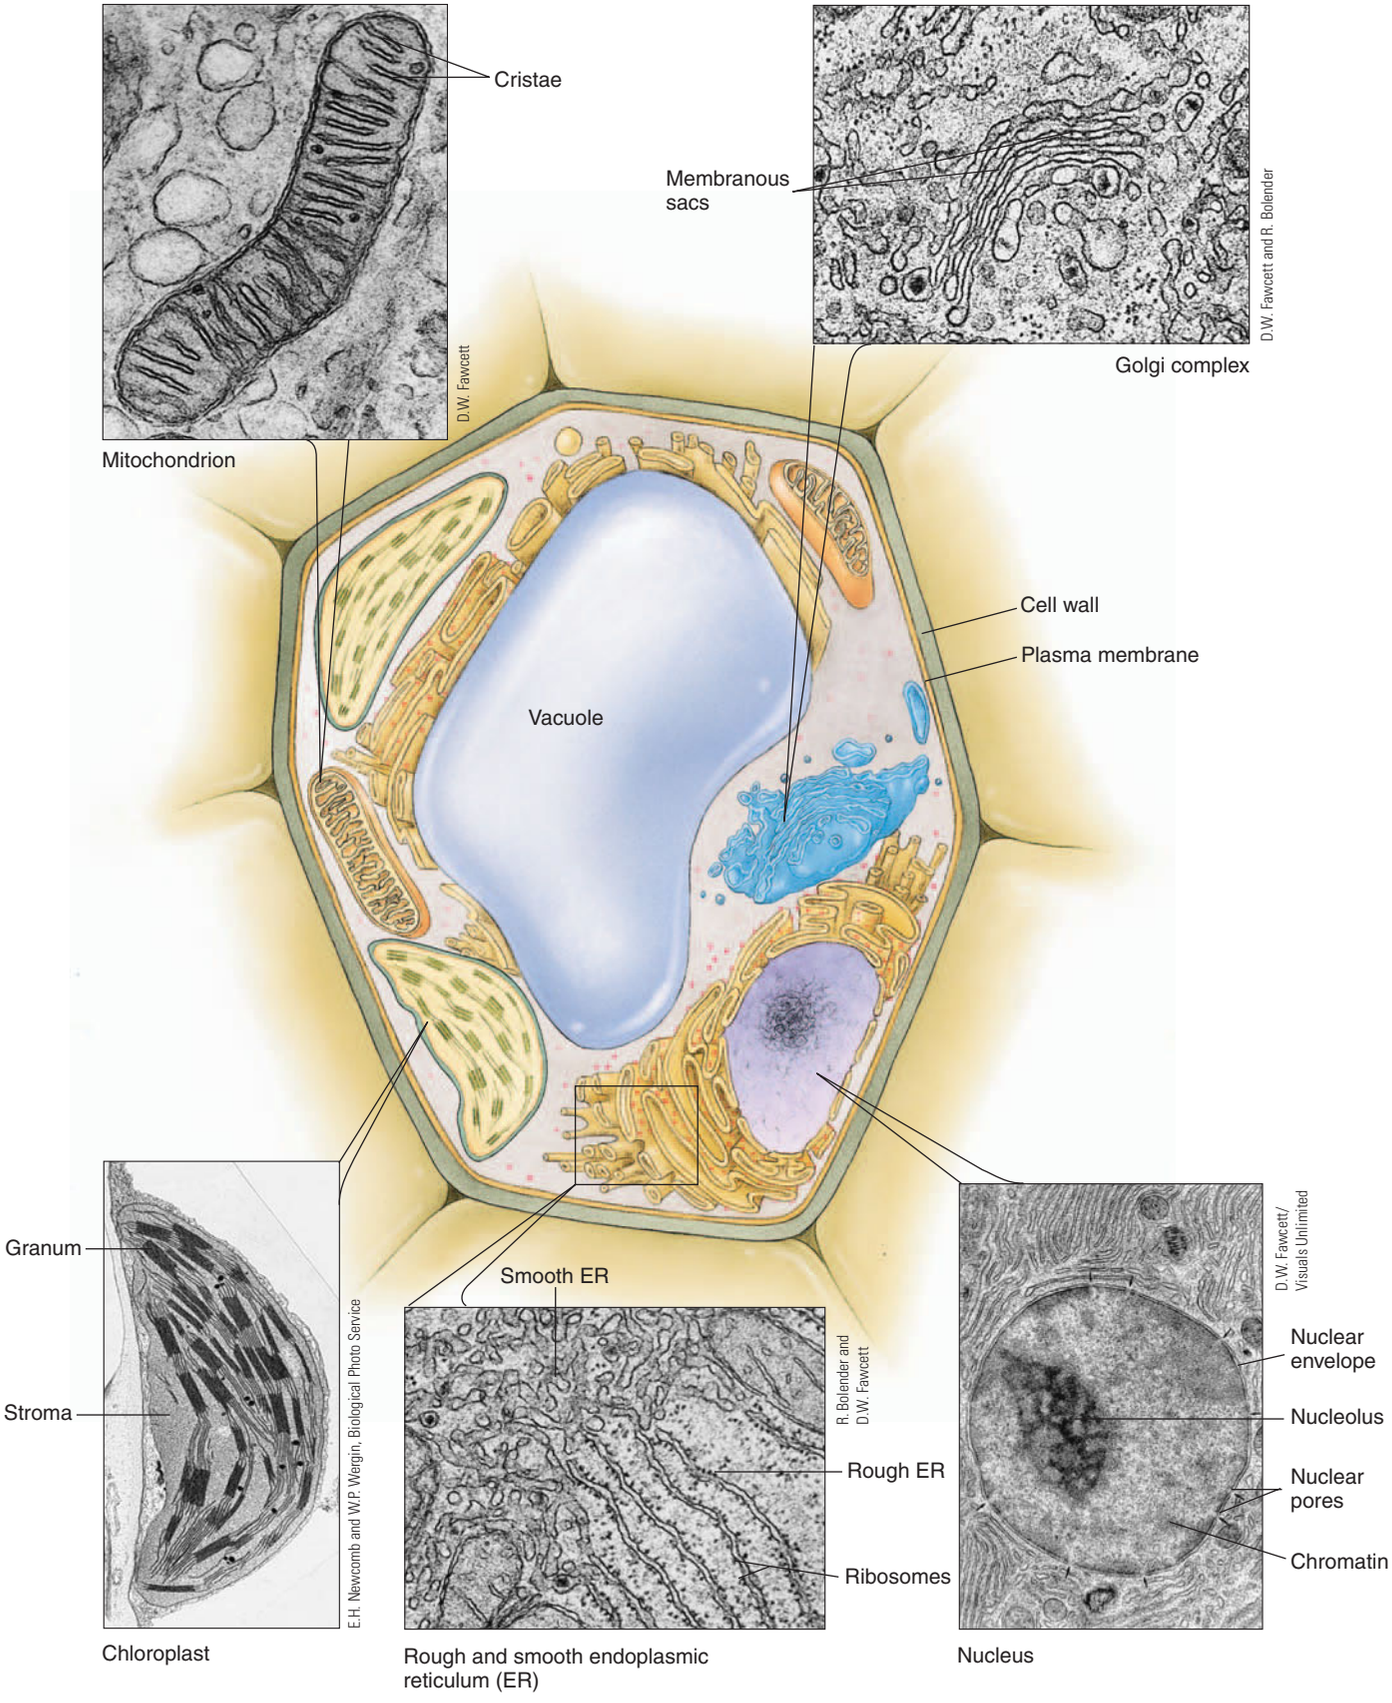
Membranes divide the eukaryotic cell into compartments, and their unique properties enable membranous organelles to carry out a wide variety of functions. For example, cell membranes never have free ends; therefore, a membranous organelle always contains at least one enclosed internal space or compartment. These membrane-enclosed compartments allow certain cell activities to be localized within specific regions of the cell. Reactants located in only a small part of the total cell volume are far more likely to come in contact, dramatically increasing the rate of the reaction. Membrane-enclosed compartments keep certain reactive compounds away from other parts of the cell that they might adversely affect. Compartmentalizing also allows many different activities to go on simultaneously.

Membranes allow cells to store energy. The membrane serves as a barrier that is analogous to a dam on a river. A difference in the concentration of some substance on the two sides of a membrane is a form of stored energy or *potential energy* (see Chapter 6). As particles of the substance move across the membrane from the side of higher concentration to the side of lower concentration, the cell converts some of this potential energy to the chemical energy of ATP molecules. This process of energy conversion (discussed in Chapters 7 and 8) is a basic mechanism that cells use to capture and convert the energy necessary to sustain life.

Membranes also serve as important work surfaces. For example, many chemical reactions in cells are carried out by enzymes that are bound to membranes. Because the enzymes that carry out successive steps of a series of reactions are organized close together on a membrane surface, certain series of chemical reactions occur more rapidly.

In a eukaryotic cell, several types of membranes are generally considered part of the internal membrane system, or **endomembrane system.** In Figures 4-9 and 4-10 on page 76 (also see Figs. 4-7 and 4-8), notice how membranes divide the cell into many compartments: the nucleus, endoplasmic reticulum (ER), Golgi complex, lysosomes, vesicles, and vacuoles. Although it is not internal, the plasma membrane is also included because it participates in the activities of the endomembrane system. (Mitochondria and chloroplasts are also separate compartments but are not generally considered part of the endomembrane system, because they function somewhat independently of other membranous organelles.)

Some organelles have direct connections between their membranes and compartments. Others transport materials in **vesicles,** small, membrane-enclosed sacs formed by "budding" from the membrane of another organelle. Vesicles also carry materials from one organelle to another. Through a complex



ACTIVE FIGURE **4-7** **Composite diagram of a plant cell.**

Chloroplasts, a cell wall, and prominent vacuoles are characteristic of plant cells. The TEMs show certain structures or areas of the cell. Some plant cells do not have all the organelles shown here. For example, leaf and stem cells that carry on photosynthesis contain chloroplasts, whereas root cells do not. Many of the organelles, such as the nucleus, mitochondria, and endoplasmic reticulum (ER), are characteristic of all eukaryotic cells.

BiologyNow™ Test yourself on the **structure of the eukaryotic cell** by clicking on this figure on your BiologyNow CD-ROM.

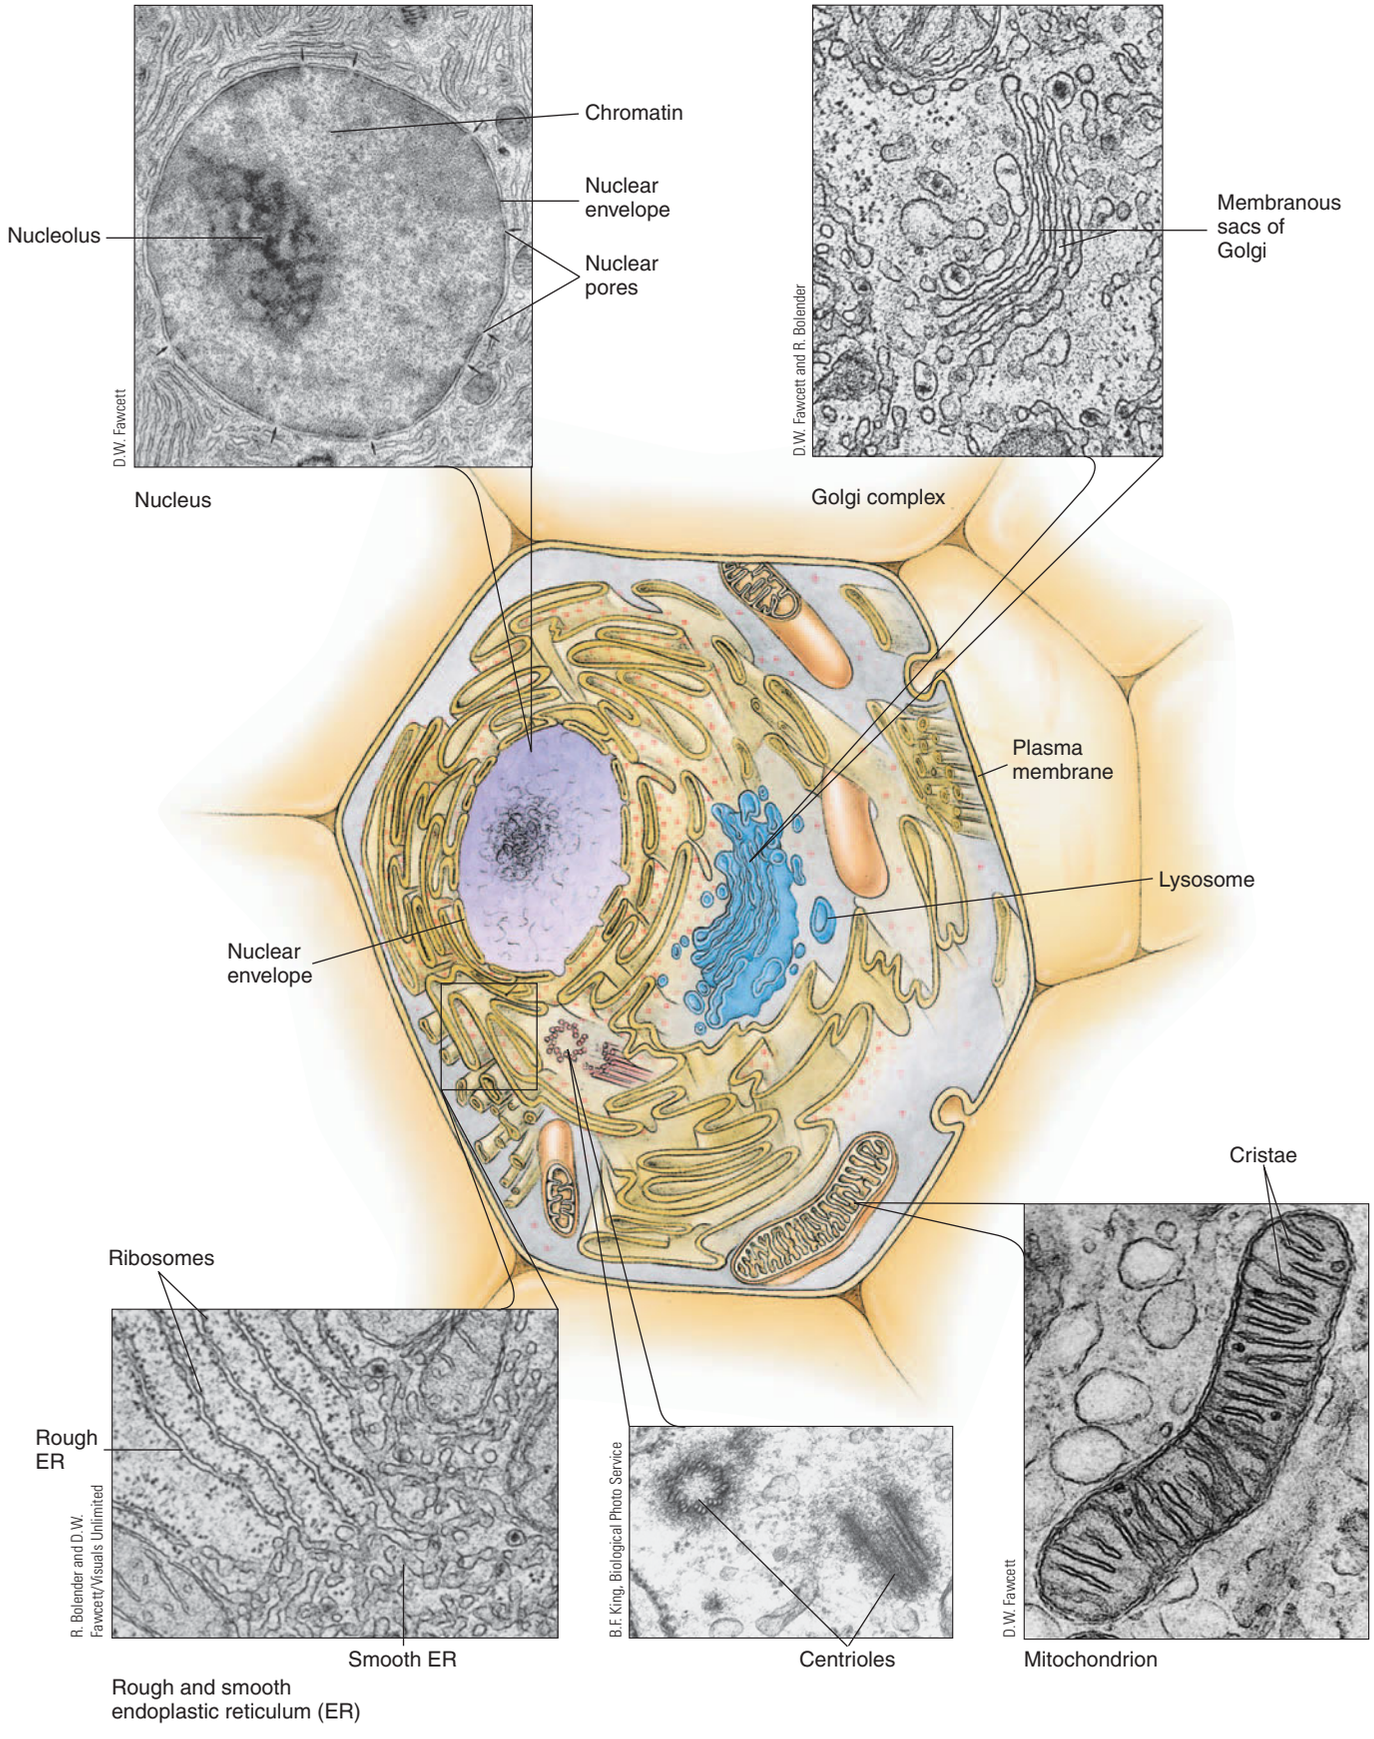


FIGURE **4-8** **Composite diagram of an animal cell.**

This generalized animal cell is shown in a realistic context surrounded by adjacent cells, which cause it to be slightly compressed. The TEMs show the structure of various organelles. Depending on the cell type, certain organelles may be more or less prominent.

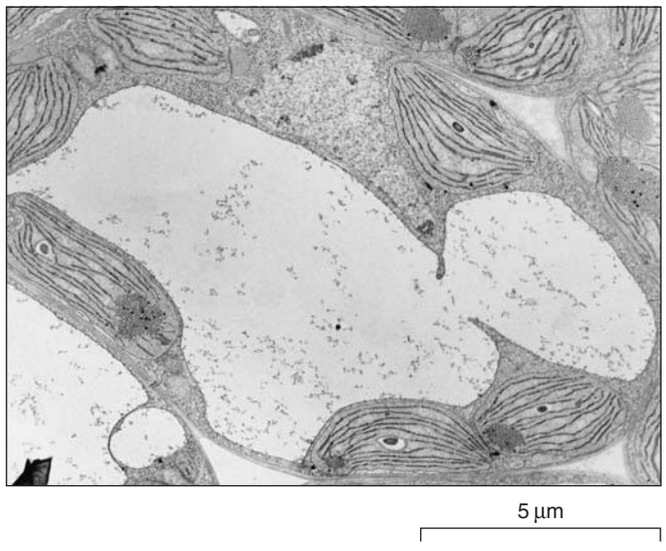

FIGURE **4-9** **TEM of a plant cell and an interpretive drawing.**

Most of this cross section of a cell from the leaf of a young bean plant (*Phaseolus vulgaris*) is dominated by a vacuole. Prolamellar bodies are membranous regions typically seen in developing chloroplasts.

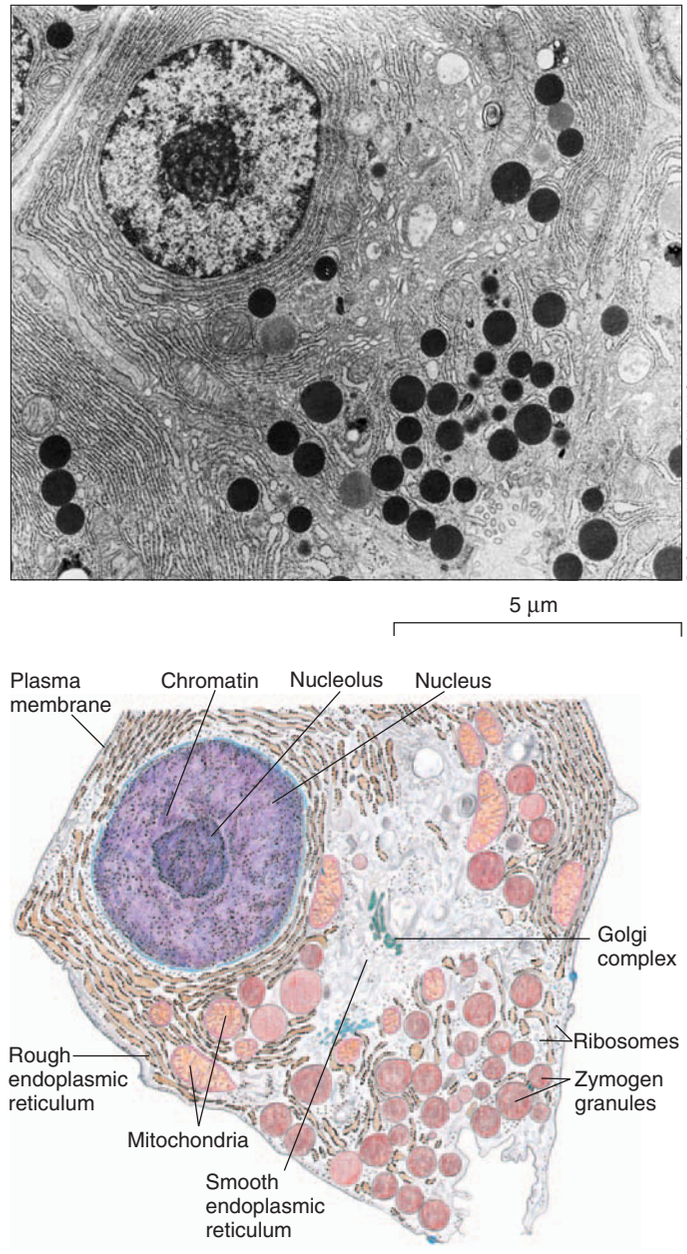

FIGURE **4-10** **TEM of a human pancreas cell and an interpretive drawing.**

Most of the structures of a typical animal cell are present. However, like most cells, this one has certain structures associated with its specialized functions. Pancreas cells such as the one shown here secrete large amounts of digestive enzymes. The large, dark, circular bodies in the TEM and the corresponding structures in the drawing are zymogen granules containing inactive enzymes. When released from the cell, the enzymes catalyze chemical reactions such as the breakdown of peptide bonds of ingested proteins in the intestine. Most of the membranes visible in this section are part of the rough endoplasmic reticulum, an organelle specialized to manufacture protein.

series of steps, a vesicle can form as a "bud" from one membrane and then be transported to another membrane to which it fuses, thus delivering its contents into another compartment.

THE CELL NUCLEUS

Learning Objective

6 Describe the structure and functions of the nucleus.

Typically, the **nucleus** is the most prominent organelle in the cell. It is usually spherical or oval in shape and averages 5 µm in diameter. Because of its size and the fact that it often occupies a relatively fixed position near the center of the cell, some early

investigators guessed long before experimental evidence was available that the nucleus served as the control center of the cell (see the *Focus On:* Acetabularia and the Control of Cell Activities). Most cells have one nucleus, although there are exceptions.

The **nuclear envelope** consists of two concentric membranes that separate the nuclear contents from the surrounding cytoplasm (Fig. 4-11). These membranes are separated by about 20 to 40 nm. At intervals the membranes come together to form **nuclear pores,** which consist of protein complexes. Nuclear pores regulate the passage of materials between nucleoplasm and cytoplasm. How materials are transported through nuclear pores and how the process is regulated are areas of active research.

The cell stores information in the form of DNA, and most of the cell's DNA is located inside the nucleus. When a cell divides, the information stored in DNA must be reproduced and passed intact to the two daughter cells. DNA has the unique ability to make an exact duplicate of itself through a process called *replication.* Recall from Chapter 3 that DNA molecules consist of sequences of nucleotides called **genes,** which contain the chemically coded instructions for producing the proteins needed by the cell. The nucleus controls protein synthesis by transcribing its information in *messenger RNA* molecules. Messenger RNA moves into the cytoplasm where proteins are manufactured.

DNA is associated with proteins, forming a complex known as **chromatin,** which appears as a network of granules and strands in cells that are not dividing. Although chromatin appears disorganized, it is not. Because DNA molecules are extremely long and thin, they must be packed inside the nucleus in a very regular fashion as part of structures called **chromosomes.** In dividing cells, the chromosomes become visible as distinct threadlike structures. If the DNA in the 46 chromosomes of one human cell could be stretched end to end, it would extend for 2 m!

Most nuclei have one or more compact structures called **nucleoli** (sing., *nucleolus*). A nucleolus, which is *not* enclosed by a membrane, usually stains differently from the surrounding chromatin. Each nucleolus contains a nucleolar organizer, made up of chromosomal regions containing instructions for making the type of RNA in ribosomes. This ribosomal RNA is synthesized in the nucleolus. The proteins needed to make ribosomes

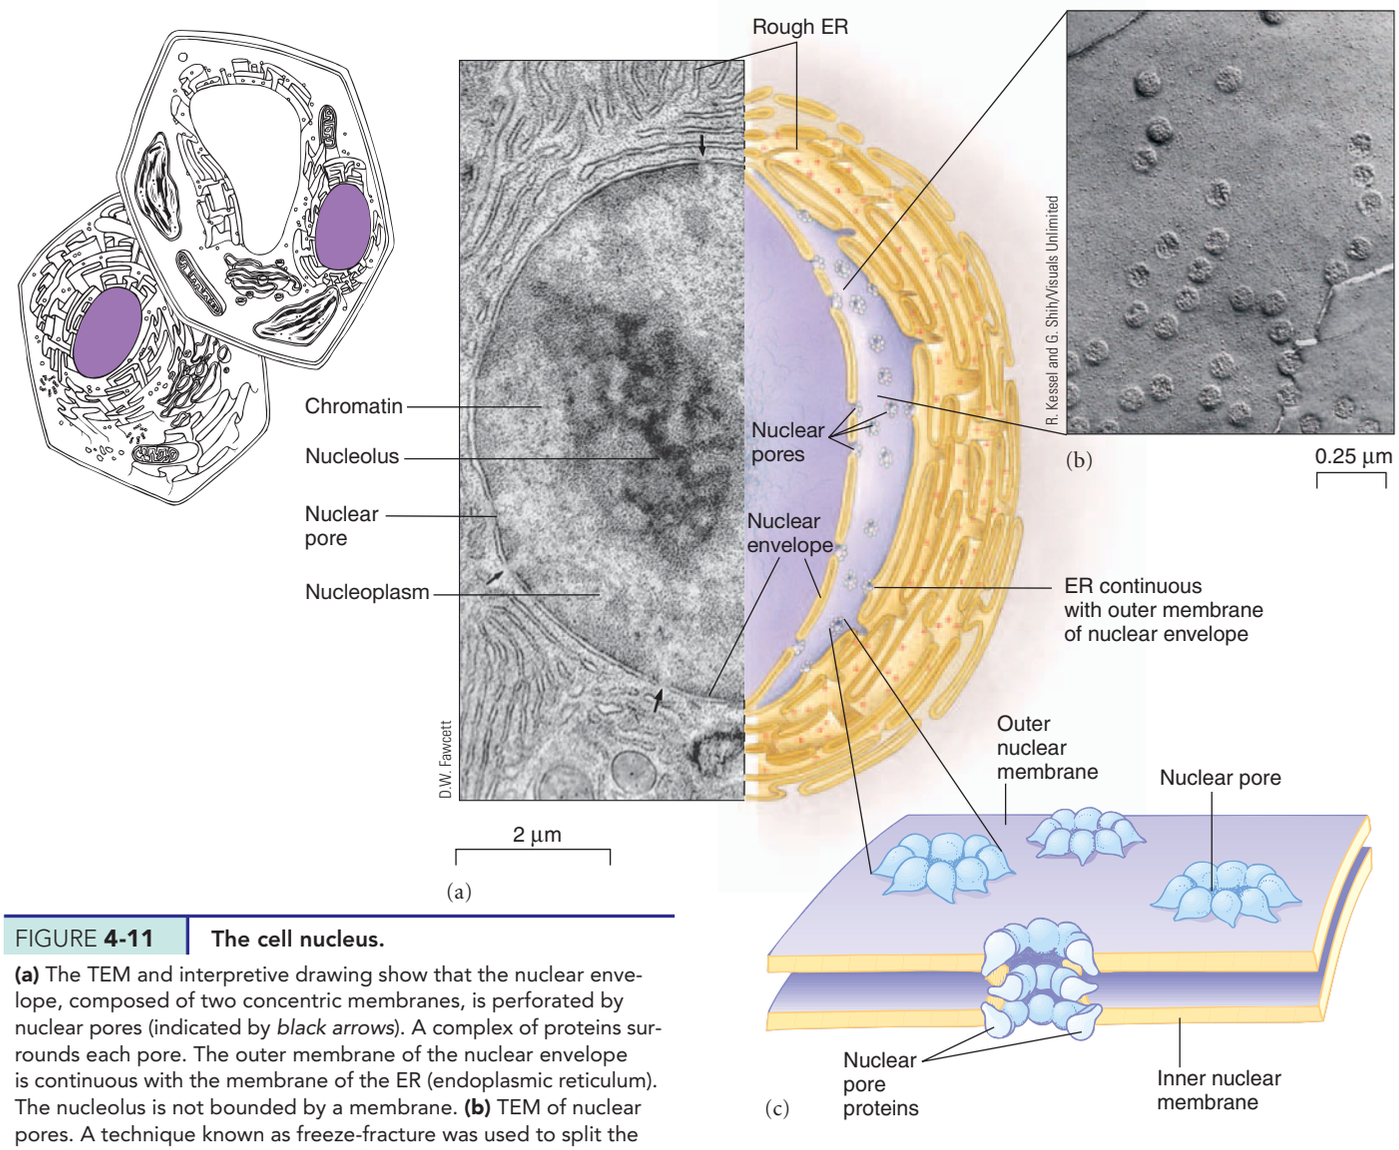

FIGURE **4-11** **The cell nucleus.**

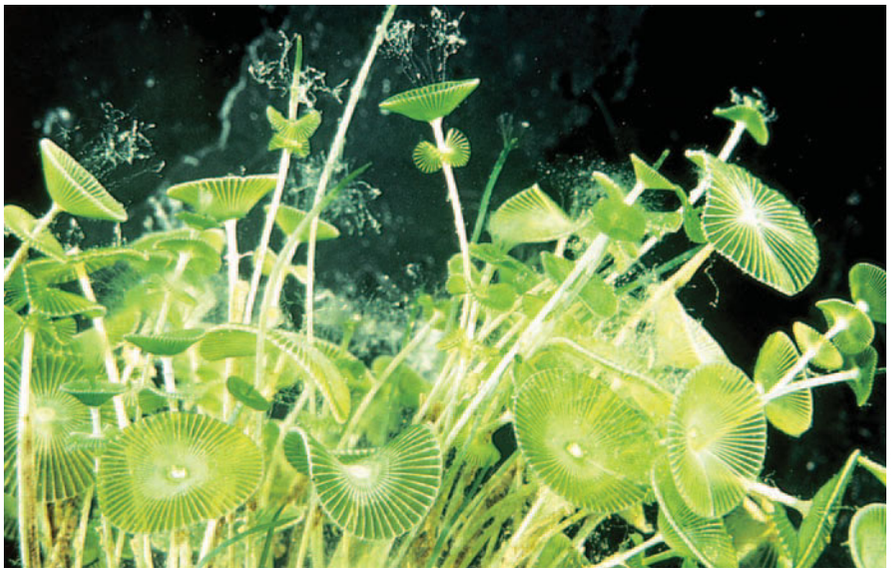
(a) The TEM and interpretive drawing show that the nuclear envelope, composed of two concentric membranes, is perforated by nuclear pores (indicated by *black arrows*). A complex of proteins surrounds each pore. The outer membrane of the nuclear envelope is continuous with the membrane of the ER (endoplasmic reticulum). The nucleolus is not bounded by a membrane. **(b)** TEM of nuclear pores. A technique known as freeze-fracture was used to split the membrane. **(c)** The nuclear pores, which are made up of proteins, form channels between the nucleoplasm and cytoplasm.

PROCESS OF SCIENCE

To the romantically inclined, the little seaweed *Acetabularia* resembles a mermaid's wineglass, although the literal translation of its name, "vinegar cup," is somewhat less elegant (Fig. A). In the 19th century, biologists discovered that this marine eukaryotic alga consists of a single cell. At up to 5 cm (2 in) in length, *Acetabularia* is small for a seaweed but gigantic for a cell. It consists of a root-like **holdfast;** a long, cylindrical **stalk;** and a cuplike **cap.** The nucleus is in the holdfast, about as far away from the cap as it can be. Because it is a single giant cell, *Acetabularia* is easy for researchers to manipulate.



L. Sims/Visuals Unlimited

FIGURE **A** **Light micrograph of *Acetabularia*.**

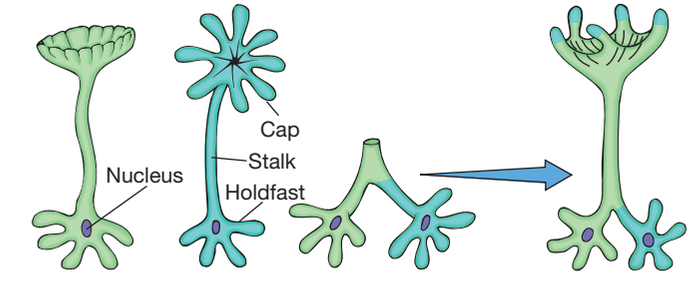


FIGURE **B**

What controls the cap shape?

If the cap of *Acetabularia* is removed experimentally, another one grows after a few weeks. Such a response, common among simple organisms, is called **regeneration.** This fact attracted the attention of investigators, especially Danish biologist J. Hämmerling and Belgian biologist J. Brachet, who became interested in whether a relationship exists between the nucleus and the physical characteristics of the alga. Because of its great size, *Acetabularia* could be subjected to surgery that would be impossible with smaller cells. During the 1930s and 1940s, these researchers performed brilliant experiments that in many ways laid the foundation for much of our modern knowledge of the nucleus. Two species were used for most experiments: *A. mediterranea,* which has a smooth cap, and *A. crenulata,* which has a cap divided into a series of finger-like projections.

The kind of cap that is regenerated depends on the species of *Acetabularia* used in the experiment. As you might expect, *A. crenulata* regenerates a "cren" cap, and *A. mediterranea* regenerates a "med" cap. But it is possible to graft together two capless algae of different species. Through this union, they regenerate a common cap that has characteristics intermediate between those of the two species involved (Fig. B). Thus, it is clear that something in the stalk or holdfast controls cap shape.

Stalk exchange experiments.

By telescoping the cell walls of the two into one another, it is possible to attach a section of *Acetabularia* to a holdfast that is not its own. In this way the stalks and holdfasts of different species may be intermixed.

First, we take *A. mediterranea* and *A. crenulata* and remove their caps. Then we sever the stalks from the holdfasts. Finally, we exchange the parts (Fig. C). What happens? Not, perhaps, what you would expect! The caps that regenerate are characteristic not of the species donating the holdfasts but of those donating the stalks!

However, if the caps are removed once again, this time the caps that regenerate are characteristic of the species that donated the holdfasts. This continues to be the case no matter how many more times the regenerated caps are removed.

From all these results Hämmerling and Brachet deduced that the ultimate control of the *Acetabularia* cell is associated with the holdfast. Because there is

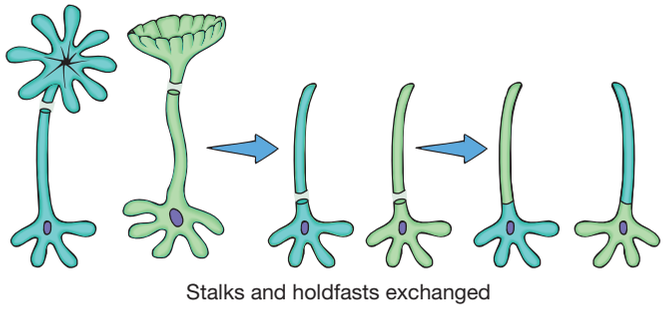

FIGURE **C**

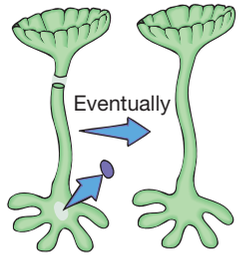

FIGURE **D**

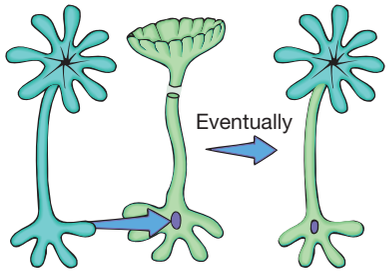

FIGURE **E**

a time lag before the holdfast appears to take over, they hypothesized it produces some temporary cytoplasmic messenger substance whereby it exerts its control. They further hypothesized that the grafted stalks initially contain enough of the substance from their former holdfasts to regenerate a cap of the former shape. But this still leaves the question of how the holdfast exerts its apparent control. An obvious suspect is the nucleus.

Nuclear exchange experiments.

If the nucleus is removed and the cap cut off, a new cap regenerates (Fig. D). *Acetabularia*, however, can usually regenerate only once without a nucleus. If the nucleus of another species is now inserted and the cap is cut off once again, a new cap regenerates that is characteristic of the species of the nucleus (Fig. E)! If two kinds of nuclei are inserted, the regenerated cap is intermediate in shape between those of the species that donated the nuclei.

As a result of these and other experiments, biologists began to develop some basic ideas about the control of cell activities. The holdfast controls the cell because the nucleus is located there. Further, the nucleus is the apparent source of some "messenger substance" that temporarily exerts control but is limited in quantity and cannot be produced without the nucleus (Fig. F). This information helped provide a starting point for research on the role of nucleic acids in the control of all cells.

Cell biologists extended these early findings as they developed our modern view of information flow and control in the cell. We now know that the nucleus of eukaryotes controls the cell's activities because it contains DNA, the ultimate source of biological information. DNA passes its information to successive generations because it is able to precisely replicate itself. The information in DNA specifies the sequence of amino acids in all the proteins of the cell. To carry out its mission, DNA uses a type of ribonucleic acid (RNA) as a cytoplasmic messenger substance.

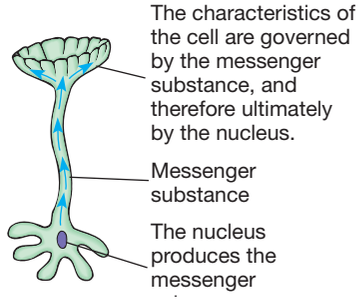

FIGURE **F**

are synthesized in the cytoplasm and imported into the nucleolus. Ribosomal RNA and proteins are then assembled into ribosomal subunits that leave the nucleus through the nuclear pores.

ORGANELLES IN THE CYTOPLASM

Learning Objectives:

7 Distinguish between smooth and rough endoplasmic reticulum in terms of both structure and function.

8 Trace the path of proteins synthesized in the rough endoplasmic reticulum as they are subsequently processed, modified, and sorted by the Golgi complex and then transported to specific destinations.

9 Describe the functions of lysosomes and peroxisomes.

10 Compare the functions of mitochondria and chloroplasts, and discuss ATP synthesis by each of these organelles.

Cell biologists have identified many types of organelles in the cytoplasm of eukaryotic cells. Among them are the endoplasmic reticulum, ribosomes, Golgi complex, lysosomes, peroxisomes, vacuoles, mitochondria, and chloroplasts. Eukaryotic cell structures and functions are summarized in Table 4-1.

The endoplasmic reticulum and ribosomes manufacture proteins

One of the most prominent features in the electron micrographs in Figures 4-7 and 4-8 is a maze of parallel internal membranes that encircle the nucleus and extend into many regions of the cytoplasm. This complex of membranes, the **endoplasmic reticulum (ER),** forms a network that makes up a significant part of the total volume of the cytoplasm in many cells. A higher-magnification TEM of the ER is shown in Figure 4-12. Remember that a TEM represents only a thin cross section of the cell, so there is a tendency to interpret the ER as a series of tubes. In fact, many ER membranes consist of a series of tightly packed and flattened, saclike structures that form interconnected compartments within the cytoplasm.

The internal space the membranes enclose is called the **ER lumen.** In most cells the ER lumen forms a single internal compartment that is continuous with the compartment formed between the outer and inner membranes of the nuclear envelope (see Fig. 4-11). The membranes of other organelles are not directly connected to the ER and appear to form distinct and separate compartments within the cytoplasm.

The ER membranes and lumen contain enzymes that catalyze many different types of chemical reactions. In some cases the membranes serve as a framework for systems of enzymes that carry out sequential biochemical reactions. The two surfaces of the membrane contain different sets of enzymes and represent regions of the cell with different synthetic capabilities, just as different regions of a factory are used to make different parts of a particular product. Still other enzymes are located within the ER lumen.

Two distinct regions of the ER can be distinguished in TEMs: rough ER and smooth ER. Although these regions have different functions, their membranes are connected and their internal spaces are continuous. **Smooth ER** has a tubular appearance and its outer membrane surfaces appear smooth. The smooth ER is the primary site of phospholipid, steroid, and fatty acid metabolism. Whereas the smooth ER may be a minor membrane component in some cells, extensive amounts of smooth ER are present in others. For example, extensive smooth ER is present in human liver cells, where it synthesizes and processes cholesterol and other lipids and serves as a major detoxification site. Enzymes located along the smooth ER of liver cells break down toxic chemicals such as carcinogens (cancer-causing agents). The cell then converts these compounds to water-soluble products that it excretes.

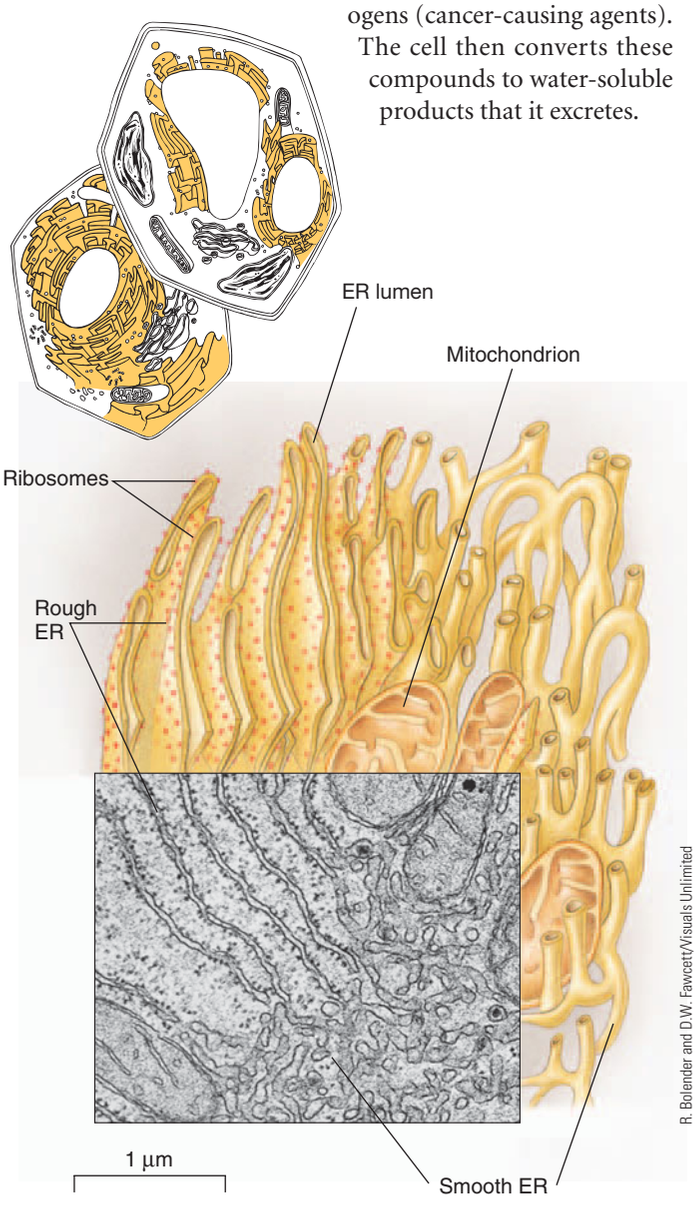

FIGURE **4-12** **Endoplasmic reticulum (ER).**
The TEM shows both rough and smooth ER in a liver cell.

TABLE **4-1** **Eukaryotic Cell Structures and Their Functions**

Structure	Description	Function
Cell Nucleus		
Nucleus	Large structure surrounded by double membrane; contains nucleous and chromosomes	Information in DNA is transcribed in RNA synthesis; specifies cell proteins
Nucleous	Granular body within nucleus; consists of RNA and protein	Site of ribosomal RNA synthesis; ribosome subunit assembly
Chromosomes	Composed of a complex DNA and protein known as *chromatin;* condense during cell division, becoming visible as rodlike structures	Contain genes (units of hereditary information) that govern structure and activity of cell
Cytoplasmic Organelles		
Plasma membrane	Membrane boundary of cell	Encloses cell contents; regulates movement of materials in and out of cell; helps maintain cell shape; communicates with other cells (also present in prokaryotes)
Endoplasmic reticulum (ER)	Network of internal membranes extending through cytoplasm	Synthesizes lipids and modifies many proteins; origin of intracellular transport vesicles that carry proteins
Smooth	Lacks ribosomes on outer surface	Lipid biosynthesis; drug detoxification
Rough	Ribosomes stud outer surface	Manufacture of many proteins destined for secretion or for incorporation into membranes
Ribosomes	Granules composed of RNA and protein; some attached to ER, some free in cytosol	Synthesize polypeptides in both prokaryotes and eukaryotes
Golgi complex	Stacks of flattened membrane sacs	Modifies proteins; packages secreted proteins; sorts other proteins to vacuoles and other organelles
Lysosomes	Membranous sacs (in animals)	Contain enzymes to break down ingested materials, secretions, wastes
Vacuoles	Membranous sacs (mostly in plants, fungi, algae)	Store materials, wastes, water; maintain hydrostatic pressure
Peroxisomes	Membranous sacs containing a variety of enzymes	Site of many diverse metabolic reactions
Mitochondria	Sacs consisting of two membranes; inner membrane is folded to form cristae and encloses matrix	Site of most reactions of cellular respiration; transformation of energy originating from glucose or lipids into ATP energy
Plastids (e.g., chloroplasts)	Double-membrane structure enclosing internal thylakoid membranes; chloroplasts contain chlorophyll in thylakoid membranes	Chloroplasts are site of photosynthesis; chlorophyll captures light energy; ATP and other energy-rich compounds are formed and then used to convert CO_2 to carbohydrate
Cytoskeleton		
Microtubules	Hollow tubes made of subunits of tubulin protein	Provide structural support; have role in cell and organelle movement and cell division; components of cilia, flagella, centrioles, basal bodies
Microfilaments	Solid, rodlike structures consisting of actin protein	Provide structural support; play role in cell and organelle movement and cell division
Intermediate filaments	Tough fibers made of protein	Help strengthen cytoskeleton; stabilize cell shape
Centrioles	Pair of hollow cylinders located near nucleus; each centriole consists of nine microtubule triplets (9×3 structure)	Mitotic spindle forms between centrioles during animal cell division; may anchor and organize microtubule formation in animal cells; absent in most plants
Cilia	Relatively short projections extending from surface of cell; covered by plasma membrane; made of two central and nine pairs of peripheral microtubules ($9 + 2$ structure)	Movement of some unicellular organisms; used to move materials on surface of some tissues
Flagella	Long projections made of two central and nine pairs of peripheral microtubules ($9 + 2$ structure); extend from surface of cell; covered by plasma membrane	Cell locomotion by sperm cells and some unicellular eukaryotes

The outer surface of **rough ER** is studded with **ribosomes** that appear as dark granules. Notice in Figure 4-12 the lumen side of the rough ER appears bare, whereas the outer surface (the cytosolic side) looks rough. Ribosomes contain the enzyme necessary to form peptide bonds (see Chapter 3), and they function as manufacturing plants that assemble proteins. The ribosomes attached to the rough ER are known as *bound ribosomes; free ribosomes* are suspended in the cytosol.

Ribosomes consist of RNA and protein. Each eukaryotic ribosome is actually a knot of three *ribosoma RNA* strands in association with about 75 different proteins. Each ribosome has two main components: a large subunit and a small subunit.

The rough ER plays a central role in the synthesis and assembly of proteins. Many proteins that are exported from the cell (such as digestive enzymes), and those destined for other organelles, are synthesized on ribosomal bound to the ER mem-

brane. The ribosome forms a tight seal with the ER membrane. A tunnel within the ribosome connects to an ER pore, or *translocon.* Proteins are transported through the tunnel and the pore in the ER membrane into the ER lumen. In the ER lumen, proteins may be modified by enzymes that add complex carbohydrates or lipids to them. Other enzymes, called **molecular chaperones,** in the ER lumen catalyze the efficient folding of proteins into proper conformations. The proteins are then transferred to other compartments within the cell by small **transport vesicles,** which bud off the ER membrane and then fuse with the membrane of some target organelle.

The Golgi complex processes, sorts, and modifies proteins

The **Golgi complex** (also known as the *Golgi body* or *Golgi apparatus*) was first described in 1898 by the Italian microscopist Camillo Golgi, who found a way to specifically stain this organelle. However, many investigators thought the Golgi was an artifact, and its legitimacy as a cell organelle was not confirmed until cells were studied with the electron microscope in the 1950s.

In many cells, the Golgi complex consists of stacks of flattened membranous sacs called **cisternae** (sing., *cisterna*). In certain regions, cisternae may be distended because they are filled with cell products (Fig. 4-13). Each of the flattened sacs has an internal space, or lumen. However, unlike the ER, most of these internal spaces of the Golgi complex and the membranes that form them are not continuous. The Golgi complex contains a number of separate compartments, as well as some that are interconnected.

Each Golgi stack has three areas referred to as the *cis face,* the *trans face,* and a *medial region* between. Typically, the *cis* face is located nearest the nucleus and receives materials from transport vesicles from the ER. The *trans* face, closest to the plasma membrane, packages molecules in vesicles and transports them out of the Golgi.

In a cross-sectional view like that in the TEM in Figure 4-13, many ends of the sheetlike layers of Golgi membranes are distended, an arrangement characteristic of well-developed Golgi complexes in many cells. In some animal cells, the Golgi complex lies at one side of the nucleus; other animal cells and plant cells have many Golgi complexes, usually consisting of separate stacks of membranes dispersed throughout the cell. Cells that secrete large amounts of *glycoproteins* have large numbers of Golgi stacks. (Recall from Chapter 3 that a glycoprotein is a protein with a covalently attached carbohydrate.) Golgi complexes of plant cells produce extracellular polysaccharides that are used as components of the cell wall.

PROCESS OF SCIENCE

Cell biologists have demonstrated that the Golgi complex processes, sorts, and modifies proteins. Researchers have studied the function of the Golgi complex by radioactively labeling newly manufactured amino acids or carbohydrates and observing their movement. Glycoproteins are synthesized and are first located in the rough ER (see Figure 4-13). The proteins are transported from the rough ER to the *cis* face of the Golgi complex in small transport vesicles formed from the ER membrane. Until recently, researchers thought glycoprotein molecules released into the Golgi complex became enclosed in new vesicles that shuttle them from one compartment to another within the Golgi. A competing hypothesis, now the focus of research, holds that the cisternae themselves may move from *cis* to *trans* positions. The vesicles may move backward to recycle materials.

Regardless of how proteins are moved through the Golgi complex, while there they are modified in different ways, resulting in the formation of complex biological molecules. For example, the carbohydrate part of a glycoprotein (first added to proteins in the rough ER) may be modified. In some cases the carbohydrate component may be a "sorting signal," a kind of zip code that routes the protein to a specific organelle.

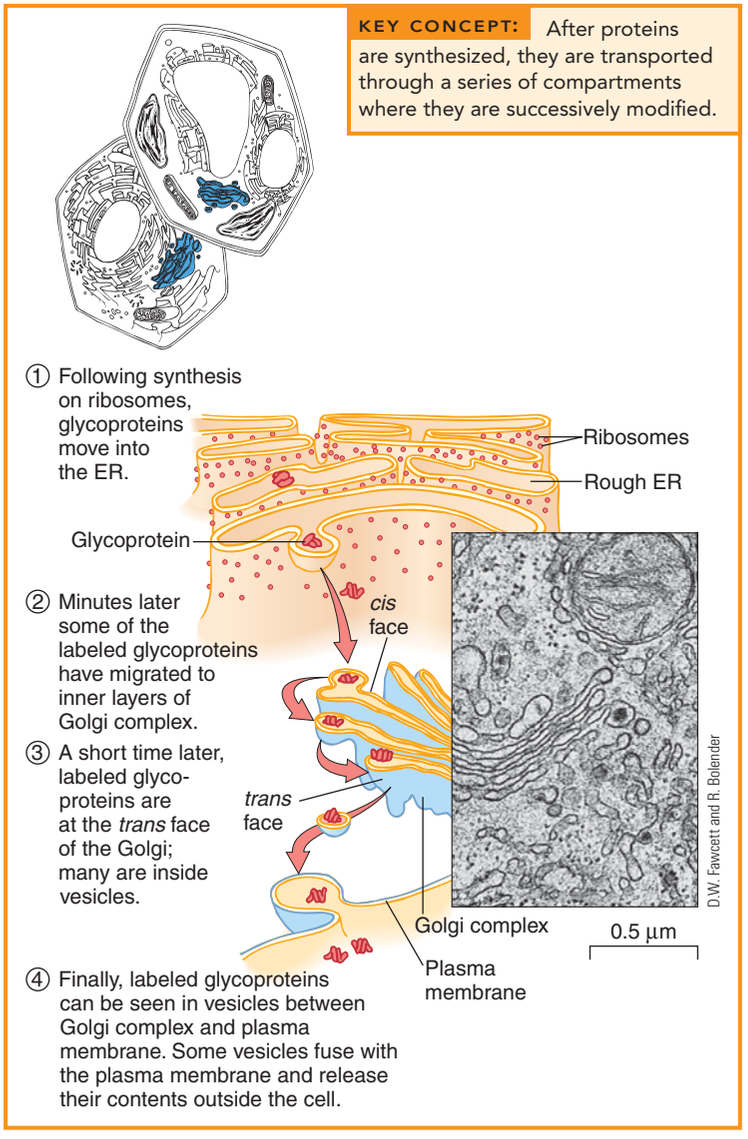

FIGURE **4-13** **TEM and an interpretive drawing of the Golgi complex.**

Glycoproteins are transported from the rough ER to the Golgi, where they are modified. This diagram shows the passage of glycoproteins through the Golgi complex during the secretory cycle of a mucus-secreting goblet cell that lines the intestine. Mucus is a complex mixture of covalently linked proteins and carbohydrates.

Glycoproteins are packaged in secretory vesicles in the *trans* face. These vesicles pinch off from the Golgi membrane and transport their contents to a specific destination. Vesicles transporting products for export from the cell fuse with the plasma membrane. The vesicle membrane becomes part of the plasma membrane, and the glycoproteins are secreted from the cell. Other vesicles may store glycoproteins for secretion at a later time, and still others are routed to various organelles of the endomembrane system. In animal cells, the Golgi complex also manufactures lysosomes.

In summary, here is a typical sequence followed by a protein destined for secretion from the cell:

protein synthesized on ribosomes ⟶ carbohydrate component added in lumen of ER ⟶ transport vesicles move glycoprotein to Golgi (*cis* face) ⟶ protein further modified in Golgi ⟶ vesicle transports glycoprotein from Golgi (*trans* face) to plasma membrane ⟶ contents released from cell

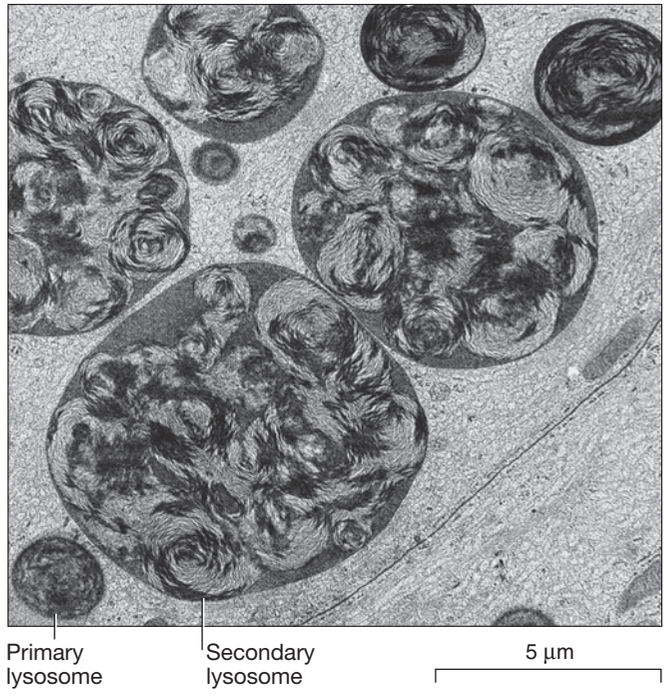
Lysosomes are compartments for digestion

Lysosomes are small sacs of digestive enzymes dispersed in the cytoplasm of most eukaryotic cells (Fig. 4-14). Researchers have identified about 40 different digestive enzymes in lysosomes. Most lysosomal enzymes are active under rather acidic conditions (about pH 5) and the lysosome maintains a pH of about 5 in its interior. Lysosomal enzymes break down complex molecules in bacteria and debris that scavenger cells ingest. The powerful enzymes and low pH that the lysosome maintains provide an excellent example of the importance of separating functions within the cell into different compartments. Under most normal conditions, the lysosome membrane confines its enzymes and their actions. However, some forms of tissue damage have been related to "leaky" lysosomes.

Primary lysosomes are formed by budding from the Golgi complex. Their hydrolytic enzymes are synthesized in the rough ER. As these enzymes pass through the lumen of the ER, sugars attach to each molecule, identifying it as bound for a lysosome. This signal permits the Golgi complex to appropriately sort the enzyme to the lysosomes rather than to export it from the cell.

When scavenger cells ingest bacteria (or debris), they are enclosed in a vesicle formed from part of the plasma membrane. One or more primary lysosomes fuse with the vesicle containing the ingested material, forming a larger vesicle called a *secondary lysosome.* In the secondary lysosome the powerful enzymes come in contact with the ingested molecules and degrade them into their components. Under some conditions lysosomes break down organelles so their components can be recycled or used as an energy source.

In certain genetic diseases of humans, known as *lysosomal storage diseases,* one of the normally present digestive enzymes is absent. Its substrate (a substance the enzyme would normally break down) accumulates in the lysosomes, ultimately interfering with cell activities. An example is Tay-Sachs disease (see Chapter 15), in which a normal lipid cannot be broken down in brain cells. The lipid accumulates in the cells, resulting in mental retardation and death.



Don Fawcett/Photo Researchers, Inc.

FIGURE **4-14** **Lysosomes.**
The dark vesicles in this TEM are lysosomes, compartments that separate powerful digestive enzymes from the rest of the cell. Primary lysosomes bud off from the Golgi complex. After a lysosome encounters and takes in material to be digested, it is known as a *secondary lysosome.* The large vesicles shown here are secondary lysosomes containing various materials being digested.

Peroxisomes metabolize small organic compounds

Peroxisomes are membrane-enclosed organelles containing enzymes that catalyze an assortment of metabolic reactions in which hydrogen is transferred from various compounds to oxygen (Fig. 4-15). During these reactions, they produce hydrogen peroxide (H_2O_2), which they use to detoxify certain compounds. Too much hydrogen peroxide is toxic to the cell; peroxisomes contain the enzyme catalase that splits excess hydrogen peroxide, rendering it harmless.

Peroxisomes are found in large numbers in cells that synthesize, store, or degrade lipids. For example, they synthesize certain phospholipids that are components of the insulating covering of nerve cells. In fact, certain neurological disorders occur when peroxisomes do not perform this function.

When yeast cells are grown in an alcohol-rich medium, they manufacture large peroxisomes, containing an enzyme that degrades the alcohol. Peroxisomes in human liver and kidney cells detoxify certain toxic compounds, including ethanol, the alcohol in alcoholic beverages.

In plant seeds, specialized peroxisomes, called *glyoxysomes,* contain enzymes that convert stored fats to sugars. The sugars are used by the young plant as an energy source and as a component for synthesizing other compounds. Animal cells lack glyoxysomes and cannot convert fatty acids into sugars.

FIGURE **4-15** **Peroxisomes.**

In this TEM of a tobacco (*Nicotiana tabacum*) leaf cell, peroxisomes are seen in close association with chloroplasts and mitochondria. These organelles may cooperate in carrying out some metabolic processes.

Vacuoles are large, fluid-filled sacs with a variety of functions

Although lysosomes have been identified in almost all kinds of animal cells, their occurrence in plant and fungal cells is open to debate. Many of the functions carried out in animal cells by lysosomes are performed in plant cells by a large, single, membrane-enclosed sac referred to as a **vacuole.** The vacuolar membrane, part of the endomembrane system, is called a **tonoplast.** The term *vacuole,* which means "empty," refers to the fact that these organelles have no internal structure. Although some biologists use the terms *vacuole* and *vesicle* interchangeably, vacuoles are usually larger structures, sometimes produced by the merging of many vesicles. Some biologists define a *vesicle* as a small, membrane-enclosed structure that holds cargo.

Vacuoles play a significant role in plant growth and development. Immature plant cells are generally small and contain numerous small vacuoles. As water accumulates in these vacuoles, they tend to coalesce, forming a large central vacuole. A plant cell increases in size mainly by adding water to this central vacuole.

As much as 90% of the volume of a plant cell may be occupied by a large central vacuole containing water, as well as stored food, salts, pigments, and metabolic wastes (see Figs. 4-7 and 4-9). The vacuole may serve as a storage compartment for inorganic compounds and for molecules such as proteins in seeds. Plants lack organ systems for disposing of toxic metabolic waste products. Wastes may be recycled in the vacuole, or they may aggregate and form small crystals inside the vacuole. Compounds that are noxious to herbivores (animals that eat plants) may also be stored in some plant vacuoles as a means of defense. Plant vacuoles are like lysosomes in their ability to break down unneeded organelles and other cell components. The vacuole is also important in maintaining hydrostatic (turgor) pressure in the plant cell.

Vacuoles have numerous other functions and are also present in many types of animal cells and in unicellular protists. Most protozoa have **food vacuoles,** which fuse with lysosomes so that the food they contain can be digested (Fig. 4-16). Some types of protozoa also have **contractile vacuoles,** which remove excess water from the cell (see Chapter 24).

Mitochondria and chloroplasts are energy-converting organelles

When a cell obtains energy from its environment, it is usually in the form of chemical energy in food molecules (such as glucose) or in the form of light energy. These types of energy must be converted to forms that cells can use more conveniently. Some energy conversions occur in the cytosol, but other types take place in mitochondria and chloroplasts, organelles specialized to facilitate the conversion of energy from one form to another. Chemical energy is most commonly stored in ATP. Recall from Chapter 3 that the chemical energy of ATP can be used to drive a variety of chemical reactions in the cell. Figure 4-17 summarizes the main activities that take place in mitochondria, found in almost all eukaryotic cells (including algae and plants), and in chloroplasts, found only in algae and certain plant cells.

Mitochondria and chloroplasts grow and reproduce themselves. They contain small amounts of DNA that code for a small number of the proteins found in these organelles. These proteins are synthesized by mitochondrial or chloroplast ribosomes, which are similar to the ribosomes of prokaryotes. The existence

FIGURE **4-16** **LM of food vacuoles.**

This protist, *Chilodonella,* has ingested many small, photosynthetic protists called *diatoms (dark areas)* that have been enclosed in food vacuoles. From the number of diatoms scattered about its cell, one might judge that *Chilodonella* has a rather voracious appetite.

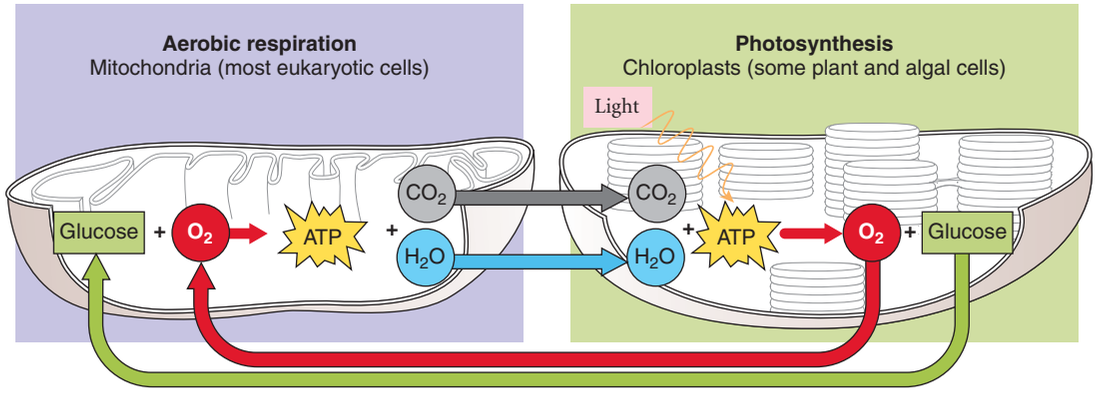

FIGURE **4-17** **Cellular respiration and photosynthesis.**

Cellular respiration takes place in the mitochondria of virtually all eukaryotic cells. In this process, some of the chemical energy in glucose is transferred to ATP. Photosynthesis, which is carried out in chloroplasts in some plant and algal cells, converts light energy to ATP and to other forms of chemical energy. This energy is used to synthesize glucose from carbon dioxide and water.

of a separate set of ribosomes and DNA molecules in mitochondria and chloroplasts and their similarity in size to many bacteria provide support for the **endosymbiont theory** (discussed in Chapters 20 and 24; see Figs. 20-7 and 24-2). According to this theory, mitochondria and chloroplasts evolved from prokaryotic organisms that took up residence inside larger cells and eventually lost the ability to function as autonomous organisms.

Mitochondria make ATP through cellular respiration

Virtually all eukaryotic cells (plant, animal, fungal, and protist) contain complex organelles called **mitochondria** (sing., *mitochondrion*). These organelles are the site of **aerobic respiration,** an oxygen-requiring process that includes most of the reactions that convert the chemical energy present in certain foods to ATP (see Chapter 7). During aerobic respiration, carbon and oxygen atoms are removed from food molecules, such as glucose, and converted to carbon dioxide and water.

Mitochondria are most numerous in cells that are very active and therefore have high energy requirements. More than 1000 mitochondria have been counted in a single liver cell! These organelles vary in size, ranging from 2 to 8 μm in length, and change size and shape rapidly. Mitochondria usually give rise to other mitochondria by growth and subsequent division.

Each mitochondrion is enclosed by a double membrane, which forms two *different* compartments within the organelle: the intermembrane space and the matrix (Fig. 4-18; see Chapter 7 for more detailed descriptions of mitochondrial structure). The **intermembrane space** is the compartment formed between the outer and inner mitochondrial membranes. The **matrix,** the compartment enclosed by the inner mitochondrial membrane, contains enzymes that break down food molecules and convert their energy to other forms of chemical energy.

The **outer mitochondrial membrane** is smooth and allows many small molecules to pass through it. By contrast, the **inner mitochondrial membrane** has numerous folds and strictly regulates the types of molecules that can move across it. The folds, called **cristae** (sing., *crista*), extend into the matrix. Cristae greatly increase the surface area of the inner mitochondrial membrane, providing a surface for the chemical reactions that transform the chemical energy in food molecules into the energy of ATP. The membrane contains the complex series of enzymes and other proteins needed for these reactions.

In a mammalian cell, each mitochondrion has 5 to 10 identical, circular molecules of DNA, accounting for up to 1% of the total DNA in the cell. Mutations in mitochondrial DNA have been associated with certain genetic diseases, including a form of young adult blindness, and certain types of progressive muscle degeneration. Mitochondrial DNA mutates far more frequently than nuclear DNA, and an accumulation of mutations may interfere

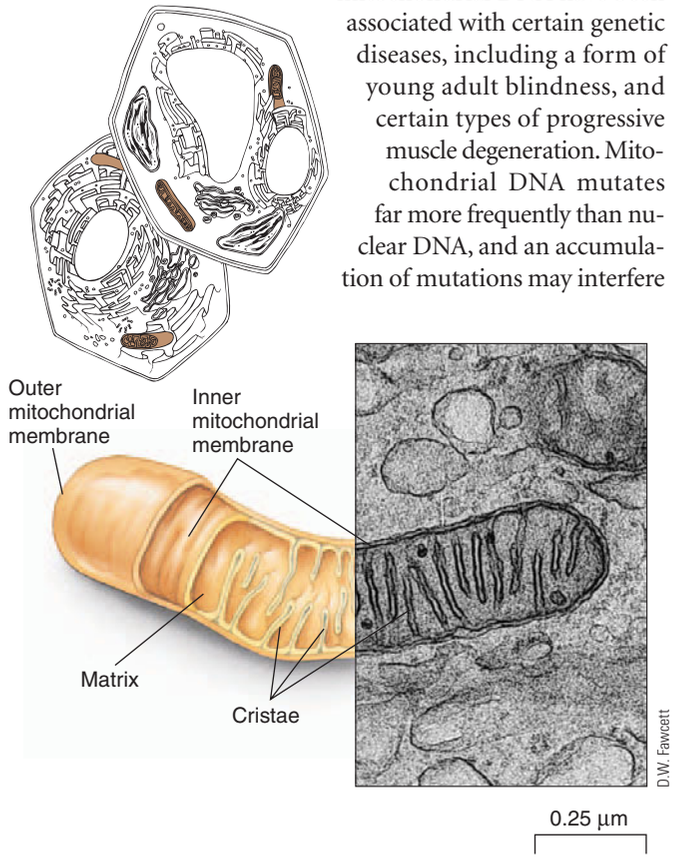

FIGURE **4-18** **Mitochondria.**

Aerobic respiration takes place within mitochondria. Cristae are evident in the TEM as well as in the drawing. The drawing shows the relationship between the inner and outer mitochondrial membranes.

with mitochondrial function. A diminished capacity to generate energy may contribute to the aging process.

Mitochondria also affect health and aging by leaking electrons. These electrons form **free radicals,** which are toxic, highly reactive compounds with unpaired electrons. These electrons bond with other compounds in the cell, interfering with normal function.

Mitochondria play an important role in programmed cell death, or **apoptosis.** Unlike **necrosis,** which is uncontrolled cell death that causes inflammation and damages other cells, apoptosis is a normal part of development and maintenance. For example, during the metamorphosis of a tadpole to a frog the cells of the tadpole tail must die. The hand of a human embryo is webbed until apoptosis destroys the tissue between the fingers. Cell death also occurs in the adult. For example, cells in the upper layer of human skin and in the intestinal wall are continuously destroyed, and replaced by new cells.

Mitochondria initiate cell death in several different ways. For example, they can interfere with energy metabolism or activate enzymes that mediate cell destruction. When a mitochondrion is injured, large pores open in its membrane, and cytochrome *c,* a protein important in energy production, is released into the cytoplasm. Cytochrome *c* triggers apoptosis by activating a group of enzymes known as **caspases,** which cut up vital compounds in the cell. Inappropriate initiation or inhibition of apoptosis may contribute to a variety of diseases, including cancer, acquired immunodeficiency syndrome (AIDS), and Alzheimer's disease. Pharmaceutical companies are developing drugs that block apoptosis. However, cell dynamics are extremely complex, and blocking apoptosis could lead to a worse fate, including necrosis.

Chloroplasts convert light energy to chemical energy through photosynthesis

Certain plant and algal cells carry out **photosynthesis,** a complex set of reactions during which light energy is transformed into the chemical energy of glucose and other carbohydrates. Carbon dioxide and water are used as raw materials (see Chapters 1 and 8). **Chloroplasts** are organelles that contain **chlorophyll,** a green pigment that traps light energy for photosynthesis. Chloroplasts also contain a variety of light-absorbing yellow and orange pigments known as **carotenoids** (see Chapter 3). A unicellular alga may have only a single large chloroplast, whereas a leaf cell may have 20 to 100. Chloroplasts tend to be somewhat larger than mitochondria, with lengths typically ranging from about 5 to 10 µm or longer.

Chloroplasts are typically disc-shaped structures and, like mitochondria, have a complex system of folded membranes (Fig. 4-19; see Chapter 8 for more detailed descriptions of chloroplast structure). Two membranes, separated by a small space, separate the chloroplast from the cytosol. The inner membrane encloses a fluid-filled space called the **stroma,** which contains enzymes responsible for producing carbohydrates from carbon dioxide and water, using energy trapped from sunlight. A system of internal membranes, suspended in the stroma, consists of an

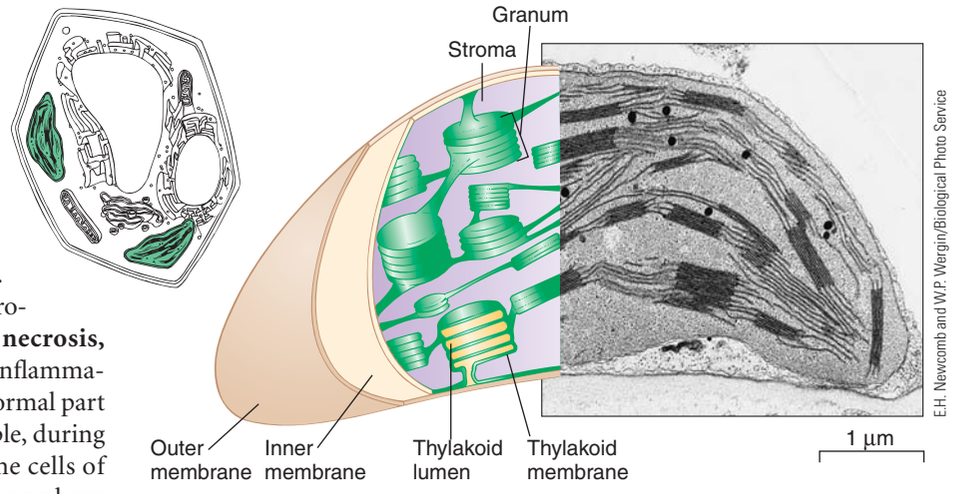

FIGURE **4-19** **A chloroplast, the organelle of photosynthesis.**

The TEM shows part of a chloroplast from a corn leaf cell. Chlorophyll and other photosynthetic pigments are found in the thylakoid membranes. One granum has been cut open to show the thylakoid lumen. The inner chloroplast membrane may or may not be continuous with the thylakoid membrane (as shown).

interconnected set of flat, disclike sacs called **thylakoids.** The thylakoids are arranged in stacks called **grana** (sing., *granum*).

The thylakoid membranes enclose a third, innermost compartment within the chloroplast, called the **thylakoid lumen.** Chlorophyll is present in the thylakoid membranes, which are similar to the inner mitochondrial membranes in that they are involved in the formation of ATP. Energy absorbed from sunlight by the chlorophyll molecules excites electrons; the energy in these excited electrons is then used to produce ATP and other molecules that transfer chemical energy.

Chloroplasts belong to a group of organelles, known as **plastids,** that produce and store food materials in cells of plants and algae. All plastids develop from **proplastids,** precursor organelles found in less specialized plant cells, particularly in growing, undeveloped tissues. Depending on the special functions a cell will eventually have, its proplastids can mature into a variety of specialized mature plastids. These are extremely versatile organelles; in fact, under certain conditions even mature plastids can convert from one form to another.

Chloroplasts are produced when proplastids are stimulated by exposure to light. **Chromoplasts** contain pigments that give certain flowers and fruits their characteristic colors; these attract animals that serve as pollinators or as seed dispersers. **Leukoplasts** are unpigmented plastids; they include **amyloplasts** (see Fig. 3-9), which store starch in the cells of many seeds, roots, and tubers (such as white potatoes).

Review

- How do the structure and function of rough ER differ from the structure of smooth ER?
- What are the functions of the Golgi complex?
- What sequence of events must take place for a protein to be manufactured and then secreted from the cell?

- How are chloroplasts like mitochondria? How are they different? Draw a chloroplast and a mitochondrion.

THE CYTOSKELETON

Learning Objectives

11 Describe the structure and functions of the cytoskeleton.
12 Compare cilia and flagella, and describe their functions.

Scientists watching cells growing in the laboratory see that they frequently change shape and that many types of cells move about. The **cytoskeleton,** a dense network of protein fibers, gives cells mechanical strength, shape, and their ability to move (Fig. 4-20). The cytoskeleton also functions in cell division and in the transport of materials within the cell.

The cytoskeleton is highly dynamic and constantly changing. Its framework is made of three types of protein filaments: microtubules, microfilaments, and intermediate filaments. Both microfilaments and microtubules are formed from beadlike, globular protein subunits, which can be rapidly assembled and disassembled. Intermediate filaments are made from fibrous protein subunits and are more stable than microtubules and microfilaments.

Microtubules are hollow cylinders

Microtubules, the thickest filaments of the cytoskeleton, are about 25 nm in outside diameter and up to several micrometers in length. In addition to playing a structural role in the formation of the cytoskeleton, these extremely adaptable structures are involved in the movement of chromosomes during cell division. They serve as tracks for several other kinds of intracellular movement and are the major structural components of cilia and flagella—specialized structures used in some cell movements.

Microtubules consist of two very similar proteins: **α-tubulin** and **β-tubulin** that combine to form a dimer. (Recall from Chapter 3 that a dimer forms from the association of two similar, simpler units, referred to as monomers.) A microtubule elongates by the addition of tubulin dimers (Fig. 4-21). Microtubules are disassembled by the removal of dimers, which are recycled to form microtubules in other parts of the cell. Each

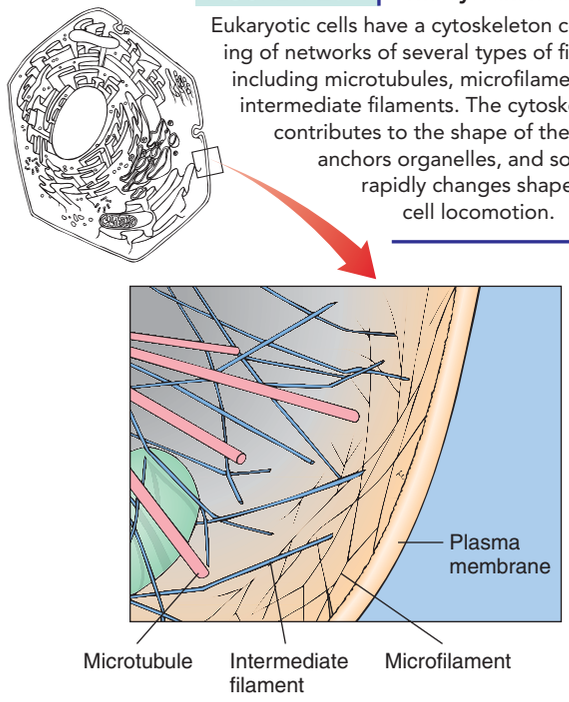

FIGURE 4-20 The cytoskeleton.
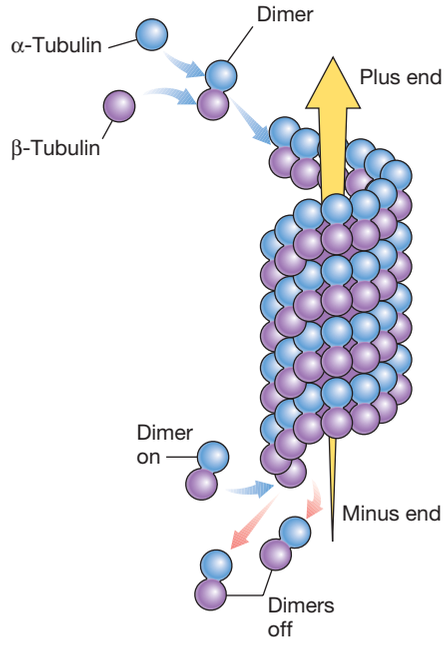
Eukaryotic cells have a cytoskeleton consisting of networks of several types of fibers, including microtubules, microfilaments, and intermediate filaments. The cytoskeleton contributes to the shape of the cell, anchors organelles, and sometimes rapidly changes shape during cell locomotion.



(a)

FIGURE 4-21 Organization of microtubules.
(a) Microtubules are manufactured in the cell by adding dimers of α-tubulin and β-tubulin to an end of the hollow cylinder. Notice that the cylinder has polarity. The end shown at the top of the figure is the fast-growing, or plus, end; the opposite end is the minus end. Each turn of the spiral requires 13 dimers.

microtubule has polarity, and its two ends are referred to as *plus* and *minus*. The plus end elongates more rapidly.

For microtubules to act as a structural framework or participate in cell movement, they must be anchored to other parts of the cell. In nondividing cells, the minus ends of microtubules appear to be anchored in regions called **microtubule-organizing centers (MTOCs).** In animal cells, the main MTOC is the cell center or **centrosome,** a structure that is important in cell division. In many cells, including almost all animal cells, the centrosome contains two structures called **centrioles** (Fig. 4-22). These structures, which are oriented within the centrosome at right angles to each other, are known as *9 × 3 structures;* they consist of nine sets of three attached microtubules arranged to form a hollow cylinder. The centrioles are duplicated before cell division and may play a role in some types of microtubule assembly. Most plant cells and fungal cells have an MTOC but lack centrioles. This suggests either that centrioles are not essential to most microtubule assembly processes or that alternative assembly mechanisms are present.

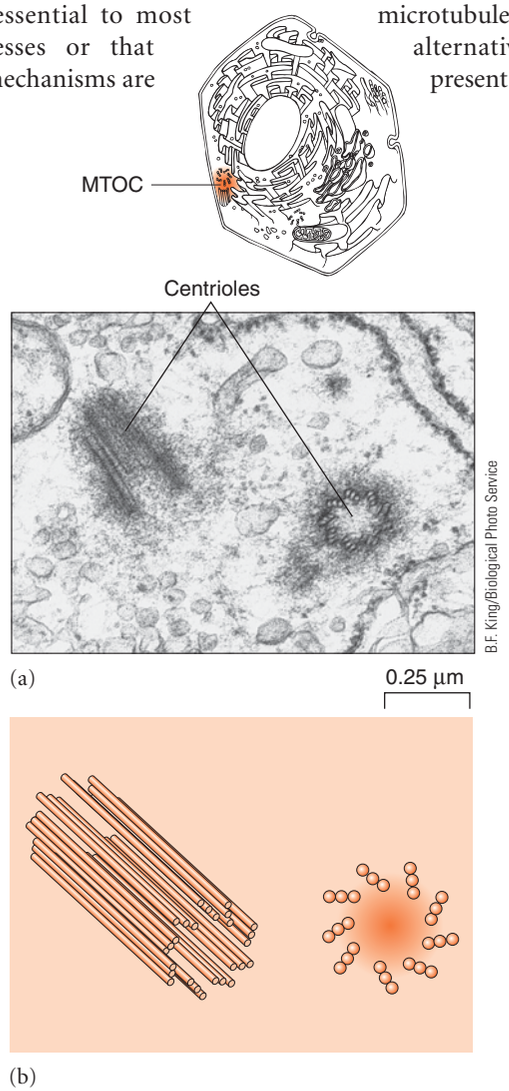

FIGURE **4-22** **Centrioles.**

(a) In the TEM, the centrioles are positioned at right angles to each other, near the nucleus of a nondividing animal cell. **(b)** Note the 9 × 3 arrangement of microtubules. The centriole on the right has been cut transversely.

The ability of microtubules to assemble and disassemble rapidly is seen during cell division, when much of the cytoskeleton appears to break down (see Chapter 9). Many of the tubulin subunits organize into a structure called the **spindle,** which serves as a framework for the orderly distribution of chromosomes during cell division.

Microtubule-associated proteins (MAPs) are classified into two groups: structural MAPs and motor MAPs. *Structural MAPs* may help regulate microtubule assembly, and they cross-link microtubules to other cytoskeletal polymers. *Motor MAPs* use ATP energy to produce movement.

Investigators are studying the mechanisms by which organelles and other materials move within the cell. Nerve cells typically have long extensions called *axons* that transmit signals to other nerve cells, muscle cells, or cells that produce hormones. Because of its length and accessibility and because other cells use similar transport mechanisms, researchers have used the axon as a model for studying the transport of organelles within the cell. They have found that mitochondria, transport and secretory vesicles, and other organelles may attach to microtubules, which then serve as tracks along which organelles move to different cell locations.

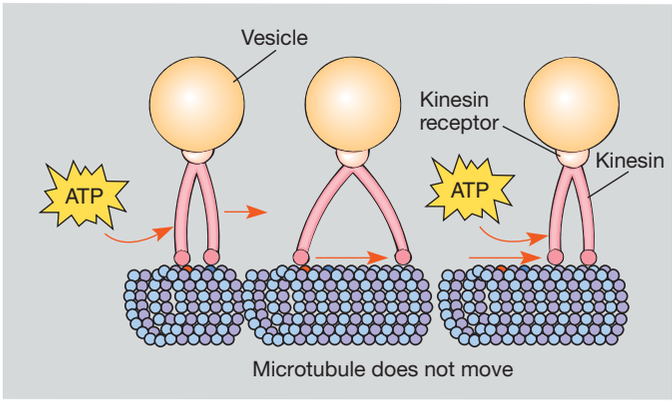
One motor protein, *kinesin,* moves organelles toward the plus end of a microtubule (Fig. 4-23). *Dynein,* another motor protein, transports organelles in the opposite direction, toward the minus end. This dynein movement is referred to as *retrograde transport.* A protein complex called *dynactin* is also required for retrograde transport. Dynactin binds to both microtubules and dynein and may function in transport, linking the organelle, microtubule, and dynein.

Cilia and flagella are composed of microtubules

Thin, movable structures, important in cell movement, project from surfaces of many cells. If a cell has one, or only a few, of these appendages and if they are long (typically about 200 µm) relative to the size of the cell, they are called **flagella** (sing., *flagellum*). If the cell has many short (typically 2–10 µm long) appendages, they are called **cilia** (sing., *cilium*). Cells use both cilia and flagella to move through a watery environment, and some cells use cilia to move liquids and particles across the cell surface. Cilia and flagella are commonly found on unicellular and small multicellular organisms. In animals and certain plants, flagella serve as the tails of sperm cells. In animals, cilia commonly occur on the surfaces of cells that line internal ducts of the body (such as respiratory passageways).

Eukaryotic cilia and flagella are structurally alike (but different from bacterial flagella). Each consists of a slender, cylindrical stalk covered by an extension of the plasma membrane. The core of the stalk contains a group of microtubules arranged so there are nine attached pairs of microtubules around the circumference and two unpaired microtubules in the center (Fig. 4-24). This *9 + 2 arrangement* of microtubules is characteristic of virtually all eukaryotic cilia and flagella.

The microtubules in cilia and flagella move by sliding in pairs past each other. The sliding force is generated by dynein proteins, which are attached to the microtubules like small



ACTIVE FIGURE **4-23** **A hypothetical model of a kinesin motor.**

A kinesin molecule attaches to a specific receptor on the vesicle. Energy from ATP allows the kinesin molecule to change its conformation and "walk" along the microtubule, carrying the vesicle along.

BiologyNow™ Learn more about **kinesin motors** by clicking on this figure on your BiologyNow CD-ROM.

arms. These proteins use the energy from ATP to power the cilia or flagella. The dynein proteins (arms) on one pair of tubules change their shape and "walk" along the adjacent microtubule pair. Thus, the microtubules on one side of a cilium or a flagellum extend farther toward the tip than those on the other side. This sliding of microtubules translates into a bending motion (Fig. 4-24b). Cilia typically move like oars, alternating power and recovery strokes and exerting a force that is parallel to the cell surface. A flagellum moves like a whip, exerting a force perpendicular to the cell surface.

Each cilium or flagellum is anchored in the cell by a **basal body,** which has nine sets of three attached microtubules in a cylindrical array (*9 × 3 structure*). The basal body appears to be the organizing structure for the cilium or flagellum when it first begins to form. However, experiments have shown that as growth proceeds, the tubulin subunits are added much faster to the tips of the microtubules than to the base. Basal bodies and centrioles may be functionally related as well as structurally similar. In fact, centrioles are typically found in the cells of organisms that produce flagellated or ciliated cells; these include animals, certain protists, a few fungi, and a few plants. Both basal bodies and centrioles replicate themselves.

Microfilaments consist of intertwined strings of actin

Microfilaments, also called *actin filaments,* are flexible, solid fibers about 7 nm in diameter. Each microfilament consists of two intertwined polymer chains of beadlike **actin** molecules (Fig. 4-25). Actin filaments are cross-linked with one another and with other proteins by linker proteins. They form bundles of fibers that provide mechanical support for various cell structures. In many cells, a network of microfilaments is visible in the cytosol just inside the plasma membrane.

In muscle cells, actin is associated with another protein, **myosin,** to form fibers that generate the forces that contract muscles (see Chapter 38). In nonmuscle cells, actin can also associate with myosin, forming contractile structures involved in various cell movements. Actin filaments themselves cannot contract, but they can generate movement by rapidly assembling and disassembling. Actin filaments associated with myosin are involved in certain transient functions. For example, in animal cell division, contraction of a ring of actin associated with myosin constricts the cell, forming two daughter cells (see Chapter 9). Certain organelles in the giant axons of the squid move along microfilaments. A type of myosin appears to be the motor for this transport.

As mentioned earlier in the chapter, some types of cells have microvilli, projections of the plasma membrane that increase

FIGURE **4-24** **Structure of cilia.**

(a) This 3-D representation shows nine attached microtubule pairs (doublets) arranged in a cylinder, with two unattached microtubules in the center. The dynein "arms," shown widely spaced for clarity, are actually much closer together along the longitudinal axis. **(b)** The dynein arms move the microtubules by forming and breaking cross bridges on the adjacent microtubules, so that one microtubule "walks" along its neighbor. **(c)** TEM of cross sections through cilia showing the 9 + 2 arrangement of microtubules. **(d)** TEM of a longitudinal section of three cilia of the protist *Tetrahymena,* an organism often used in genetic research. Some of the interior microtubules are visible.

the surface area of the cell for transporting materials across the plasma membrane. Composed of bundles of microfilaments, microvilli extend and retract as the microfilaments assemble and disassemble.

Intermediate filaments help stabilize cell shape

Intermediate filaments are tough, flexible fibers, about 10 nm in diameter (Fig. 4-26). They provide mechanical strength and help stabilize cell shape. These filaments are abundant in regions of a cell that may be subject to mechanical stress applied from outside the cell. Certain proteins cross-link intermediate filaments with other types of filaments and mediate interactions between them.

All eukaryotic cells have microtubules and microfilaments, but only some animal groups, including vertebrates, are known to have intermediate filaments. Even when present, intermediate filaments vary widely in protein composition and size among different cell types and different organisms. Examples of intermediate filaments are the keratins found in the epithelial cells of the vertebrate skin and neurofilaments found in vertebrate nerve cells.

Certain mutations in genes coding for intermediate filaments weaken the cell and have been associated with several diseases. For example, in the neurodegenerative disease amyotrophic lateral sclerosis (ALS, or Lou Gehrig's disease), abnormal neurofilaments have been identified in nerve cells that control muscles. This condition interferes with normal transport of materials in the nerve cells and degeneration of the nerve cells. The resulting loss of muscle function is typically fatal.

Review

- What are the main functions of the cytoskeleton?
- How are microfilaments and microtubules similar? How are they different?
- How are cilia and flagella similar? How are they different?

CELL COVERINGS

Learning Objective

13 Describe the glycocalyx, extracellular matrix, and cell wall.

Most eukaryotic cells are surrounded by a **glycocalyx,** or **cell coat,** formed by polysaccharide side chains of proteins and lipids that are part of the plasma membrane. The glycocalyx protects the cell and may help keep other cells at a distance. Certain molecules of the glycocalyx enable cells to recognize one an-

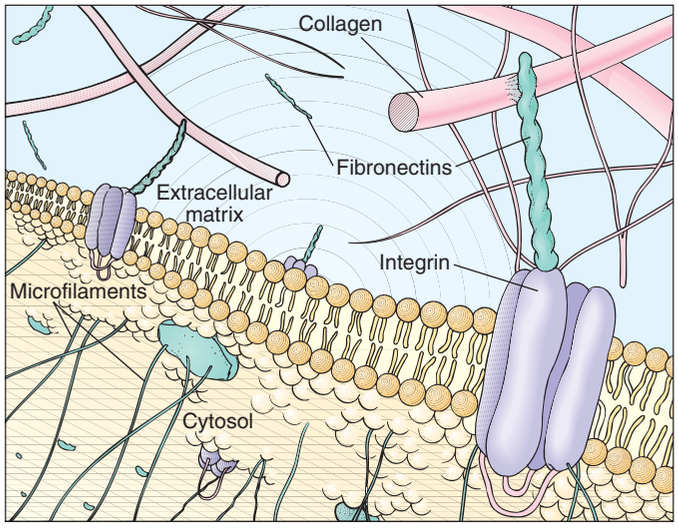

FIGURE **4-27** **The extracellular matrix (ECM).**

Fibronectins, glycoproteins of the ECM, bind to integrins and other receptors in the plasma membrane.

other, to make contact, and in some cases to form adhesive or communicating associations. Other molecules of the cell coat contribute to the mechanical strength of multicellular tissues.

Many animal cells are also surrounded by an **extracellular matrix (ECM),** which they secrete. It consists of a gel of carbohydrates and fibrous proteins (Fig. 4-27). The main structural protein in the ECM is **collagen,** which forms very tough fibers. Certain glycoproteins of the ECM, called **fibronectins,** help organize the matrix and help cells attach to it. Fibronectins bind to protein receptors that extend from the plasma membrane.

Integrins are proteins that serve as membrane receptors for the ECM. These proteins activate many **cell signaling** pathways that communicate information to the cell from the ECM. Integrins appear to be important in cell movement and in organizing the cytoskeleton so that cells assume a definite shape. In many types of cells, integrins anchor the external ECM to the microfilaments of the internal cytoskeleton. When these cells are not appropriately anchored, apoptosis results. Cancer cells apparently lose this requirement to be anchored to the ECM.

Most bacteria, fungi, and plant cells are surrounded by a **cell wall** and proteins. Plant cells have thick cell walls that contain multiple layers of the polysaccharide **cellulose** (see Fig. 3-10). Other polysaccharides in the plant cell wall form cross links between the bundles of cellulose fibers. Each cellulose fiber layer runs in a different direction from the adjacent layer, giving the cell wall great mechanical strength.

Image not available due to copyright restrictions

A growing plant cell secretes a thin, flexible *primary cell wall,* which stretches and expands as the cell increases its size (Fig. 4-28). After the cell stops growing, either new wall material is secreted that thickens and solidifies the primary wall or multiple layers of a *secondary cell wall* with a different chemical composition are formed between the primary wall and the plasma membrane. Wood is made mainly of secondary cell walls. Between the primary cell walls of adjacent cells lies the **middle lamella,** a layer of gluelike polysaccharides called *pectins.* The middle lamella causes the cells to adhere tightly to one another. (For more information on plant cell walls, see Chapter 31's discussion of the ground tissue system.)

Review

- What are the functions of the glycocalyx?
- How do the functions of fibronectins and integrins differ?
- What is the main component of plant cell walls?
- How are cell walls formed?

Biology Now™ Assess your understanding of **cell coverings** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Summarize the relationship between cell organization and homeostasis.

- The **cell** must maintain **homeostasis,** an appropriate internal environment.
- Every cell is surrounded by a **plasma membrane** that forms a cytoplasmic compartment. The plasma membrane helps maintain homeostasis by allowing the cell to exchange materials with its external environment and to maintain internal conditions that may be very different from those of the outer environment.
- Cells have **organelles,** internal structures that carry out specific functions that help maintain homeostasis.

2 Explain the relationship between cell size and maintaining homeostasis.

- Most cells are microscopic. Most prokaryotic cells are smaller than eukaryotic cells.
- A critical factor in determining cell size is the ratio of the plasma membrane (surface area) to the cell's volume; the plasma membrane must be large enough to regulate the passage of materials into and out of the cell.
- Cell size and shape are related to function and are limited by the need to maintain homeostasis.

3 Describe methods that biologists use to study cells, including microscopy and cell fractionation.

- Biologists have learned about cell structure by studying cells with **light** and **electron microscopes** and by using a variety of chemical methods.
- The electron microscope has superior **resolving power,** enabling investigators to see details of cell structures not observable with conventional microscopes.
- Cell biologists use **cell fractionation** methods for purifying organelles, to gain information about the function of cell structures.

4 Compare and contrast the general characteristics of prokaryotic and eukaryotic cells, and contrast plant and animal cells.

- **Prokaryotic cells** are bounded by a plasma membrane but have little or no internal membrane organization. They have a **nuclear area** rather than a membrane-enclosed nucleus. Prokaryotes typically have a **cell wall** and **ribosomes** and may have propeller-like **flagella.**
- **Eukaryotic cells** have a membrane-enclosed **nucleus** and **cytoplasm,** which contains a variety of organelles; the fluid component of the cytoplasm is the **cytosol.**
- Plant cells differ from animal cells in that they have rigid cell walls, **plastids,** and large **vacuoles;** cells of most plants lack centrioles. Vacuoles are important in plant growth and development.

5 Describe three functions of cell membranes.

- Membranes divide the cell into compartments, allowing it to conduct specialized activities within small areas of the cytoplasm, concentrate molecules, and organize metabolic reactions. Membranes are also important in energy storage and conversion.
- A system of interacting membranes forms the **endomembrane system.**
- Small membrane-bounded sacs, called **vesicles,** transport materials between compartments.

6 Describe the structure and functions of the nucleus.

- The nucleus, the control center of the cell, contains genetic information coded in DNA.
- The nucleus is bounded by a **nuclear envelope** consisting of a double membrane perforated with **nuclear pores** that communicate with the cytoplasm.
- DNA in the nucleus associates with protein to form **chromatin** which is organized into **chromosomes.** During cell division, the chromosomes condense and become visible as thread-like structures.
- The **nucleolus** is a region in the nucleus that is the site of ribosomal RNA synthesis and ribosome assembly.

7 Distinguish between smooth and rough endoplasmic reticulum in terms of both structure and function.

- The **endoplasmic reticulum (ER)** is a network of folded internal membranes in the cytosol. **Smooth ER** is the site of lipid synthesis and detoxifying enzymes.
- **Rough ER** is studded along its outer surface with ribosomes that manufacture proteins. Proteins synthesized on rough ER may be moved into the **ER lumen,** where they are modified by the addition of a carbohydrate or lipid.

8 Trace the path of proteins synthesized in the rough endoplasmic reticulum as they are subsequently processed, modified, and sorted by the Golgi complex and then transported to specific destinations.

- The **Golgi complex** consists of stacks of flattened membranous sacs called **cisternae** that process, sort, and modify proteins synthesized on the ER. The Golgi complex also manufactures lysosomes.
- Glycoproteins are transported from the ER to the *cis* face of the Golgi complex by **transport vesicles,** formed by membrane budding.
- The Golgi modifies carbohydrates and lipids that were added to proteins by the ER, and packages them in vesicles. Glycoproteins exit the Golgi at its *trans* face. The Golgi routes some proteins to the plasma membrane for export from the cell. Others are transported to lysosomes or other organelles within the cytoplasm.

9 Describe the functions of lysosomes and peroxisomes.

- **Lysosomes** contain enzymes that break down worn-out cell structures, bacteria, and other substances taken into cells.
- **Peroxisomes** contain enzymes that produce and degrade hydrogen peroxide. They are involved in lipid metabolism and detoxify harmful compounds.

10 Compare the functions of mitochondria and chloroplasts, and discuss ATP synthesis by each of these organelles.

- **Mitochondria,** the sites of aerobic respiration, are organelles enclosed by a double-membrane. The inner membrane is folded, forming **cristae** that increase its surface area. Mitochondria contain DNA that codes for some of its proteins.
- Mitochondria play an important role in **apoptosis,** or programmed cell death.

SUMMARY WITH KEY TERMS *(continued)*

- The cristae and the compartment enclosed by the inner membrane, the **matrix,** contain enzymes for the reactions of aerobic respiration. During aerobic respiration, nutrients are broken down in the presence of oxygen. Energy captured from nutrients is packaged in ATP, and carbon dioxide and water are produced as by-products.
- **Chloroplasts** are plastids that carry out **photosynthesis.**
- The inner membrane of the chloroplast encloses a fluid-filled space, the **stroma. Grana,** stacks of disclike membranous sacs called **thylakoids,** are suspended in the stroma.
- During photosynthesis, **chlorophyll,** the green pigment found in the thylakoid membranes, traps light energy. This energy is converted to chemical energy in ATP and used to synthesize carbohydrates from carbon dioxide and water.

11 Describe the structure and functions of the cytoskeleton.

- The **cytoskeleton** is a dynamic internal framework made of microtubules, microfilaments, and intermediate filaments. The cytoskeleton provides structural support and functions in various types of cell movement, including transport of materials in the cell.
- **Microtubules** are hollow cylinders assembled from subunits of the protein **tubulin.** In cells that are not dividing, the minus ends of microtubules appear to be anchored in **microtubule-organizing centers (MTOCs).**
- The main MTOC of animal cells is the **centrosome,** which usually contains two **centrioles.** Each centriole has a 9 × 3 arrangement of microtubules.
- **Microtubule-associated proteins (MAPs)** include structural MAPs and motor MAPs. Two motor MAPs are kinesin and dynein.
- **Microfilaments,** or actin filaments, formed from subunits of the protein **actin,** are important in cell movement.
- **Intermediate filaments** strengthen the cytoskeleton and stabilize cell shape.

12 Compare cilia and flagella, and describe their functions.

- **Cilia** and **flagella** are thin, movable structures that project from the cell surface and function in movement. Each consists of a 9 + 2 arrangement of microtubules, and each is anchored in the cell by a **basal body** that has a 9 × 3 organization of microtubules. Cilia are short and flagella are long.

13 Describe the glycocalyx, extracellular matrix, and cell wall.

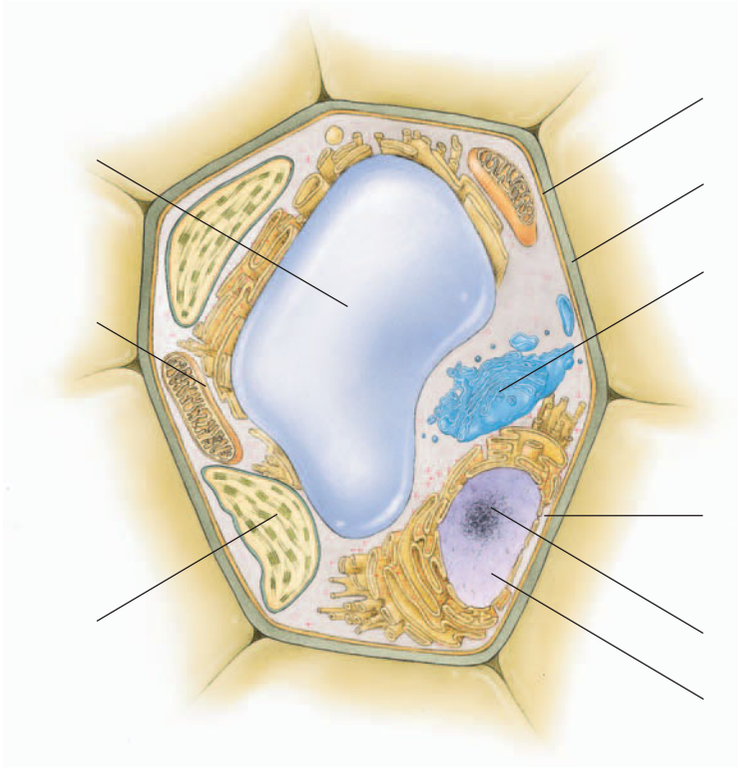
- Most cells are surrounded by a **glycocalyx,** or **cell coat,** formed by polysaccharides extending from the plasma membrane.
- Many animal cells are also surrounded by an **extracellular matrix (ECM)** consisting of carbohydrates and protein. **Fibronectins** are glycoproteins of the ECM that bind to **integrins,** receptor proteins in the plasma membrane.
- Most bacteria, fungi, and plant cells are surrounded by a cell wall made of carbohydrates. Plant cells secrete **cellulose** and other polysaccharides that form rigid cell walls.

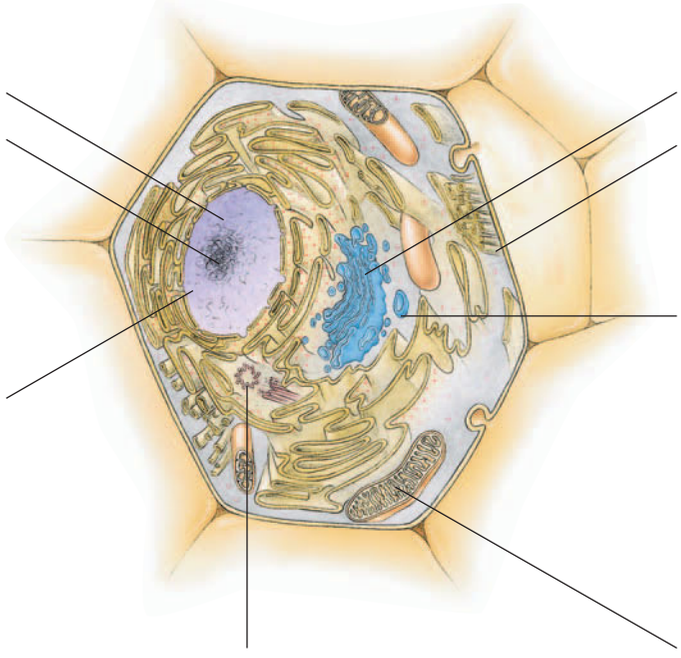
POST-TEST

1. The ability of a microscope to reveal fine detail is known as (a) magnification (b) resolving power (c) cell fractionation (d) scanning electron microscopy (e) phase contrast
2. A plasma membrane is characteristic of (a) all cells (b) prokaryotic cells only (c) eukaryotic cells only (d) animal cells only (e) eukaryotic cells except for plant cells
3. Detailed information about the shape and external features of a specimen can best be obtained by using a (a) differential centrifuge (b) fluorescence microscope (c) transmission electron microscope (d) scanning electron microscope (e) light microscope
4. In eukaryotic cells, DNA is found in (a) chromosomes (b) chromatin (c) mitochondria (d) answers a, b, and c are correct (e) only answers a and b are correct
5. Which of the following structures would *not* be found in prokaryotic cells? (a) cell wall (b) ribosomes (c) nuclear area (d) nucleus (e) propeller-like flagellum
6. Which of the following is/are most closely associated with protein synthesis? (a) ribosomes (b) smooth ER (c) mitochondria (d) microfilaments (e) lysosomes
7. Which of the following is/are most closely associated with the breakdown of ingested material? (a) ribosomes (b) smooth ER (c) mitochondria (d) microfilaments (e) lysosomes
8. Which of the following are most closely associated with photosynthesis? (a) basal bodies (b) smooth ER (c) cristae (d) thylakoids (e) MTOCs
9. A 9 + 2 arrangement of microtubules best describes (a) cilia (b) centrosomes (c) basal bodies (d) microfilaments (e) microvilli
10. Which sequence most accurately describes information flow in the eukaryotic cell? (a) DNA in nucleus ⟶ messenger RNA ⟶ ribosomes ⟶ protein synthesis (b) DNA in nucleus ⟶ ribosomal RNA ⟶ mitochondria ⟶ protein synthesis (c) RNA in nucleus ⟶ messenger DNA ⟶ ribosomes ⟶ protein synthesis (d) DNA in nucleus ⟶ messenger RNA ⟶ Golgi complex ⟶ protein synthesis (e) DNA in nucleus ⟶ messenger RNA ⟶ smooth ER ⟶ protein synthesis
11. Which sequence most accurately describes glycoprotein processing in the eukaryotic cell? (a) smooth ER ⟶ transport vesicle ⟶ *cis* region of Golgi ⟶ *trans* region of Golgi ⟶ plasma membrane or other organelle (b) rough ER ⟶ transport vesicle ⟶ *cis* region of Golgi ⟶ *trans* region of Golgi ⟶ plasma membrane or other organelle (c) rough ER ⟶ transport vesicle ⟶ *trans* region of Golgi ⟶ *cis* region of Golgi ⟶ plasma membrane or other organelle (d) rough ER ⟶ nucleus ⟶ *cis* region of Golgi ⟶ *trans* region of Golgi ⟶ plasma membrane or other organelle (e) smooth ER ⟶ transport vesicle ⟶ *cis* region of Golgi ⟶ chloroplast
12. Which of the following is/are part of the cytoskeleton? (a) microfilaments (b) lysosomes (c) peroxisomes (d) ribosomes (e) endoplasmic reticulum
13. Which of the following function(s) in cell movement? (a) microtubules (b) cristae (c) grana (d) smooth ER (e) rough ER

POST-TEST *(continued)*

14. Which of the following is/are *not* associated with mitochondria? (a) cristae (b) aerobic respiration (c) apoptosis (d) free radicals (e) thylakoids
15. The extracellular matrix (a) consists mainly of myosin and RNA (b) projects to form microvilli (c) houses the centrioles (d) contains fibronectins that bind to integrins (e) has an elaborate system of cristae
16. Label the diagrams of the animal and plant cells. How is the structure of each organelle related to its function? Use Figures 4-7 and 4-9 to check your answers.





CRITICAL THINKING

1. Explain why the cell is considered the basic unit of life, and discuss some of the implications of the cell theory.
2. Why does a eukaryotic cell need both membranous organelles and fibrous cytoskeletal components?
3. Describe a specific example of the correlation between cell structure and function. (*Hint:* Think of mitochondrial structure.)
4. The *Acetabularia* experiments described in this chapter suggest that DNA is much more stable in the cell than is messenger RNA. Is this advantageous or disadvantageous to the cell? Why? How can *Acetabularia* continue to live for a few days after its nucleus is removed?

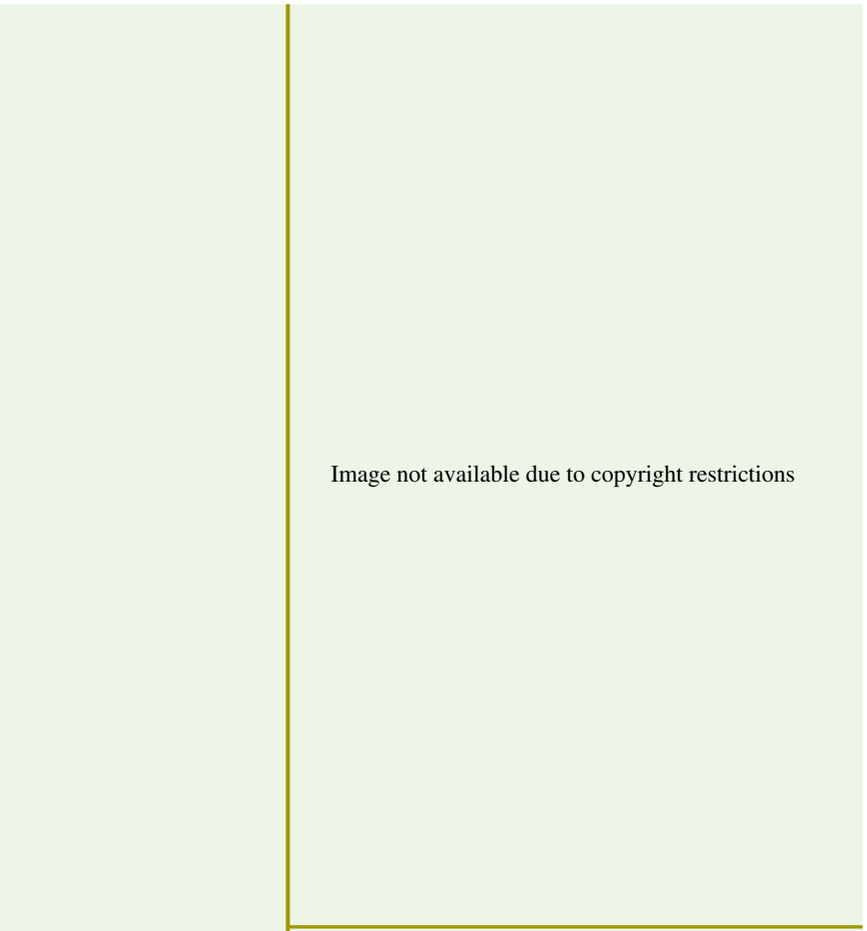
Biological Membranes



CHAPTER OUTLINE

- The Structure of Biological Membranes
- Passage of Materials Through Cell Membranes
- Cell Signaling
- Cell Junctions

The evolution of biological membranes was an essential step in the origin of life. Later, membranes made the evolution of complex cells possible, because the extensive internal membranes of eukaryotes form multiple compartments with unique environments for highly specialized activities. In Chapter 4, we discussed the importance of cell membranes in maintaining homeostasis. Biological membranes are not inanimate barriers; they are complex, dynamic structures made of lipid and protein molecules that are in constant motion. The unusual properties of membranes allow them to perform many functions in addition to defining the cell as a compartment and regulating the passage of materials. These functions include participating in many chemical reactions, transmitting signals and information between the environment and the interior of the cell, and acting as an essential part of energy transfer and storage systems (see Chapters 7 and 8).

The plasma membrane that surrounds every cell physically separates the cell from the outside world and defines the cell as a distinct entity. The plasma membrane helps maintain a life-supporting internal environment by regulating passage of materials into and out of the cell. To carry out the many chemical reactions necessary to sustain life, the cell must maintain an appropriate internal environment.

One exciting area of cell membrane research focuses on membrane proteins. Many proteins associated with the plasma membrane are enzymes. Others transport materials or transfer information. Still others, known as *cell adhesion molecules,* are important in connecting cells to one another to form tissues. Researchers are studying how membrane proteins function in health and disease.

The principal cell adhesion molecules in vertebrates and in many invertebrates are **cadherins.** These molecules are responsible for calcium-dependent adhesion between cells that form multicellular sheets. For example, cadherins form cell junctions important in maintaining the structure of the epithelium that makes up human skin (see photograph). An absence of these membrane proteins is associated with the invasiveness of some malignant

tumors. Certain cadherins mediate the way cells adhere in the early embryo, and thus they are important in development.

In this chapter, we first consider what is known about the composition and structure of biological membranes. We survey how various materials, ranging from ions to complex molecules and even bacteria, move across membranes. We then consider how information crosses the plasma membrane through a signal relay system. Finally, we examine specialized structures that enable membranes of different cells to interact. Although much of our discussion centers on the structure and functions of plasma membranes, many of the concepts apply to other cell membranes. ■

THE STRUCTURE OF BIOLOGICAL MEMBRANES

Learning Objectives

1. Evaluate the importance of membranes to the homeostasis of the cell, emphasizing their various functions.
2. Describe the fluid mosaic model of cell membrane structure.
3. Explain how the properties of the lipid bilayer govern many properties of the cell membrane and of the cell.
4. Describe how membrane proteins associate with the lipid bilayer, and discuss the functions of membrane proteins.

In Chapter 4 and in the introduction to this chapter, we discussed the importance of membranes to the cell in maintaining homeostasis. How do the properties of cell membranes enable the cell to carry on such varied functions as regulating passage of materials, compartmentalizing the cell, serving as a surface for chemical reactions, adhering to and communicating with other cells, and receiving information from the environment?

Long before the development of the electron microscope, scientists knew that membranes consist of both lipids and proteins. Work by researchers in the 1920s and 1930s had provided clues that the core of cell membranes consist of lipids, mostly phospholipids (see Chapter 3).

Phospholipids form bilayers in water

Phospholipids are primarily responsible for the physical properties of biological membranes. This is because certain phospholipids have unique attributes, including features that allow them to form bilayered structures. A phospholipid contains two fatty acid chains linked to two of the three carbons of a glycerol molecule (see Fig. 3-13). The fatty acid chains make up the nonpolar, *hydrophobic* ("water-fearing") portion of the phospholipid. Bonded to the third carbon of the glycerol is a negatively charged, *hydrophilic* ("water-loving") phosphate group, which in turn is linked to a polar, hydrophilic organic group. Molecules of this type, which have distinct hydrophobic and hydrophilic regions, are called **amphipathic molecules.** All lipids that make up the core of biological membranes have amphipathic characteristics.

Because one end of each phospholipid associates freely with water and the opposite end does not, the most stable orientation for them to assume in water results in the formation of a bilayer structure (Fig. 5-1a). This arrangement allows the hydrophilic heads of the phospholipids to be in contact with the aqueous medium while their oily tails, the hydrophobic fatty acid chains, are buried in the interior of the structure away from the water molecules.

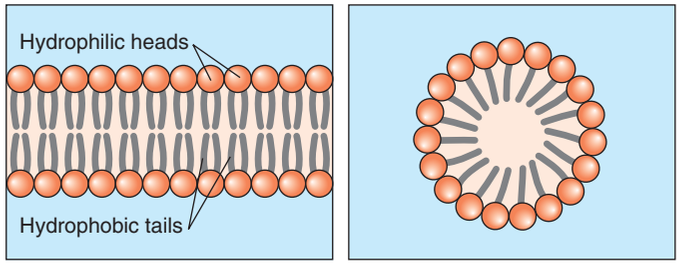
Amphipathic properties alone do not predict the ability of lipids to associate as a bilayer. Shape is also important. Phospholipids tend to have uniform widths; their roughly cylindrical shapes, together with their amphipathic properties, are responsible for bilayer formation. In summary, phospholipids form bilayers because the molecules have (1) two distinct regions, one strongly hydrophobic and the other strongly hydrophilic (making them strongly amphipathic); and (2) cylindrical shapes that allow them to associate with water most easily as a bilayer structure.

Do you know why detergents remove grease from your hands or from dirty dishes? Many common detergents are amphipathic molecules, each containing a single hydrocarbon chain (like a fatty acid) at one end and a hydrophilic region at the other. These molecules are roughly cone shaped, with the hydrophilic end forming the broad base and the hydrocarbon tail leading to the point. Because of their shapes, these molecules do not associate as bilayers but instead tend to form spherical structures in water (see Fig. 5-1b). Detergents can "solubilize" oil because the oil molecules associate with the hydrophobic interiors of the spheres.

Current data support a fluid mosaic model of membrane structure

PROCESS OF SCIENCE

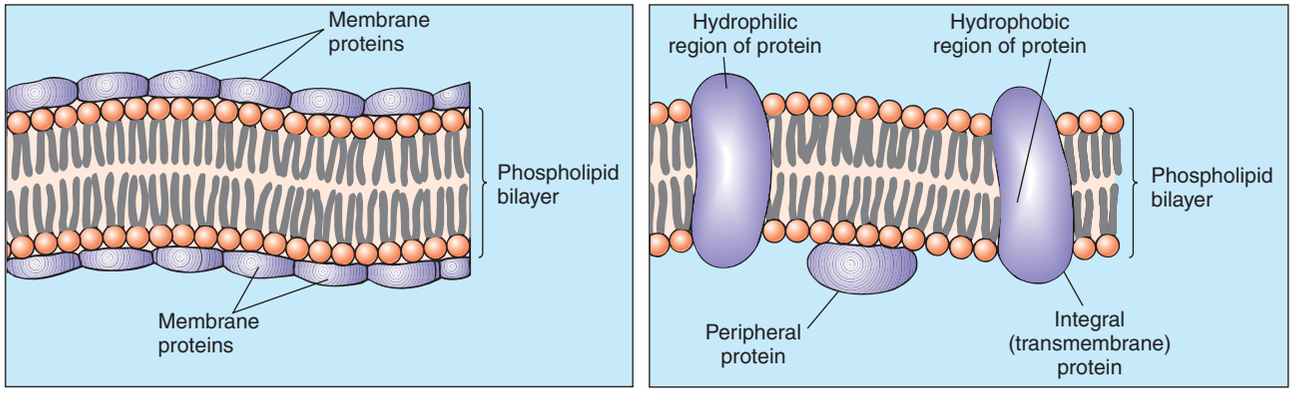
By examining the plasma membrane of the mammalian red blood cell and comparing its surface area with the total number of lipid molecules per cell, early investigators calculated that the membrane is no more than two phospholipid molecules thick. These findings, together with other data, led Hugh Davson and James Danielli, working at London's University College, in



(a) Phospholipids in water (b) Detergent in water

FIGURE **5-1** **Lipid membranes.**

(a) Phospholipids associate as bilayers in water because they are roughly cylindrical amphipathic molecules. The hydrophobic fatty acid chains associate with each other and are not exposed to water. The hydrophilic phospholipid heads are in contact with water. **(b)** Detergent molecules are roughly cone-shaped amphipathic molecules that associate in water as spherical structures.



(a) The Davson-Danielli "sandwich" model

(b) Fluid mosaic model

ACTIVE FIGURE **5-2** **Two models of membrane structure.**

(a) According to the Davson-Danielli model, the membrane is a sandwich of phospholipids spread between two layers of protein. Although accepted for more than 20 years, this model was shown to be incorrect. **(b)** According to the fluid mosaic model, a cell membrane is a fluid lipid bilayer with a constantly changing "mosaic pattern" of associated proteins.

BiologyNow™ Watch protein movement in the **fluid mosaic model** by clicking on this figure on your BiologyNow CD-ROM.

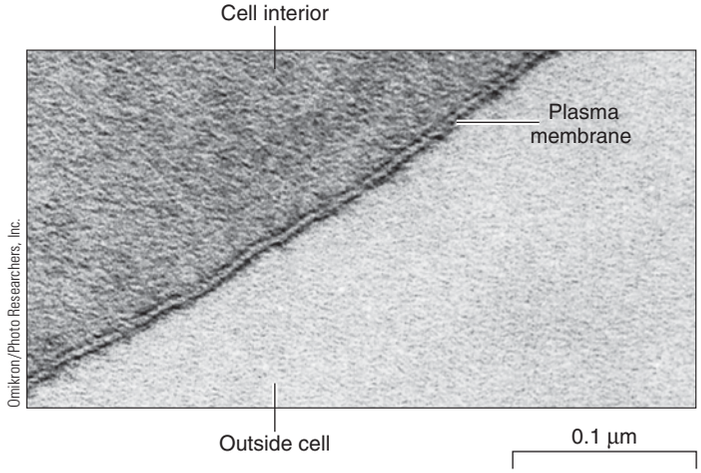
1935 to propose a model in which they envisioned a membrane as a kind of "sandwich" consisting of a *lipid bilayer* (a double layer of lipid) between two protein layers (Fig. 5-2a). This useful model had a great influence on the direction of membrane research for more than 20 years. Models are important in the scientific process; good ones not only explain the available data but are testable. Scientists use the model to help them develop hypotheses that can be tested experimentally (see Chapter 1).

With the development of the electron microscope in the 1950s, cell biologists were able to see the plasma membrane for the first time. One of their most striking observations was how uniform and thin the membranes are. The plasma membrane is no more than 10 nm thick. The electron microscope revealed a three-layered structure, something like a railroad track, with two dark layers separated by a lighter layer (Fig. 5-3). Their findings seemed to support the protein-lipid-protein sandwich model.

During the 1960s, a paradox emerged regarding the arrangement of the proteins. Biologists assumed membrane proteins were uniform and had shapes that would allow them to lie like thin sheets on the membrane surface. But when purified by cell fractionation, the proteins were far from uniform; in fact, they varied widely in composition and size. Some proteins are quite large. How could they fit within a surface layer of a membrane less than 10 nm thick? At first, some researchers tried to answer this question by modifying the model with the hypothesis that the proteins on the membrane surfaces were a flattened, extended form, perhaps a β-pleated sheet (see Figure 3-20b).

Other cell biologists found that instead of having sheetlike structures, many membrane proteins are rounded, or globular. Studies of a number of membrane proteins showed that one region (or domain) of the molecule could always be found on one side of the bilayer, whereas another part of the protein might be located on the opposite side. Rather than forming a thin surface layer, many membrane proteins extended completely through the lipid bilayer. Thus the evidence suggested that membranes contain many different types of proteins of different shapes and sizes that are associated with the bilayer in a mosaic pattern.

In 1972, S. Jonathan Singer and Garth Nicolson of the University of California, at San Diego, proposed a model of membrane structure that represented a synthesis of the known properties of biological membranes. According to their **fluid mosaic model,** a cell membrane consists of a fluid bilayer of phospholipid molecules in which the proteins are embedded or otherwise associated, much like the tiles in a mosaic picture. This mosaic pattern is not static, however, because the positions of the proteins are constantly changing as they move about like icebergs in a fluid sea of phospholipids. This model has provided great impetus to research; it has been repeatedly tested and has been shown to accurately predict the properties of many kinds of cell membranes. Figure 5-2b depicts the plasma membrane of a eukaryotic cell according to the fluid mosaic model; prokaryotic plasma membranes are discussed in Chapter 23.



Omikron/Photo Researchers, Inc.

FIGURE **5-3** **TEM of the plasma membrane of a mammalian red blood cell.**

The plasma membrane separates the cytoplasm *(darker region)* from the external environment *(lighter region).* The hydrophilic heads of the phospholipids are seen as the parallel dark lines, whereas the hydrophobic tails are visible as the light zone between them.

Biological membranes are two-dimensional fluids

An important physical property of phospholipid bilayers is that they behave like *liquid crystals.* The bilayers are crystal-like in that the lipid molecules form an ordered array with the heads on the outside and fatty acid chains on the inside; they are liquid-like in that, despite the orderly arrangement of the molecules, their hydrocarbon chains are in constant motion. Thus molecules are free to rotate and can move laterally within their single layer (Fig. 5-4). Such movement gives the bilayer the property of a *two-dimensional fluid.* Under normal conditions this means that a single phospholipid molecule can travel laterally across the surface of a eukaryotic cell in seconds.

PROCESS OF SCIENCE

The fluid qualities of lipid bilayers also allow molecules embedded in them to move along the plane of the membrane (as long as they are not anchored in some way). This was elegantly demonstrated by David Frye and Michael Edidin in 1970. They conducted experiments in which they followed the movement of membrane proteins on the surface of two cells that had been joined (Fig. 5-5). When the plasma membranes of a mouse cell and a human cell are fused, within minutes, at least some of the membrane proteins from each cell migrate and become randomly distributed over the single continuous plasma membrane that surrounds the joined cells. Frye and Edidin showed that the fluidity of the lipids in the membrane allows many of the proteins to move, producing an ever-changing configuration.

For a membrane to function properly, its lipids must be in a state of optimal fluidity. The membrane's structure is weakened if its lipids are too fluid. However, many membrane functions, such as the transport of certain substances, are inhibited or cease if the lipid bilayer is too rigid. At normal temperatures, cell membranes are fluid, but at low temperatures the motion of the fatty acid chains is slowed. If the temperature decreases to a critical point, the membrane is converted to a more solid gel state.

Certain properties of membrane lipids have significant effects on the fluidity of the bilayer. Recall from Chapter 3 that molecules are free to rotate around single carbon-to-carbon covalent bonds. Because most of the bonds in hydrocarbon chains are single bonds, the chains themselves twist more and more rapidly as the temperature rises.

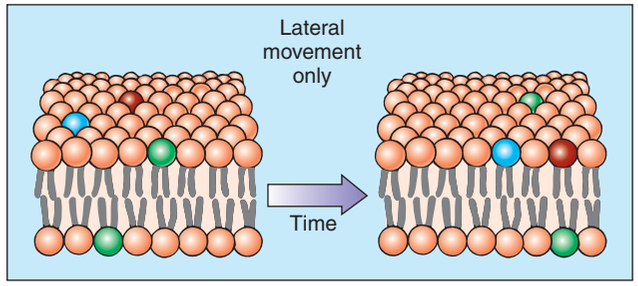


FIGURE **5-4** **Membrane fluidity.**

The ordered arrangement of phospholipid molecules makes the cell membrane a liquid crystal. The hydrocarbon chains are in constant motion, allowing each molecule to move laterally on the same side of the bilayer.

The fluid state of the membrane depends on its component lipids. You have probably noticed that when melted butter is left at room temperature, it solidifies. Vegetable oils, however, remain liquid at room temperature. Recall from our discussion of fats in Chapter 3 that animal fats such as butter are high in saturated fatty acids that lack double bonds. In contrast, a vegetable oil may be polyunsaturated, with most of its fatty acid chains having two or more double bonds. At each double bond there is a bend in the molecules that prevents the hydrocarbon chains from coming close together and interacting through van der Waals interactions. In this way, unsaturated fats lower the temperature at which oil or membrane lipids solidify.

Many organisms have regulatory mechanisms for maintaining cell membranes in an optimally fluid state. For example, some organisms compensate for temperature changes by altering the fatty acid content of their membrane lipids. When the outside temperature is cold, the membrane lipids contain relatively high proportions of unsaturated fatty acids.

Some membrane lipids stabilize membrane fluidity within certain limits. One such "fluidity buffer" is cholesterol, a steroid found in animal cell membranes. A cholesterol molecule is largely hydrophobic but is slightly amphipathic owing to the presence of a single hydroxyl group (see Fig. 3-15a). This hydroxyl group associates with the hydrophilic heads of the phospholipids; the hydrophobic remainder of the cholesterol molecule fits between the fatty acid hydrocarbon chains (Fig. 5-6).

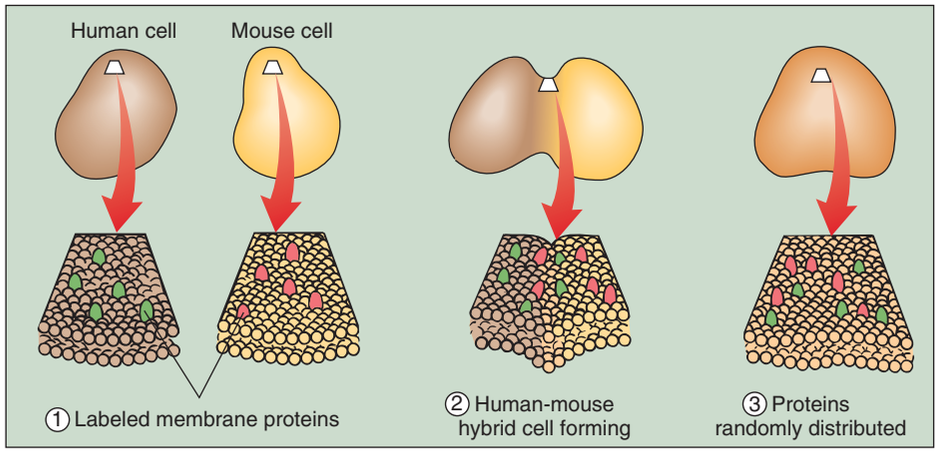

FIGURE **5-5** **Frye and Edidin's experiment.**

① Membrane proteins of mouse cells and human cells were labeled with fluorescent dye markers in two different colors. ② When the plasma membranes of a mouse cell and a human cell were fused, mouse proteins migrated to the human side and human proteins to the mouse side. ③ After a short time, mouse and human proteins became randomly distributed on the cell surface.

At low temperatures cholesterol molecules act as "spacers" between the hydrocarbon chains, restricting van der Waals interactions that would promote solidifying. Cholesterol also helps prevent the membrane from becoming weakened or unstable at higher temperatures. This is because the cholesterol molecules interact strongly with the portions of the hydrocarbon chains closest to the phospholipid head. This interaction restricts motion in these regions. Plant cells have steroids other than cholesterol that carry out similar functions.

Biological membranes fuse and form closed vesicles

Lipid bilayers, particularly those in the liquid-crystalline state, have additional important physical properties. Bilayers tend to resist forming free ends; as a result, they are self-sealing and under most conditions spontaneously round up to form closed vesicles. Lipid bilayers are also flexible, allowing cell membranes to change shape without breaking. Under appropriate conditions lipid bilayers fuse with other bilayers.

Membrane fusion is an important cell process. When a vesicle fuses with another membrane, both membrane bilayers and their compartments become continuous. Various transport and secretory vesicles form from and also merge with membranes of the ER and Golgi complex, facilitating the transfer of materials from one compartment to another. A secretory vesicle fuses with the plasma membrane when a product is secreted from the cell.

Membrane proteins include integral and peripheral proteins

The two major classes of membrane proteins, integral proteins and peripheral proteins, are defined by how tightly they are associated with the lipid bilayer (see Fig. 5-6). **Integral membrane**

KEY CONCEPT: According to the fluid mosaic model, a cell membrane is composed of a fluid bilayer of phospholipids in which proteins move about like icebergs in a sea.

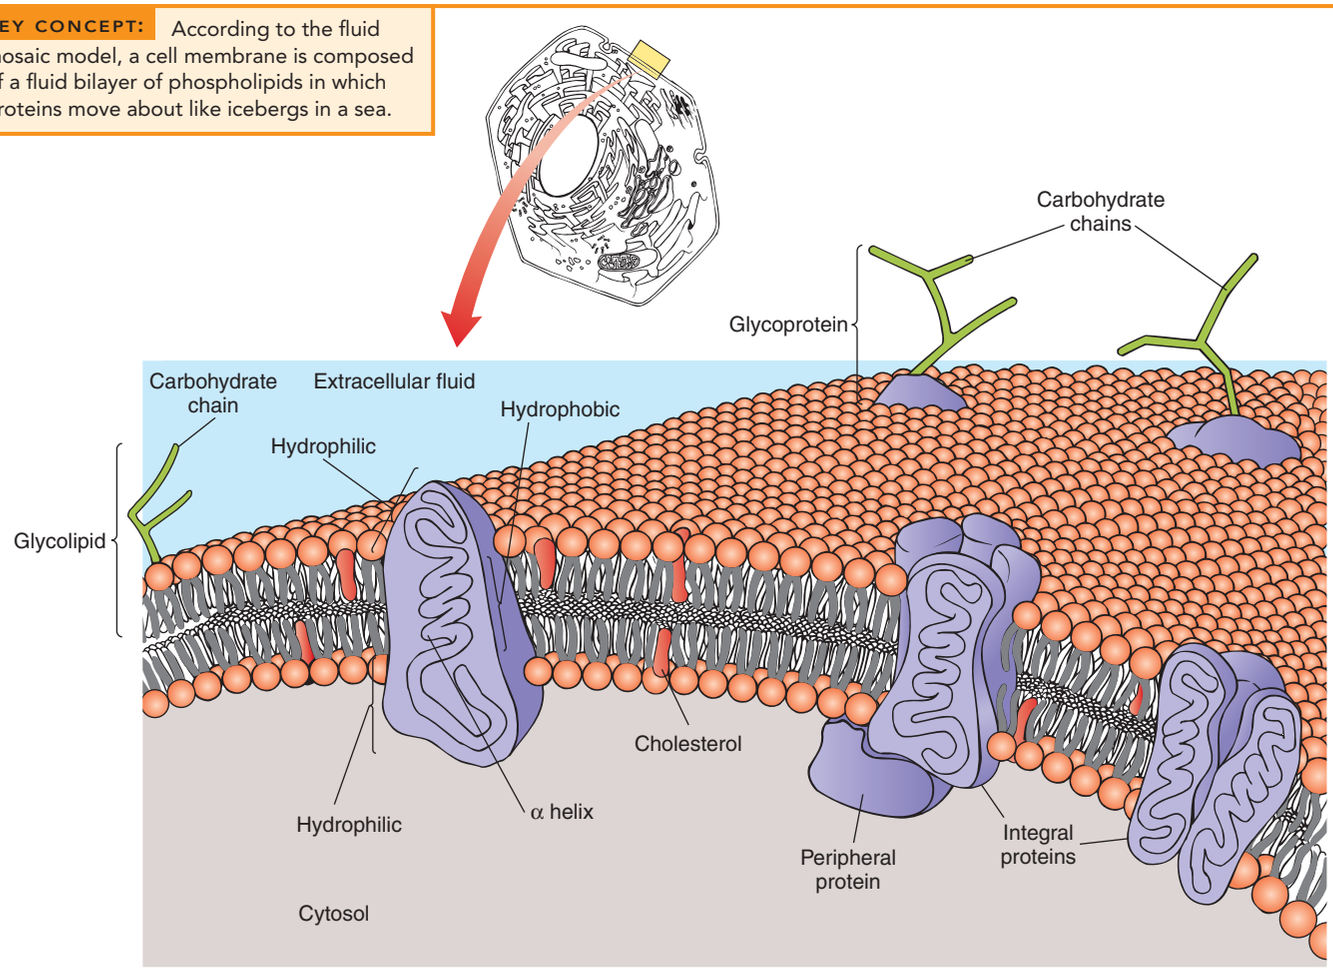

FIGURE **5-6** **Detailed structure of the plasma membrane.**

Although the lipid bilayer consists mainly of phospholipids, other lipids, such as cholesterol and glycolipids, are present. Peripheral proteins are loosely associated with the bilayer, whereas integral proteins are tightly bound. The integral proteins shown here are transmembrane proteins that extend through the bilayer. They have hydrophilic regions on both sides of the bilayer, connected by a membrane-spanning α-helix. Glycolipids (carbohydrates attached to lipids) and glycoproteins (carbohydrates attached to proteins) are exposed on the extracellular surface; they play roles in cell recognition and adhesion.

proteins are firmly bound to the membrane. Cell biologists usually can release them only by disrupting the bilayer with detergents. These proteins are amphipathic. Their hydrophilic regions extend out of the cell or into the cytoplasm, while their hydrophobic regions interact with the fatty acid tails of the membrane phospholipids.

Some integral proteins do not extend all the way through the membrane. Many others, called **transmembrane proteins,** extend completely through the membrane. Some span the membrane only once, whereas others wind back and forth as many as 24 times. The most common kind of transmembrane protein is an α-helix (see Chapter 3) with hydrophobic amino acid side chains projecting out from the helix into the hydrophobic region of the lipid bilayer.

Peripheral membrane proteins are not embedded in the lipid bilayer. They are located on the inner or outer surface of the plasma membrane, usually bound to exposed regions of integral proteins by noncovalent interactions. Peripheral proteins can be easily removed from the membrane without disrupting the structure of the bilayer.

Proteins are oriented asymmetrically across the bilayer

PROCESS OF SCIENCE

One of the most remarkable demonstrations that proteins are actually embedded in the lipid bilayer comes from *freeze-fracture* electron microscopy, a technique that enables a researcher to literally see the membrane from "inside out." When cell biologists examine membranes in this way, they observe numerous particles on the fracture faces. These particles are clearly integral membrane proteins, because researchers never see them in freeze-fractured artificial lipid bilayers. These findings profoundly influenced Singer and Nicolson in developing the fluid mosaic model.

When we compare the two sides of a membrane, large numbers of particles are found on one side and very few on the other (Fig. 5-7). This does not necessarily mean more proteins are on one side of the membrane than on the other but rather that most are more firmly attached to a given side. Thus the protein molecules are *asymmetrically oriented.* Each side of a membrane has different characteristics because each type of protein is oriented in the bilayer in only one way. Proteins are not randomly placed into membranes; asymmetry is produced by the highly specific way in which each protein is inserted into the bilayer.

Membrane proteins that will become part of the inner surface of the plasma membrane are manufactured by free ribosomes and move to the membrane through the cytoplasm. Membrane proteins that will be associated with the cell's outer surface are manufactured like proteins destined to be exported from the cell. As discussed in Chapter 4, these proteins are initially formed by ribosomes on the rough ER. They pass through the ER membrane into the ER lumen, where sugars are added, making them **glycoproteins.** Only a part of each protein passes through the ER membrane, so each completed protein has some regions that are located in the ER lumen and other regions that remain in the cytosol. Enzymes that attach the sugars to certain amino acids on the protein are found only in the lumen of the ER. Thus carbohydrates can be added only to the parts of proteins that are located in that compartment.

In Figure 5-8, follow from top to bottom the vesicle budding and membrane fusion events that are part of the transport process. You can see that the same region of the protein that protruded into the ER lumen is also transported to the lumen of the Golgi complex. There additional enzymes further modify the carbohydrate chains. Within the Golgi complex, the glycoprotein is sorted and directed to the plasma membrane. The modified region of the protein remains inside the membrane compartment of a transport (secretory) vesicle as it buds from the Golgi com-

FIGURE **5-7** **Asymmetry of the plasma membrane.**

(a) In the freeze-fracture method, the path of membrane cleavage is along the hydrophobic interior of the lipid bilayer. Two complementary fracture faces result. The inner half-membrane presents the P-face (or protoplasmic face), from which project most of the membrane proteins. A relatively smooth, outer half-membrane presents the E-face (or external face), which shows fewer protein particles. In a good fracture, particles are visible on both of the inside faces of the fractured membrane, as shown here. These particles are transmembrane proteins inserted into the lipid bilayer. Freeze-fractured bilayers of lipids alone do not have particles on the fracture planes. **(b)** A freeze-fracture TEM. Notice the greater number of proteins on the P-face of the membrane.

plex. When the transport vesicle fuses with the plasma membrane, the carbohydrate chain becomes the part of the membrane protein that extends to the exterior of the cell surface.

In summary, this is the sequence:

ER lumen ⟶ transport vesicle ⟶ vesicles in Golgi (transport to successive compartments) ⟶ transport (secretory) vesicle ⟶ plasma membrane

Membrane proteins function in transport, in information transfer, and as enzymes

Why does the plasma membrane require so many different proteins? This diversity reflects the multitude of activities that take place in or on the membrane. Generally, plasma membrane proteins fall into several broad functional categories as shown in Figure 5-9. Some membrane proteins anchor the cell to its substrate. For example, integrins, described in Chapter 4, attach to the extracellular matrix while simultaneously binding to microfilaments inside the cell (Fig. 5-9a). They also serve as receptors, or docking sites, for proteins of the extracellular matrix.

Many membrane proteins are involved in the transport of molecules across the membrane. Some form channels that selectively allow the passage of specific ions or molecules (Fig. 5-9b). Other proteins form pumps that use ATP to actively transport solutes across the membrane (Fig. 5-9c).

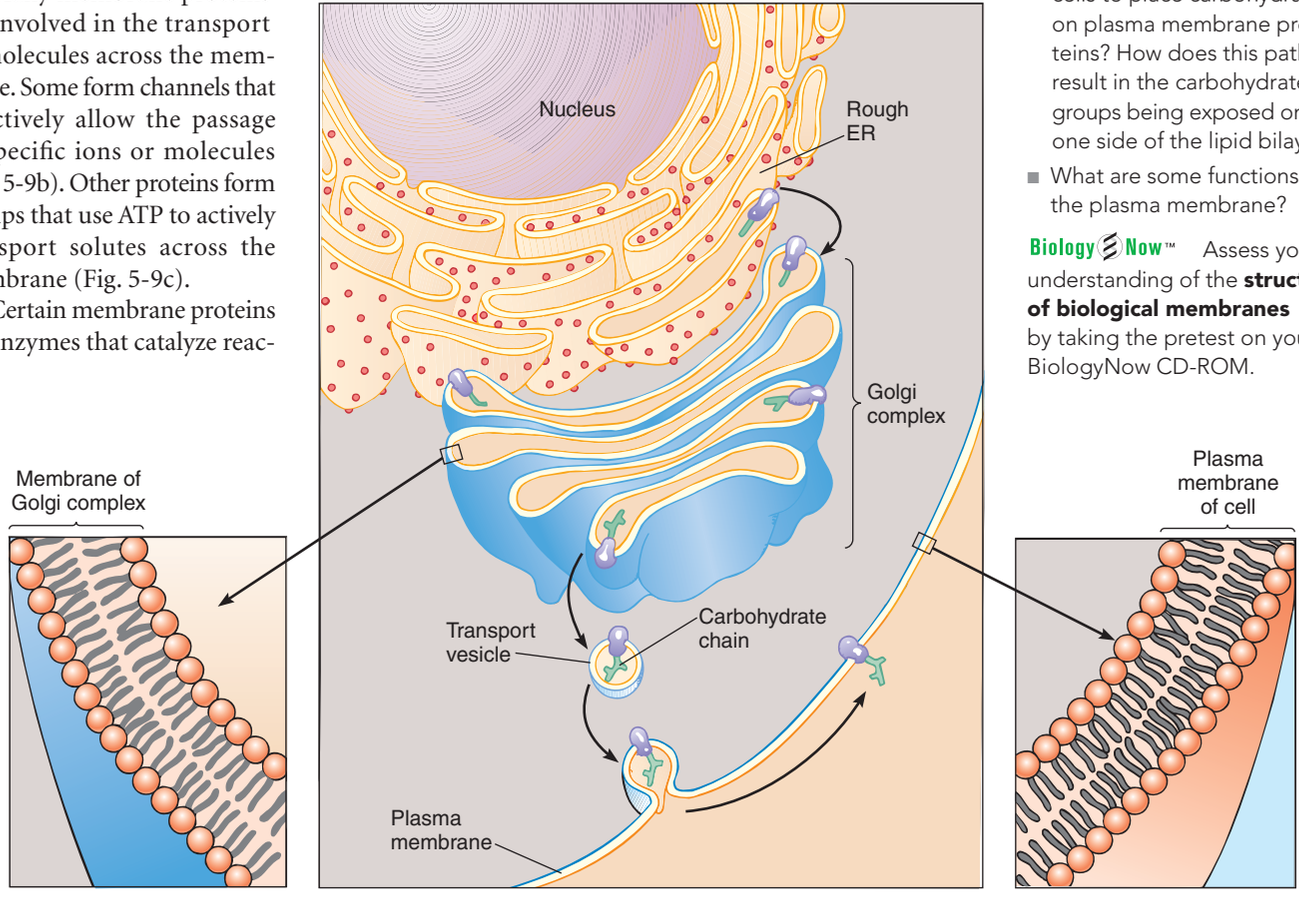
Certain membrane proteins are enzymes that catalyze reactions near the cell surface (Fig. 5-9d). For example, in mitochondrial or chloroplast membranes, enzymes may be organized in a sequence to regulate a series of reactions, as in cellular respiration or photosynthesis.

Some membrane proteins are receptors that receive information from other cells. For example, cells receive hormonal signals from endocrine cells. This information may be transmitted to the cell interior by *signal transduction,* discussed later in this chapter (Fig. 5-9e).

Some membrane proteins serve as identification tags that other cells recognize. Cells that recognize one another may connect to form a tissue. Human cells have distinctive receptors that identify them as part of a particular individual. Certain cells recognize the surface proteins, or antigens, of bacterial cells as foreign. Antigens stimulate immune defenses that destroy the bacteria (Fig. 5-9f). Some membrane proteins form junctions between adjacent cells (Fig. 5-9g). These proteins may also serve as anchoring points for networks of cytoskeletal elements.

FIGURE **5-8** **The formation of a membrane protein.**

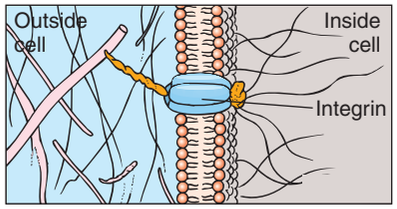
The orientation of a protein in the plasma membrane results from the pathway of its synthesis and transport in the cell. The surface of the rough ER membrane that faces the lumen of the rough ER also faces the lumen of the Golgi complex and vesicles. When a vesicle fuses with the plasma membrane, its inner surface becomes the extracellular surface of the plasma membrane. Carbohydrates added to proteins in the ER and then modified in the Golgi complex are associated with the extracellular surface of the plasma membrane.



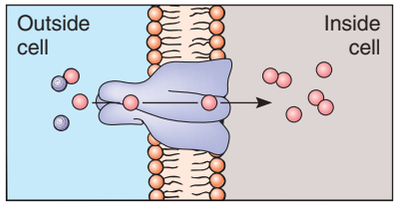
Review

- What molecules are responsible for the physical properties of a cell membrane?
- How might a transmembrane protein be positioned in a lipid bilayer? How do the hydrophilic and hydrophobic regions of the protein affect its orientation?
- What is the pathway used by cells to place carbohydrates on plasma membrane proteins? How does this pathway result in the carbohydrate groups being exposed on only one side of the lipid bilayer?
- What are some functions of the plasma membrane?

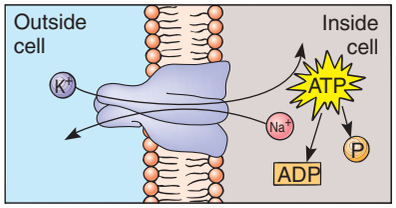
BiologyNow™ Assess your understanding of the **structure of biological membranes** by taking the pretest on your BiologyNow CD-ROM.



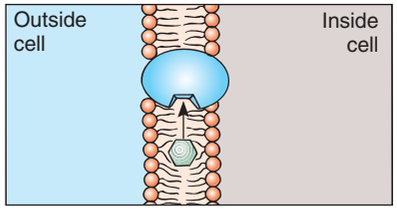
(a) Anchoring. Some membrane proteins, such as integrins, anchor the cell to the extracellular matrix; they also connect to microfilaments within the cell.



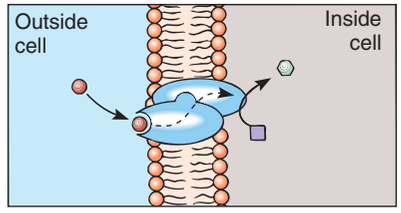
(b) Passive transport. Certain proteins form channels for selective passage of ions or molecules.



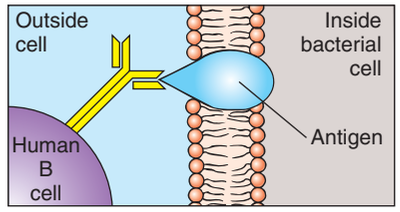
(c) Active transport. Some transport proteins pump solutes across the membrane, which requires a direct input of energy.



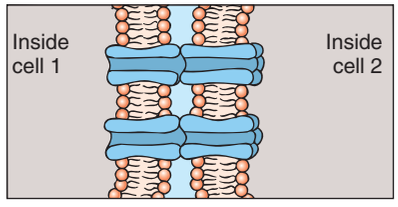
(d) Enzymatic activity. Many membrane-bound enzymes catalyze reactions that take place within or along the membrane surface.



(e) Signal transduction. Some receptors bind with signal molecules such as hormones and transmit information into the cell.



(f) Cell recognition. Some receptor proteins function as identification tags. For example, bacterial cells have surface proteins, or antigens, that human cells recognize as foreign.



(g) Intercellular junction. Cell adhesion proteins attach membranes of adjacent cells.

FIGURE **5-9** **Functions of membrane proteins.**

PASSAGE OF MATERIALS THROUGH CELL MEMBRANES

Learning Objectives

5 Contrast the physical processes of simple diffusion and osmosis with the carrier-mediated physiological processes by which materials are transported across cell membranes.

6 Solve simple problems involving osmosis; for example, predict whether cells will swell or shrink under various osmotic conditions.

7 Differentiate between the processes of facilitated diffusion and active transport, and identify energy sources for each process.

8 Compare endocytotic and exocytotic transport mechanisms.

A membrane is *permeable* to a given substance if it allows that substance to pass through, and impermeable if it does not. Biological membranes are **selectively permeable membranes**—they allow some but not all substances to pass through them. In general, biological membranes are most permeable to small molecules and to lipid-soluble substances able to pass through the hydrophobic interior of the bilayer. Because the interior of its lipid bilayer is hydrophobic, biological membranes present a barrier to most polar (and therefore not lipid-soluble) molecules.

In response to varying environmental conditions or cell needs, a membrane may be a barrier to a particular substance at one time and actively promote its passage at another time. By regulating chemical traffic across its plasma membrane, a cell controls its volume and its internal ionic and molecular composition, which can be quite different from the outside.

Although they are polar, water molecules rapidly cross a lipid bilayer. They are small enough to pass through gaps that occur as a fatty acid chain momentarily moves out of the way. The following also cross the lipid bilayer rapidly: gases such as oxygen, carbon dioxide, and nitrogen; small polar molecules like glycerol; and larger, nonpolar (hydrophobic) substances such as hydrocarbons. Slightly larger polar molecules, such as glucose, and charged ions of any size pass through the bilayer slowly.

The bilayer is relatively impermeable to ions, but cells must move ions, as well as amino acids, sugars, and other water-soluble molecules, across membranes. The permeability of membranes to those substances is due primarily to the activities of specialized membrane **transport proteins.** In the following sections, we will discuss the roles of two main types of membrane transport proteins: carrier proteins and channel proteins.

Some ions and molecules move through membranes by passive processes such as diffusion. Passive transport does not require the cell to expend metabolic energy. Many materials must be actively transported across the membrane. Active transport mechanisms include active transport, exocytosis, and endocytosis (discussed later in this chapter). These processes require a direct expenditure of metabolic energy by the cell.

Random motion of particles leads to diffusion

Some substances pass into or out of cells and move about within cells by simple **diffusion,** a physical process based on random motion. All atoms and molecules possess kinetic energy, or energy of motion, at temperatures above absolute zero (0°Kelvin, −273°Celsius, or −459.4°F). Matter may exist as a solid, liquid, or gas, depending on the freedom of movement of its constituent particles. The particles of a solid are closely packed, and the forces of attraction between them let them vibrate, but not move around. In a liquid the particles are farther apart; the intermolecular attractions are weaker, and the particles move about with considerable freedom. In a gas the particles are so far apart that intermolecular forces are negligible; molecular movement is restricted only by the walls of the container that encloses the gas. Atoms and molecules in liquids and gases move in a kind of "random walk," changing directions as they collide.

Although the movement of individual particles is undirected and unpredictable, we can nevertheless make predictions about the behavior of groups of particles. If the particles (atoms, ions, or molecules) are not evenly distributed, then at least two regions exist: one with a higher concentration of particles and the other with a lower concentration. Such a difference in the concentration of a substance from one place to another establishes a **concentration gradient.**

In diffusion, the random motion of particles results in their net movement "down" their own concentration gradient, from the region of higher concentration to the one of lower concentration. This does not mean individual particles are prohibited from moving "against" the gradient. However, because there are initially more particles in the region of high concentration, it logically follows that more particles move randomly from there into the low-concentration region than the reverse (Fig. 5-10).

Diffusion occurs rapidly over very short distances. The rate of diffusion is determined by the movement of the particles, which in turn is a function of their size and shape, their electrical charges, and the temperature. As the temperature rises, particles move faster and the rate of diffusion increases.

Particles of different substances in a mixture diffuse independently of each other. If particles are not added to or removed from the system, a state of **equilibrium,** a condition of no net change in the system, is ultimately reached. At equilibrium the particles are uniformly distributed.

In organisms, equilibrium is rarely attained. For example, carbon dioxide continually forms within a human cell as sugars and other molecules are metabolized during aerobic respiration. Carbon dioxide readily diffuses across the plasma membrane but then is rapidly removed by the blood. This limits the opportunity for the molecules to re-enter the cell, so a sharp concentration gradient of carbon dioxide molecules always exists across the plasma membrane.

Osmosis is diffusion of water across a selectively permeable membrane

Osmosis is a special kind of diffusion that involves the net movement of water (the principal *solvent* in biological systems) through a selectively permeable membrane from a region of higher concentration to a region of lower concentration. Water molecules pass freely in both directions, but, as in all types of diffusion, *net* movement is from the region where the water molecules are more concentrated to the region where they are less concentrated. Most *solute molecules* (for example, sugar and salt) cannot diffuse freely through the selectively permeable membranes of the cell.

The principles involved in osmosis can be illustrated using an apparatus called a U-tube (Fig. 5-11). The U-tube is divided into two sections by a selectively permeable membrane that allows solvent (water) molecules to pass freely but excludes solute molecules). A water/solute solution is placed on one side, and pure water is placed on the other. The side containing the solute has a lower effective concentration of water than the pure water side. This is because the solute particles, which are charged (ionic) or polar, interact with the partial electrical charges on the polar water molecules. Many of the water molecules are thus "bound up" and no longer free to diffuse across the membrane.

Because of the difference in effective water concentration, there is net movement of water molecules from the pure water side (with a high effective concentration of water) to the water/solute side (with a lower effective concentration of water). As a result, the fluid level drops on the pure water side and rises on the water/solute side. Because the solute molecules do not diffuse across the membrane, equilibrium is never attained. Net movement of water continues, and the fluid level rises on the side containing the solute. The weight of the rising column of fluid eventually exerts enough pressure to stop further changes in fluid levels, although water molecules continue to pass through the selectively permeable membrane in both directions.

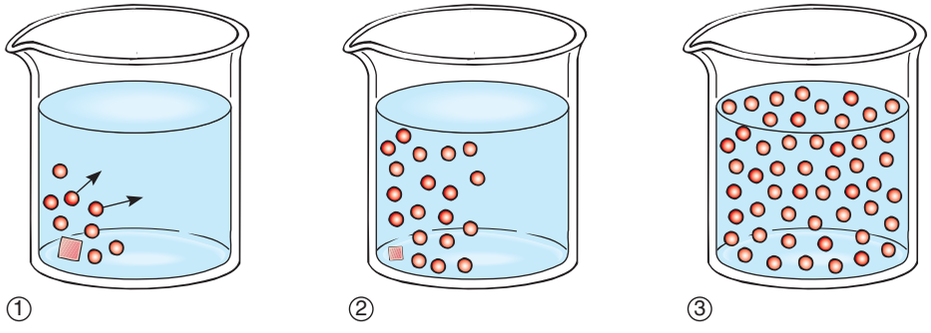


FIGURE **5-10** **Diffusion.**
① When a lump of sugar is dropped into a beaker of pure water, ② its molecules dissolve and begin to diffuse through the water. ③ Eventually the sugar molecules become distributed equally throughout the water.

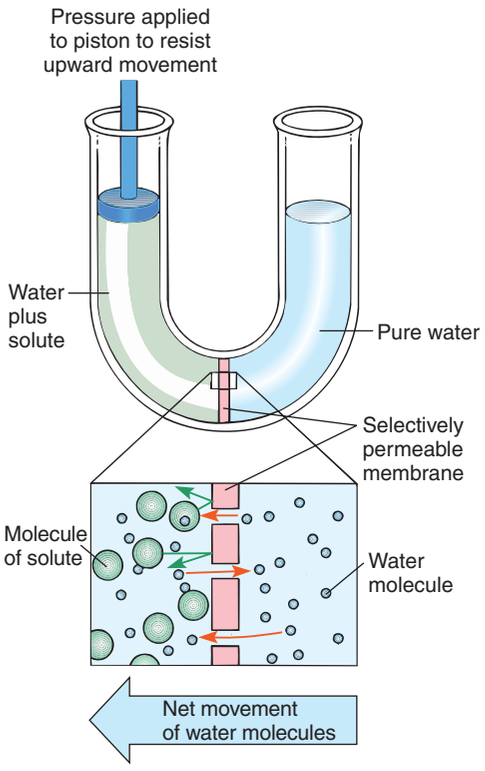

FIGURE **5-11** **Osmosis.**

The U-tube contains pure water on the right and water plus a solute on the left, separated by a selectively permeable membrane. Water molecules cross the membrane in both directions *(red arrows)*. Solute molecules cannot cross *(green arrows)*. The fluid level rises on the left and falls on the right because net movement of water *(blue arrow)* is to the left. The force that must be exerted by the piston to prevent the rise in fluid level is equal to the osmotic pressure of the solution.

We define the **osmotic pressure** of a solution as the pressure that must be exerted on the side of a selectively permeable membrane containing the higher concentration of solute, to prevent the diffusion of water (by osmosis) from the side containing the lower solute concentration. In the U-tube example, you could measure the osmotic pressure by inserting a piston on the water/solute side of the tube and measuring how much pressure must be exerted by the piston to prevent the rise of fluid on that side of the tube. A solution with a high solute concentration has a low effective water concentration and a high osmotic pressure; conversely, a solution with a low solute concentration has a high effective water concentration and a low osmotic pressure.

Two solutions may be isotonic, or one may be hypertonic and the other hypotonic

Salts, sugars, and other substances are dissolved in the fluid compartment of every cell. These solutes give the cytosol a specific osmotic pressure. Table 5-1 summarizes the movement of water into and out of a solution (or cell) depending on relative solute concentrations. When a cell is placed in a fluid with exactly the same osmotic pressure, no net movement of water molecules occurs, either into or out of the cell. The cell neither swells nor shrinks. Such a fluid is **isotonic,** of equal solute concentration, to the fluid within the cell. Normally, your blood plasma (the fluid component of blood) and all your other body fluids are isotonic to your cells; they contain a concentration of water equal to that in the cells. A solution of 0.9% sodium chloride (sometimes called *physiological saline*) is isotonic to the cells of humans and other mammals. Human red blood cells placed in 0.9% sodium chloride neither shrink nor swell (Fig. 5-12a).

If the surrounding fluid has a concentration of dissolved substances greater than the concentration within the cell, it has a higher osmotic pressure than the cell and is said to be **hypertonic** to the cell. Because a hypertonic solution has a lower effective water concentration, a cell placed in such a solution shrinks as it loses water by osmosis. Human red blood cells placed in a solution of 1.3% sodium chloride shrivel and die (Fig. 5-12b). If the surrounding fluid contains a lower concentration of dissolved materials than does the cell, it has a lower osmotic pressure and is said to be **hypotonic** to the cell; water then enters the cell and causes it to swell. Red blood cells placed in a solution of 0.6% sodium chloride gain water, swell (Fig. 5-12c), and may eventually burst. Many cells that normally live in hypotonic environments have adaptations to prevent excessive water accumulation. For example, certain protists such as *Paramecium* have contractile vacuoles that expel excess water (see Fig. 24-7).

Turgor pressure is the internal hydrostatic pressure usually present in walled cells

The relatively rigid cell walls of plant cells, algae, bacteria, and fungi enable these cells to withstand, without bursting, an external medium that is very dilute, containing only a very low concentration of solutes. Because of the substances dissolved in the cytoplasm, the cells are hypertonic to the outside medium (conversely, the outside medium is hypotonic to the cytoplasm). Water moves into the cells by osmosis, filling their central vac-

TABLE **5-1** **Osmotic Terminology**

Solute Concentration In Solution A	Solute Concentration in Solution B	Tonicity	Direction of Net Movement of Water
Greater	Less	A hypertonic to B; B hypotonic to A	B to A
Less	Greater	B hypertonic to A; A hypotonic to B	A to B
Equal	Equal	A and B are isotonic to each other	No net movement

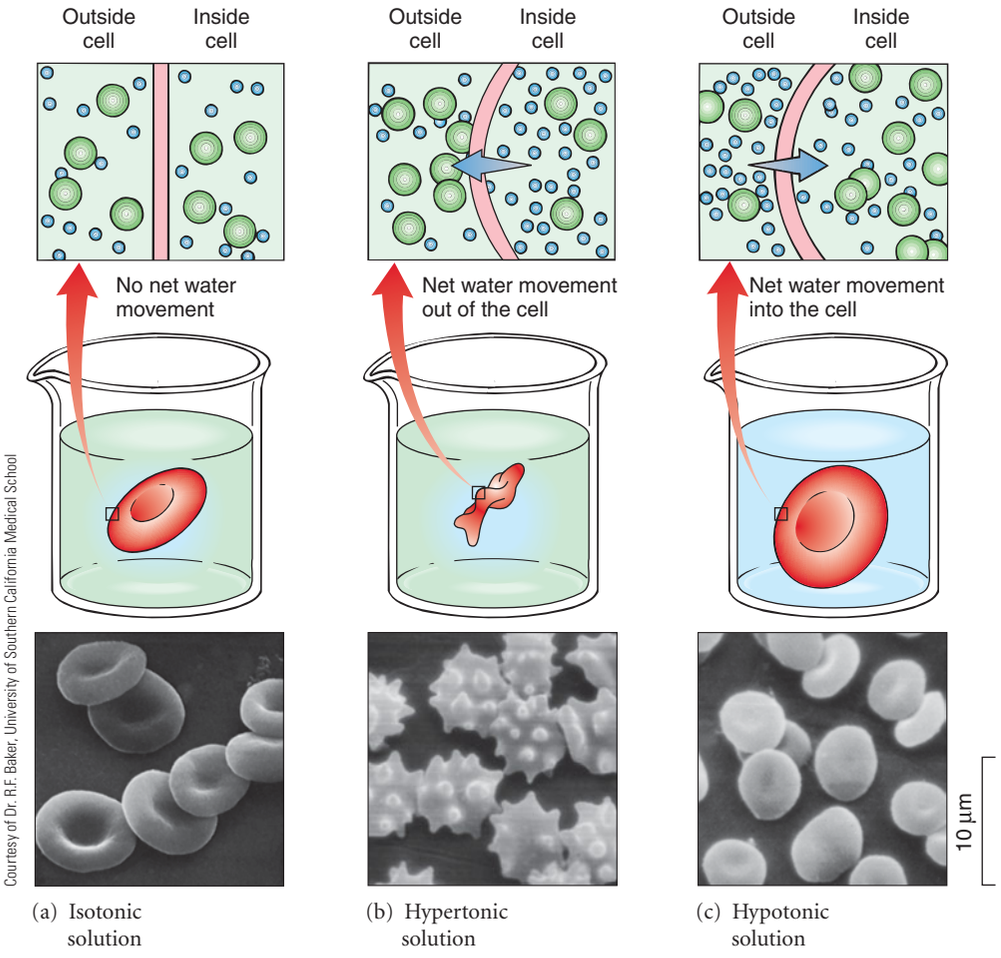

FIGURE **5-12**

The responses of animal cells to osmotic pressure differences.

(a) When a cell is placed in an isotonic solution, water molecules pass in and out of the cell, but the net movement is zero. **(b)** When a cell is placed in a hypertonic solution, there is a net movement of water out of the cell *(arrow)*, and the cell becomes dehydrated and shrunken, and may die. **(c)** When a cell is placed in a hypotonic solution, the net movement of water molecules into the cell *(arrow)* causes the cell to swell or even burst.

uoles and distending the cells. The cells swell, building up **turgor pressure** against the rigid cell walls (Fig. 5-13a). The cell walls stretch only slightly, and a steady state is reached when their resistance to stretching prevents any further increase in cell size and thereby halts the *net movement* of water molecules into the cells. (Of course, molecules continue to move back and forth across the plasma membrane.) Turgor pressure in the cells is an important factor in supporting the body of nonwoody plants.

If a cell that has a cell wall is placed in a hypertonic medium, it loses water to its surroundings. Its contents shrink, and the plasma membrane separates from the cell wall, a process known as **plasmolysis** (Fig. 5-13b and c). Plasmolysis occurs in plants when the soil or water around them contains high concentrations of salts or fertilizers. It also explains why lettuce becomes limp in a salty salad dressing, and a picked flower wilts from lack of water.

Channel proteins and carrier proteins affect membrane permeability

Cell biologists have identified transmembrane proteins called **aquaporins** that function as gated water channels. These **channel proteins** facilitate the rapid transport of water through the plasma membrane in response to osmotic gradients. Aquaporins have been identified in a wide range of cells from bacteria to humans. In some cells, such as those lining the kidney tubules of mammals, aquaporins respond to specific signals from hormones.

Ions play important roles in cell signaling and many other physiological processes. By controlling the influx and efflux of ions, the cell directly or indirectly regulates many metabolic activities. For example, changes in the cytoplasmic concentration of calcium ions trigger changes in a number of cell processes, including muscle contraction (see Chapter 38). Because of their electric charges, ions cannot cross a lipid bilayer by simple diffusion. Certain integral membrane proteins form channels through which specific ions pass. Some ions are transported through the membrane by integral membrane proteins known as **carrier proteins.**

Cells must continually acquire essential polar nutrient molecules, such as glucose and amino acids. The lipid bilayer of the plasma membrane is relatively impermeable to most large polar molecules. This is advantageous to cells for a number of reasons. Most of the compounds required in metabolism are polar, and the impermeability of the plasma membrane prevents their loss by diffusion.

Systems of carrier proteins that transport ions and nutrients through membranes apparently evolved early in the origin of cells. Transfer of solutes by proteins located within the membrane is called **carrier-mediated transport.** The two forms of carrier-mediated transport—facilitated diffusion and carrier-mediated active transport—differ in their capabilities and energy sources.

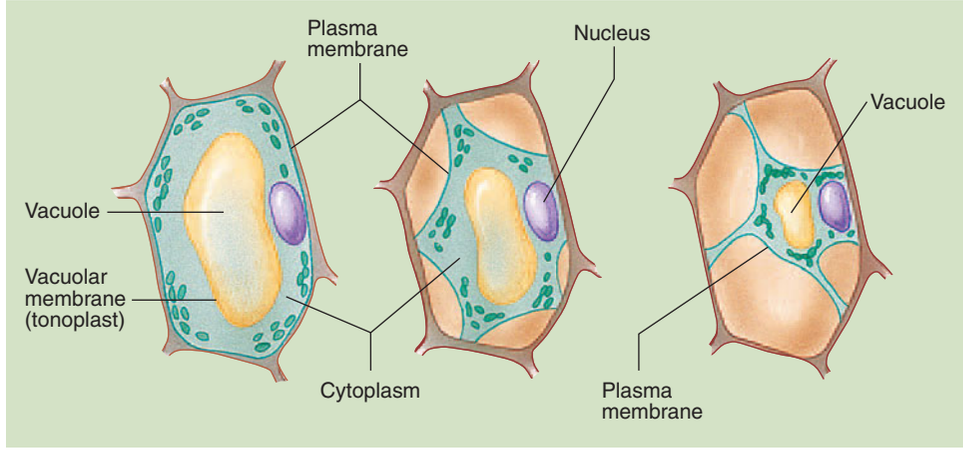
Facilitated diffusion occurs down a concentration gradient

In all processes in which substances move across membranes by passive diffusion, the net transfer of those molecules from one side to the other occurs as a result of a concentration gradient (see Fig. 6-4). If the membrane is permeable to a substance, there is net movement from the side of the membrane where it is more highly concentrated to the side where it is less concentrated. Such a gradient across the membrane is actually

FIGURE **5-13** **Turgor pressure and plasmolysis.**

(a) In hypotonic surroundings, the vacuole of a plant cell fills, but the rigid cell walls prevent the cell from expanding. The cells of this healthy begonia plant are turgid. **(b and c)** When the begonia plant is exposed to a hypertonic solution, its cells become plasmolyzed as they lose water. The plant wilts and eventually dies.

Dennis Drenner



(a) (b) (c)

a form of stored energy. A concentration gradient occurs as a result of many different processes that take place in cells. The stored energy of the concentration gradient is released when molecules move from a region of high concentration to one of low concentration; movement down a concentration gradient is therefore spontaneous. (These types of energy and spontaneous processes are discussed in greater detail in Chapter 6.)

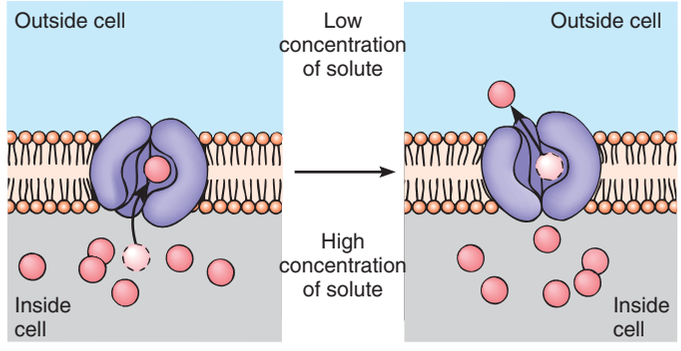
In the type of transport known as **facilitated diffusion,** the membrane may be made permeable to a solute, such as an ion or a polar molecule, by a specific carrier protein (Fig. 5-14). For example, *glucose permease* is a transmembrane carrier protein that transports glucose into red blood cells. These cells keep the internal concentration of glucose low by immediately adding a phosphate group to entering glucose molecules, converting them to highly charged glucose phosphates that cannot pass back through the membrane. Because glucose phosphate is a different molecule, it does not contribute to the glucose concentration gradient. Thus a steep concentration gradient for glucose is continually maintained, and glucose rapidly diffuses into the cell, only to be immediately changed to the phosphorylated form.

Researchers have studied facilitated diffusion for glucose using **liposomes,** artificial vesicles surrounded by phospholipid bilayers. The phospholipid membrane of a liposome does not allow the passage of glucose unless glucose permease is present in the liposome membrane. Glucose permease and similar carrier proteins temporarily bind to the molecules they transport. This mechanism appears to be similar to the way an enzyme binds with its substrate, the molecule on which it acts (see Chapter 6). In addition, as in enzyme action, binding apparently changes the shape of the carrier protein. This change allows the glucose molecule to be released on the inside of the cell. According to this model, when the glucose is released into the cytoplasm, the carrier protein reverts to its original shape and is available to bind another glucose molecule on the outside of the cell.

ACTIVE FIGURE **5-14** **Facilitated diffusion.**

A carrier protein in the membrane binds a solute particle. The protein shape changes, opening a channel through the membrane. A specific solute can be transported from the inside of the cell to the outside or from the outside to the inside, but net movement is always from a region of higher solute concentration to a region of lower concentration. Facilitated diffusion requires the potential energy of a concentration gradient.

BiologyNow™ Learn more about **membrane transport** by clicking on this figure on your BiologyNow CD-ROM.



Another similarity to enzyme action is that carrier proteins become saturated when the transported molecule is at high concentration. This may be because a finite number of carrier proteins are available and they operate at a defined maximum rate. When the concentration of solute molecules to be transported reaches a certain level, all the carrier proteins are working at their maximum rate.

Some carrier-mediated active transport systems "pump" substances against their concentration gradients

Although adequate amounts of some substances move across cell membranes by diffusion, a cell often needs to transport solutes against a concentration gradient. The cell requires many substances in concentrations higher than those outside the cell. **Carrier-mediated active transport** mechanisms move these molecules across cell membranes. Because this active transport requires that particles be "pumped" from a region of low concentration to a region of high concentration—*against a concentration gradient*—transport must be coupled to an energy source such as ATP.

One of the most striking examples of an active transport mechanism is the **sodium-potassium pump** found in virtually all animal cells (Fig. 5-15). The pump is a group of specific carrier proteins in the plasma membrane that uses energy in the form of ATP to exchange sodium ions on the inside of the cell for potassium ions on the outside of the cell. The exchange is unequal, so that usually only two potassium ions are imported for every three sodium ions exported. Because these particular concentration gradients involve ions, an electrical potential (separation of electrical charges) is generated across the membrane, and we say that the membrane is *polarized.*

Both sodium and potassium ions are positively charged, but because there are fewer potassium ions inside relative to the sodium ions outside, the inside of the cell is negatively charged relative to the outside. The unequal distribution of ions establishes an **electrical gradient** that drives ions across the plasma membrane. Sodium-potassium pumps help maintain a charge separation across the plasma membrane. The separation of charges across a plasma membrane is called a **membrane potential.** Because there is both an electrical charge difference and a concentration difference on the two sides of the membrane, the gradient is called an **electrochemical gradient.** Such gradients store energy (like water stored behind a dam) that is used to drive other transport systems. So important is the electrochemical gradient produced by these pumps that some cells (such as nerve cells) expend 70% of their total energy just to power this one transport system.

Sodium-potassium pumps (as well as all other ATP-driven pumps) are transmembrane proteins that extend entirely through the membrane. By undergoing a series of conformational changes (changes in shape), the pumps exchange sodium for potassium across the plasma membrane. Unlike facilitated diffusion, at least one of the conformational changes in the pump cycle requires energy, which is provided by ATP. The shape of the pump protein changes as a phosphate group from ATP first binds to it and is subsequently removed later in the pump cycle.

The use of electrochemical potentials for energy storage is not confined to the plasma membranes of animal cells. Plant and fungal cells use ATP-driven plasma membrane pumps to transfer protons from the cytoplasm of their cells to the outside. Removal of positively charged protons from the cytoplasm of these cells results in a large difference in the concentration of protons, such that the outside of the cells is relatively positively charged and the inside of the plasma membrane is relatively negatively charged. The energy stored in these electrochemical gradients can be used to do many kinds of cell work.

Other proton pumps are used in "reverse" to synthesize ATP. Bacteria, mitochondria, and chloroplasts use energy from food or sunlight to establish proton concentration gradients (see Chapters 7 and 8). When the protons diffuse through the proton carriers from a region of high proton concentration to one of low concentration, ATP is synthesized. These electrochemical gradients form the basis for the major energy conversion systems in virtually all cells.

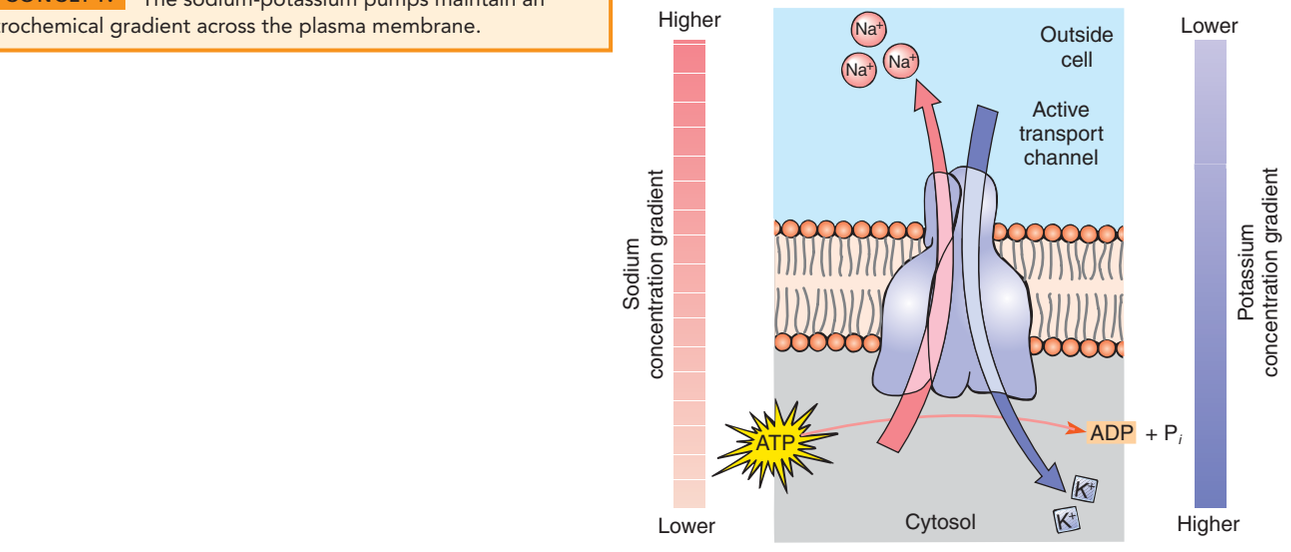
Ion pumps have other important roles. For example, they are instrumental in the ability of an animal cell to equalize the osmotic pressures of its cytoplasm and its external environment. If an animal cell does not control its internal osmotic pressure, its contents become hypertonic relative to the exterior. Water will enter the cell by osmosis, causing it to swell and possibly burst (see Fig. 5-12c). By controlling the ion distribution across the membrane, the cell indirectly controls the movement of water, because when ions are pumped out of the cell, water leaves by osmosis.

Linked cotransport systems indirectly provide energy for active transport

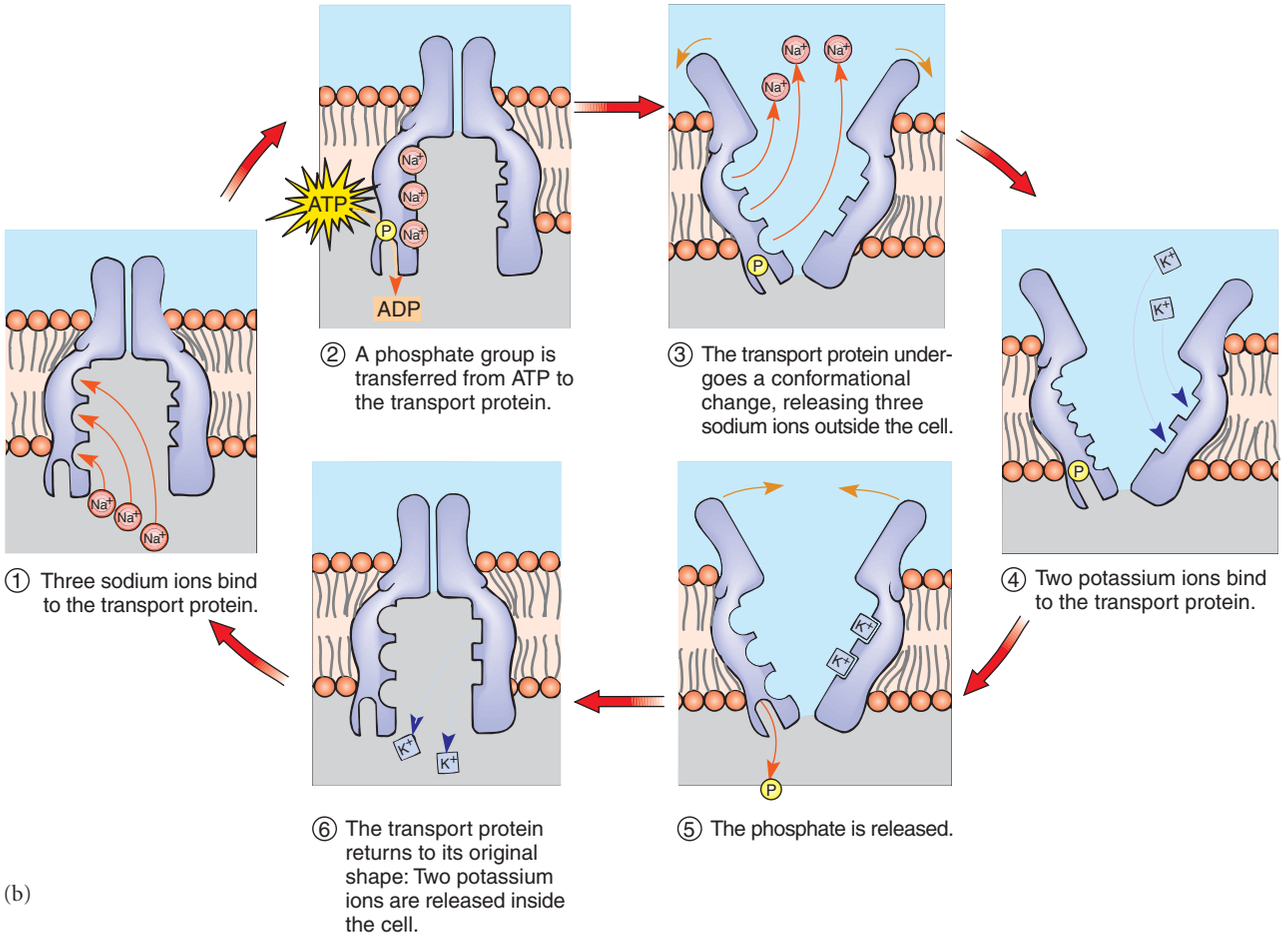
The electrochemical concentration gradients generated by the sodium-potassium pump (and other pumps) provide sufficient energy to power the active transport of other essential substances. In these systems, a transport protein **cotransports** the required molecules *against* their concentration gradient, while sodium, potassium, or hydrogen ions move *down* their gradient. Energy from ATP may be used indirectly in this process. ATP produces the ion gradient; the energy of this gradient then drives the active transport of a required substance against its gradient.

In some cells, more than one system may work to transport a given substance. For example, the transport of glucose from the intestine to the blood occurs through a thin sheet of epithelial cells that line the intestine. The surface that is exposed to the intestine has many **microvilli** (sing., *microvillus*), finger-like extensions that effectively increase the surface area of the membrane available for absorption (see Fig. 45-10c). The glucose transport protein on that region of the cell surface is part of an active transport system for glucose that is "driven" by the cotransport of sodium. The sodium concentration inside the cell is kept low by an ATP-requiring sodium-potassium pump that transports sodium out of the cell and into the blood. Because of its high concentration inside the cell (relative to the blood), glucose is transported to the blood by facilitated diffusion.

KEY CONCEPT: The sodium-potassium pumps maintain an electrochemical gradient across the plasma membrane.



(a)



(b)

What are the signals that target each transport protein to its appropriate region in the plasma membrane? Some cell biologists are focusing their research on understanding mechanisms such as those that enable the cell to place different transport proteins in separate regions of the same plasma membrane.

FIGURE **5-15** **The sodium-potassium pump.**

(a) The sodium-potassium pump is an active transport system that requires energy from ATP. Each complete pumping cycle uses one molecule of ATP; three sodium ions are exported, and two potassium ions are imported. **(b)** How the sodium-potassium pump works.

Facilitated diffusion is powered by a concentration gradient; active transport requires another energy source

It is a common misconception that diffusion, whether simple or facilitated, is somehow "free of cost" and that only active transport mechanisms require energy. Because diffusion always involves the net movement of a substance down its concentration gradient, we say that the concentration gradient "powers" the process. However, energy is required to do the work of establishing and maintaining the gradient. Think back to the example of facilitated diffusion of glucose. The cell maintains a steep concentration gradient (high outside, low inside) by phosphorylating the glucose molecules once they enter the cell. One ATP molecule is spent for every glucose molecule phosphorylated, not to mention such additional costs as the energy required to make the enzymes that carry out the reaction.

An active transport system works against a concentration gradient, pumping materials from a region of low concentration to a region of high concentration. The energy stored in the concentration gradient is not only unavailable to the system but actually works against it. For this reason, the cell needs some other source of energy. As we have seen, in many cases cells use ATP energy directly. In a cotransport system, a concentration gradient provides energy for some other substance (such as an ion), but the cell may indirectly require ATP to power the pump that produces the ion gradient.

To summarize, both diffusion and active transport require energy. The energy for diffusion is provided by a concentration gradient for the substance being transported. Active transport requires some other, usually more direct, expenditure of metabolic energy.

The patch clamp technique has revolutionized the study of ion channels

PROCESS OF SCIENCE

Because ions cannot cross a lipid bilayer by simple diffusion, every membrane of every cell contains numerous *ion channels.* The movement of ions across a membrane can result in a charge difference, or electrical gradient. If the cell is large enough, this charge difference (usually expressed in millivolts, mV) can be measured by using two microelectrodes connected to an extremely sensitive oscilloscope or voltmeter (Fig. 5-16a). One of the microelectrodes is inserted into the cell, and the other is placed just outside the plasma membrane. Although valuable, these techniques have serious limitations, because they cannot be used on smaller cells and do not provide information on the function of individual ion channels.

In the mid-1970s, Erwin Neher and Bert Sakmann, both of the Max Planck Institute in Germany, developed a method, known as the **patch clamp technique,** that enables researchers to study single ion channels of very small cells. In this technique, the tip of a micropipette is tightly sealed to a patch of membrane so small that it generally contains only a single ion channel (Fig. 5-16b). The flow of ions through the channel is measured using an extremely sensitive recording device.

Using this patch clamp technique, cell biologists study the action of a single ion channel over time. They have found that the current flow is intermittent and corresponds to the opening and closing of the ion channel. The permeability of the channel affects the magnitude of the current. The patch clamp technique has been modified in many ways and has been

KEY CONCEPT: Using the patch clamp technique, researchers can study single ion channels in cell membranes.

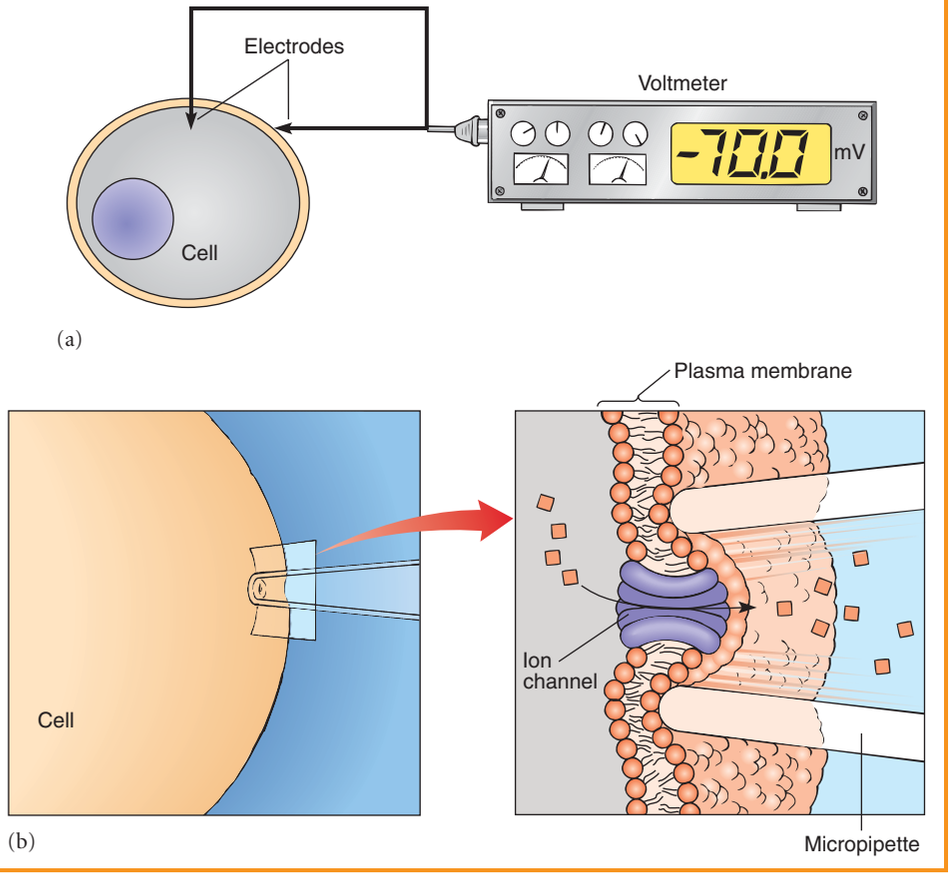


FIGURE **5-16** **The patch clamp technique.**

(a) Microelectrodes and a voltmeter measure the difference in electrical charge across a membrane. **(b)** A micropipette forms a tight seal with a patch of plasma membrane. The membrane is pulled away from the rest of the cell, enabling researchers to study the flow of ions through a single ion channel.

applied to studies of the roles of ion channels in a wide range of cell processes in both plants and animals. For example, studies of single ion channels enabled researchers to demonstrate that the genetic disease cystic fibrosis (see Chapter 15) is caused by a defect in a specific type of chloride ion channel. Because of the far-reaching implications of their work, Neher and Sakmann were awarded the 1991 Nobel Prize in Physiology or medicine.

In exocytosis and endocytosis, vesicles or vacuoles transport large particles

In both simple and facilitated diffusion, and in carrier-mediated active transport, individual molecules and ions pass through the plasma membrane. Some larger materials, such as large molecules, particles of food, and even small cells, are also moved into or out of cells. Such work requires cells to expend energy directly, making it a form of active transport.

In **exocytosis,** a cell ejects waste products, or specific products of secretion such as hormones, by the fusion of a vesicle with the plasma membrane (Fig. 5-17). Exocytosis results in the incorporation of the membrane of the secretory vesicle into the plasma membrane, as the contents of the vesicle are released from the cell. This is also the primary mechanism by which plasma membranes grow larger.

In **endocytosis,** materials are taken into the cell. Several types of endocytotic mechanisms operate in biological systems, including phagocytosis, pinocytosis, and receptor-mediated endocytosis. In **phagocytosis** (literally, "cell eating"), the cell ingests large solid particles such as bacteria and food (Fig. 5-18). Phagocytosis is used by certain protists and by several types of vertebrate white blood cells to ingest particles, some of which are as large as an entire bacterium. During ingestion, folds of the plasma membrane enclose the particle, which has bound to the surface of the cell, forming a large membranous sac, or vacuole. When the membrane has encircled the particle, it fuses at the point of contact. The vacuole then fuses with lysosomes, and the ingested material is degraded.

In the form of endocytosis known as **pinocytosis** ("cell drinking"), the cell takes in dissolved materials (Fig. 5-19). Tiny droplets of fluid are trapped by folds in the plasma membrane, which pinch off into the cytosol as tiny vesicles. The liquid contents of these vesicles are then slowly transferred into the cytosol; the vesicles become progressively smaller.

In a third type of endocytosis, **receptor-mediated endocytosis,** specific molecules combine with receptor proteins embedded in the plasma membrane. Cells take up cholesterol from the blood by this process. Cholesterol is transported in the blood as part of particles called *low-density lipoproteins (LDLs)*. Cells use cholesterol as a component of cell membranes and as a precursor of steroid hormones. Much of the receptor-mediated endocytosis pathway was detailed through studies by Michael Brown and Joseph Goldstein on the LDL receptor. In 1985, these researchers, both of the University of Texas Health Sci-

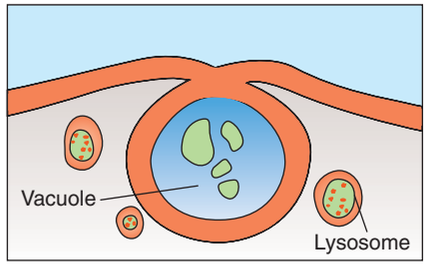
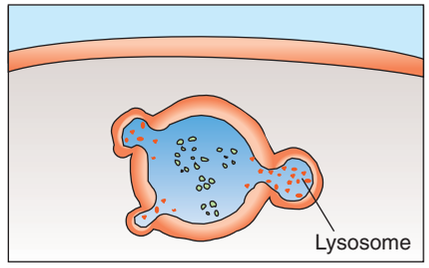
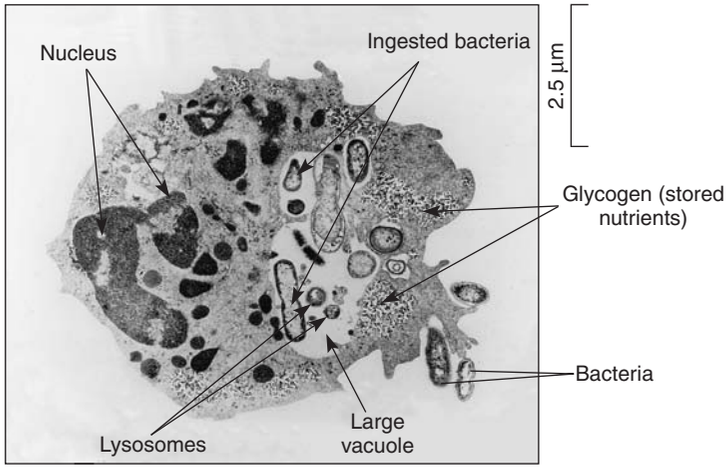
① Folds of the plasma membrane surround the particle to be ingested, forming a small vacuole around it.



② The vacuole then pinches off inside the cell.



③ Lysosomes may fuse with the vacuole and pour their potent enzymes onto the ingested material.



D.W. Fawcett

FIGURE 5-18 Phagocytosis.

In this type of endocytosis, a cell ingests relatively large solid particles. The white blood cell (a neutrophil) shown in the TEM is phagocytizing bacteria. The vacuoles contain bacteria that have already been ingested, whereas other bacteria are still outside the cell. Lysosomes in the cytosol contain digestive enzymes.

ence Center, were awarded the Nobel Prize in Physiology or medicine for their pioneering work. Their findings have important medical implications, because cholesterol that remains in the blood instead of entering the cells can become deposited in the artery walls, increasing the risk of cardiovascular disease.

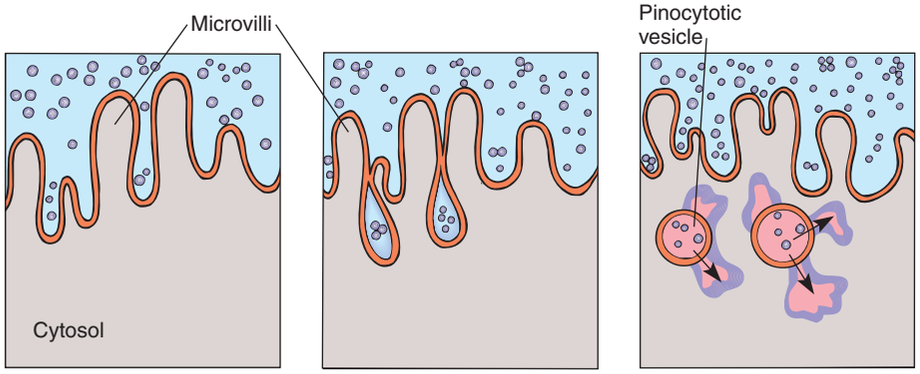
When a cell needs cholesterol, it makes LDL receptors. The receptors are concentrated in *coated pits,* depressed regions on the cytoplasmic surface of the plasma membrane. Each pit is coated by a layer of a protein, called *clathrin,* found just below the plasma membrane. A molecule that binds specifically to a receptor is called a **ligand.** In this case, LDL is the ligand. After the LDL binds with a receptor, the coated pit forms a *coated vesicle* by endocytosis.

Figure 5-20 shows the uptake of an LDL particle. Seconds after the vesicle moves into the cytoplasm, the coating dissociates from it, leaving an uncoated vesicle. The vesicles deliver their contents to compartments called *endosomes.* LDL separates from its receptor and is transferred to a lysosome. There, the LDL is broken down and cholesterol is released into the cytosol for use by the cell. The LDL receptors are transported to the plasma membrane, where they are recycled. A simplified summary of receptor-mediated endocytosis follows:

Ligand binds to receptors in coated pits of plasma membrane ⟶ coated vesicle forms by endocytosis ⟶ coating detaches from vesicle ⟶ contents transferred to endosome ⟶ ligand separates from its receptor:

- ⟶ receptors are transported to plasma membrane and recycled
- ⟶ endosome fuses with lysosome ⟶ contents are digested and released into the cytosol

FIGURE 5-19 Pinocytosis or "cell-drinking."



①Tiny droplets of fluid are trapped by folds of the plasma membrane.

②These pinch off into the cytosol as small fluid-filled vesicles.

③The contents of these vesicles are then slowly transferred to the cytosol.

The recycling of LDL receptors to the plasma membrane through vesicles illustrates a problem common to all cells that use endocytotic and exocytotic mechanisms. A type of phagocytic cell known as a *macrophage,* for example, ingests the equivalent of its entire plasma membrane in about 30 minutes, requiring an equivalent amount of recycling or new membrane synthesis for the cell to maintain its surface area. In cells that are constantly involved in secretion, an equivalent amount of membrane must be returned to the interior of the cell for each vesicle that fuses with the plasma membrane; if it is not,

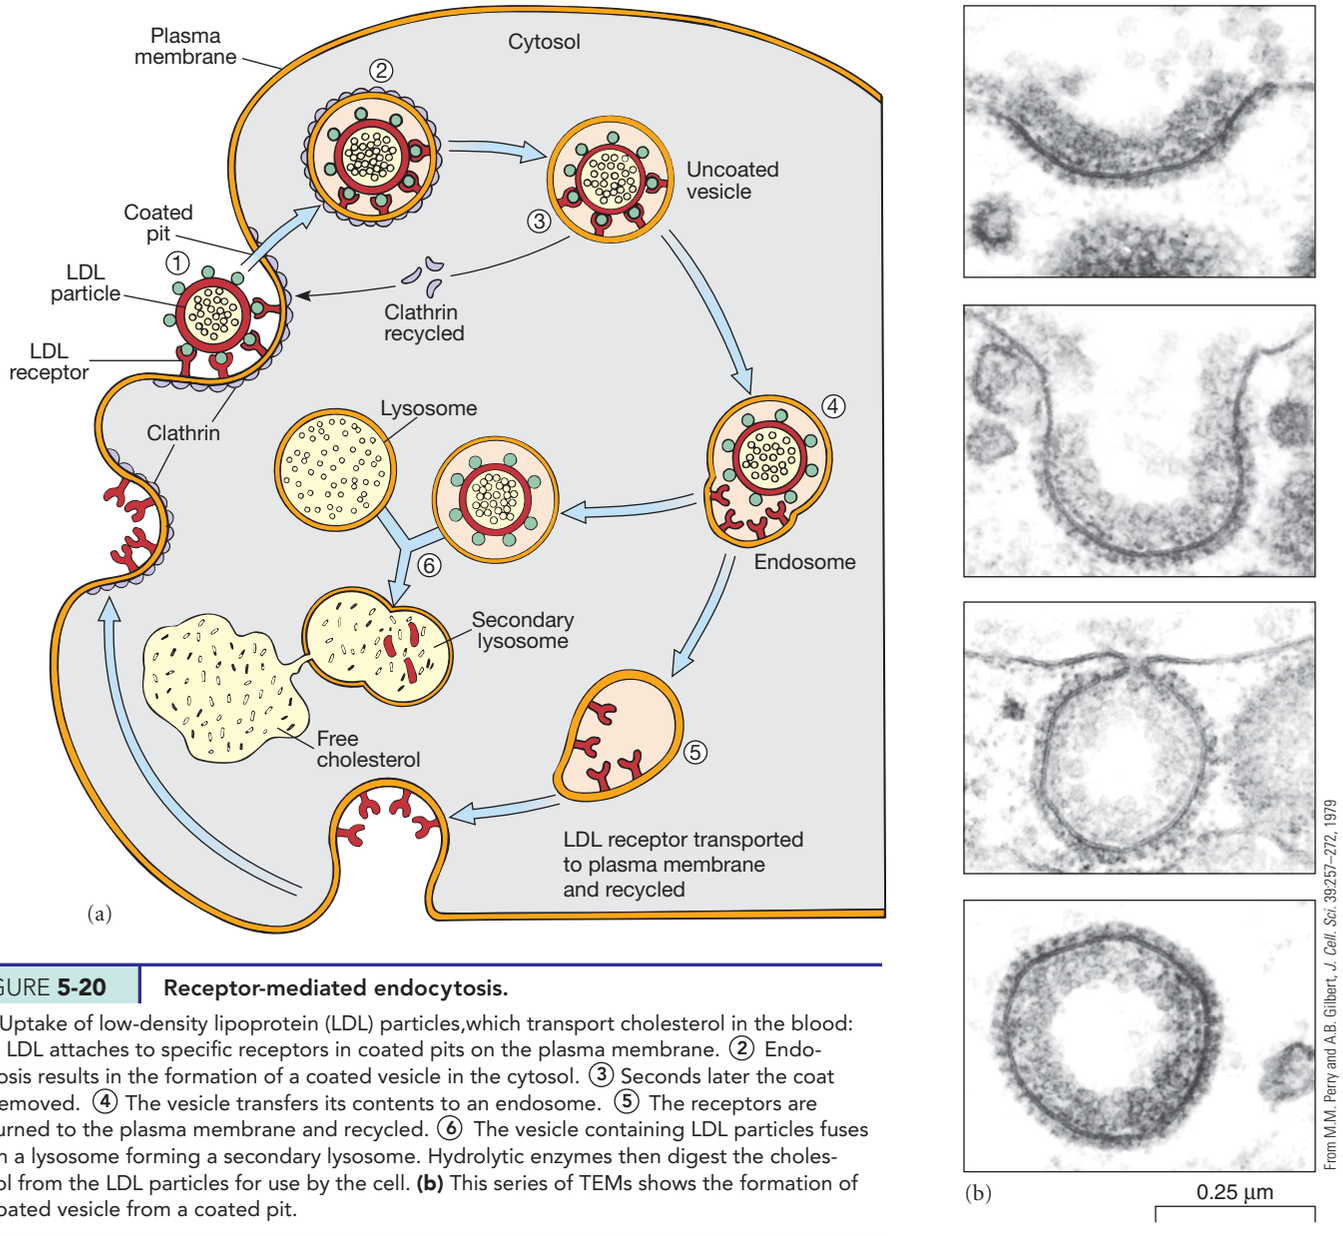


FIGURE **5-20** **Receptor-mediated endocytosis.**

(a) Uptake of low-density lipoprotein (LDL) particles,which transport cholesterol in the blood: ① LDL attaches to specific receptors in coated pits on the plasma membrane. ② Endocytosis results in the formation of a coated vesicle in the cytosol. ③ Seconds later the coat is removed. ④ The vesicle transfers its contents to an endosome. ⑤ The receptors are returned to the plasma membrane and recycled. ⑥ The vesicle containing LDL particles fuses with a lysosome forming a secondary lysosome. Hydrolytic enzymes then digest the cholesterol from the LDL particles for use by the cell. **(b)** This series of TEMs shows the formation of a coated vesicle from a coated pit.

the cell surface will keep expanding even though the growth of the cell itself may be arrested.

Review

- In what direction do particles move along their concentration gradient? Would your answers be different for facilitated diffusion compared with simple diffusion?
- What is the immediate source of energy for simple diffusion? For facilitated diffusion? For active transport?
- What would happen if a plant cell were placed in a relatively (a) isotonic, (b) hypertonic, or (c) hypotonic environment? How would you modify your predictions for an animal cell?
- How are exocytosis and endocytosis similar?
- How are the processes of phagocytosis and pinocytosis different?

CELL SIGNALING

Learning Objective

9 Describe the generalized process of cell signaling.
10 Explain how an extra cellular signal is converted to an intracellular signal in signal transduction.

The term **cell signaling** refers to the mechanisms by which cells communicate with one another. Most commonly, cells communicate with chemical signals. Cells signal one another by secreting certain molecules, or a signaling molecule on one cell combines with a receptor on another cell. Unicellular bacteria, protists, and fungi communicate with other members of their species by secreting chemical compounds. For example, when food is scarce, the amoeba-like cellular slime mold *Dictyostelium* secretes **cyclic adenosine monophosphate (cAMP)** (see Fig. 3-25). This chemical compound diffuses through the cell's

environment and induces nearby slime molds to come together and form a multicellular slug-shaped colony (see Fig. 24-24). Yeast cells identify cells of compatible mating types by chemical communication. In 2003, Marc Spehr of Ruhr University Bochum in Germany and his colleagues reported that human sperm have receptors that respond to chemical signals that guide the sperm to the egg.

About a billion years ago, when cells began to associate to form multicellular organisms, elaborate systems of cell signaling evolved. The development and functioning of complex organisms require precise internal communication, as well as effective responses to the outside environment. In plants and animals, hormones serve as important chemical signals between various cells and organs. Animals have evolved nervous systems in which neurons transmit information electrically and chemically.

The process of cell signaling includes

- Synthesis and release of the signaling molecules
- Transport to target cells
- Reception of the information by target cells
- Signal transduction
- Response by the cell
- Termination of signaling

Signaling molecules may be neurotransmitters (produced by nerve cells), hormones, or other regulatory molecules. They may be synthesized by neighboring cells or by specialized tissues some distance away from the target cells. These molecules reach target cells by diffusion or via the circulatory system. In some cases, neurons transport signaling molecules from one location to another. Reception typically depends on receptor proteins in the plasma membrane of target cells. The signaling molecules are ligands that bind with the receptors.

Many regulatory molecules transmit information to the cell interior without physically crossing the plasma membrane. These signal molecules rely on systems of interacting integral membrane proteins to transmit the information. **Signal transduction** is the process in which cells convert and amplify an extracellular signal into an intracellular signal. Each component of a signal transduction system acts as a relay "switch," which can be in an activated ("on") state or an inactive ("off") state.

The first component in a signal transduction system is typically the receptor, which may be a transmembrane protein with a domain (a structural and functional component of a protein) exposed on the extracellular surface. A receptor generally has at least three domains. The external domain is a docking site for a signaling molecule. A second domain extends through the plasma membrane, and a third domain is a "tail" that extends into the cytoplasm.

In a typical signaling pathway, when the ligand binds with the receptor, it activates it by changing the shape of the receptor tail that extends into the cytoplasm. The activated receptor changes the conformation of a second protein, which then becomes activated. The signal may be relayed through a sequence of proteins (Fig. 5-21). Ultimately these interactions result in the activation of a specific enzyme bound to the membrane. That enzyme may itself catalyze the production of large numbers of intracellular signaling molecules, or it may activate intracellular enzymes. In this way the original signal received by the receptor protein is amplified many times, and the metabolism of the cell may be profoundly altered.

The ligand that acts as a signaling molecule is sometimes referred to as the **first messenger.** Some ligand-receptor complexes bind to and activate specific integral membrane proteins, referred to as **G proteins.** In 1994, Alfred G. Gilman, of the University of Texas, and Martin Rodbell, of the National Institute of Environmental Health Sciences, were awarded the Nobel Prize for Physiology or medicine for their research on G proteins. These proteins are so named because the active form is bound to **guanosine triphosphate (GTP),** a molecule similar to ATP but containing the base guanine instead of adenine. G proteins catalyze the hydrolysis of GTP to guanosine diphosphate (GDP), a process that releases energy.

In a complex sequence of events, a G protein relays the message from the receptor to an enzyme that catalyzes the production of a **second messenger,** which is an intracellular signal. Often the second messenger is cyclic AMP. The enzyme adenylyl cyclase, which is bound to the plasma membrane, catalyzes the formation of cyclic AMP from ATP. Typically, the second messenger activates **protein kinases,** enzymes that activate specific proteins by transferring phosphate groups to them from ATP. This sequence of reactions, beginning with the binding of the signaling molecule to the receptor, leads to a change in some cell function.

G proteins are involved in a number of important signal transductions, including the action of many hormones (see Chapter 47). Some G proteins regulate channels that allow ions to cross the plasma membrane, and others play important roles in the senses of sight, smell, and taste (see Chapter 41).

Ras proteins, a group of GTP-binding proteins that function somewhat like G proteins, are thought to be important in signal transduction necessary for many cell activities. Fibroblasts (a type of connective tissue cell) require the presence of two *growth factors,* epidermal growth factor and platelet-derived growth factor, for DNA synthesis. Investigators conducted an experiment in which they injected fibroblasts with antibodies that bind to Ras proteins thereby inactivating them. These fibroblasts with inactivated Ras proteins no longer synthesized DNA in response to growth factors. Data from this and similar experiments led to the conclusion that Ras proteins are important in signal transduction involving growth factors.

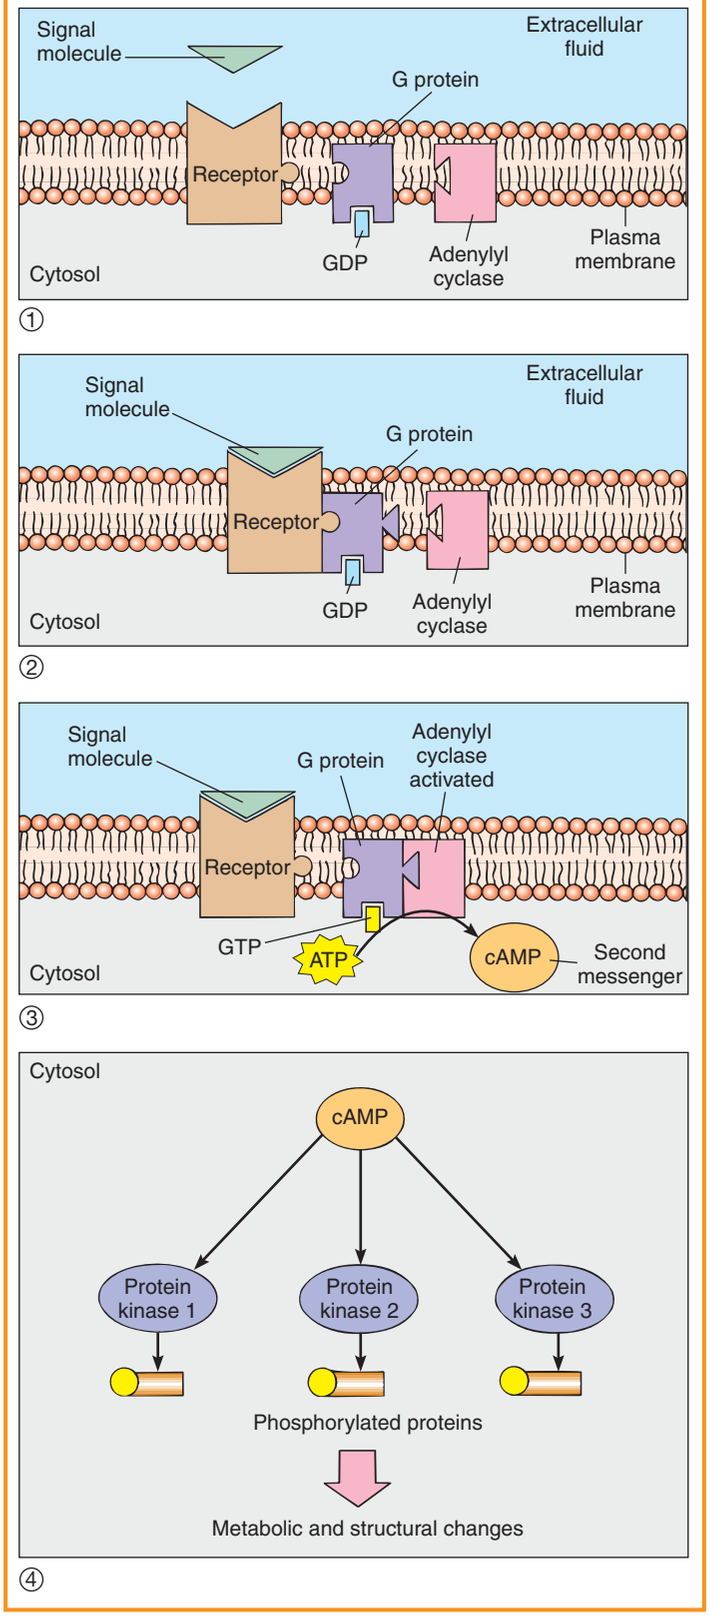
Cell biologists have demonstrated that when certain ligands bind to integrins (transmembrane proteins that connect the cell to the extracellular matrix) in the plasma membrane, specific signal transduction pathways are activated. Growth factors also turn on signaling pathways. Interestingly, growth factors and certain molecules of the extracellular matrix may modulate each other's messages. Integrins also respond to information received from inside the cell. This inside-out signaling affects how selective integrins are with respect to the molecules to which they bind and how strongly they bind to them.

Cell biologists are only beginning to identify the many ways that proteins interact in cell signaling pathways. The relay sequences we have described here are oversimplified. Some proteins in signaling pathways probably come together briefly, producing large molecular complexes that may be shared among

FIGURE **5-21** **Signal transduction.**

① A signal molecule binds with a receptor in the plasma membrane. ② The signal molecule-receptor complex activates a G protein. ③ The G protein activates an enzyme that catalyzes the production of a second messenger such as cyclic AMP (cAMP). ④ cAMP then activates one or more enzymes such as protein kinases. The enzymes may phosphorylate proteins, which then alter the activity of the cell in some way.

KEY CONCEPT: In signal transduction, cells convert an extracellular signal into an intracellular signal.



several pathways. We have much to learn about how cells "talk" to one another.

CELL JUNCTIONS

Learning Objective

11 Compare the structures and functions of anchoring junctions, tight junctions, gap junctions, and plasmodesmata.

Cells in close contact with each other typically develop specialized intercellular junctions. These structures may allow neighboring cells to form strong connections with each other, prevent the passage of materials, or establish rapid communication between adjacent cells. Several types of junctions connect animal cells, including anchoring junctions, tight junctions, and gap junctions. Plant cells are connected by plasmodesmata.

Anchoring junctions connect cells of an epithelial sheet

Adjacent epithelial cells, such as those found in the outer layer of the skin, are so tightly bound to each other by **anchoring junctions** that strong mechanical forces are required to separate them. Cadherins, transmembrane proteins shown in the chapter opening photograph, are important components of anchoring junctions. These junctions do not affect the passage of materials between adjacent cells. Two common types of anchoring junctions are desmosomes and adhering junctions.

Desmosomes are points of attachment between cells (Fig. 5-22). They hold cells together at one point like a rivet or a spot weld. As a result, cells form strong sheets, and substances still pass freely through the spaces between the plasma membranes. Each desmosome is made up of regions of dense material associated with the cytosolic sides of the two plasma membranes, plus protein filaments that cross the narrow intercellular space between them. Desmosomes are anchored to systems of intermediate filaments inside the cells. Thus the intermediate filament networks of adjacent cells are connected so that mechanical stresses are distributed throughout the tissue.

Adhering junctions cement cells together. Cadherins form a continuous adhesion belt around each cell, binding the cell to neighboring cells. These junctions connect to microfilaments

of the cytoskeleton. The cadherins of adhering junctions are a potential path for signals from the outside environment to be transmitted to the cytoplasm.

Tight junctions seal off intercellular spaces between some animal cells

Tight junctions are literally areas of tight connections between the membranes of adjacent cells. These connections are so tight that no space remains between the cells and substances cannot leak between them. TEMs of tight junctions show that in the region of the junction the plasma membranes of the two cells are in actual contact with each other, held together by proteins linking the two cells. However, as shown in Figure 5-23, tight junctions are located intermittently. The plasma membranes of the two cells are not fused over their entire surface.

Cells connected by tight junctions seal off body cavities. For example, tight junctions between cells lining the intestine prevent substances in the intestine from entering the body or the blood by passing around the cells. The sheet of cells thus acts as a selective barrier. Food substances must be transported across the plasma membranes and through the intestinal cells before they enter the blood. This arrangement helps prevent toxins and other unwanted materials from entering the blood and also prevents nutrients from leaking out of the intestine. Tight junctions are also present between the cells that line capillaries in the brain. They help form the *blood–brain barrier,* which prevents many substances in the blood from passing into the brain.

Gap junctions allow the transfer of small molecules and ions

A **gap junction** is like a desmosome in that it bridges the space between cells; however, the space it spans is somewhat narrower (Fig. 5-24). Gap junctions also differ in that they are communicating junctions. They not only connect the membranes but also contain channels connecting the cytoplasm of adjacent cells. Gap junctions are composed of *connexin,* an integral membrane protein. Groups of six connexin molecules cluster to form a cylinder that spans the plasma membrane. The connexin cylinders on adjacent cells become tightly joined. The two cylinders form a channel, about 1.5 nm in diameter. Small inorganic molecules (such as ions) and some regulatory molecules (such as cyclic AMP) pass through the channels, but larger molecules are excluded. When appropriate marker substances are injected into one of a group of cells connected by gap junctions, the marker passes rapidly into the adjacent cells but does not enter the space between the cells.

Gap junctions provide for rapid chemical and electrical communication between cells. Cells control the passage of materials through gap junctions by opening and closing the channels (Fig. 5-24d). Cells in the pancreas, for example, are linked together by gap junctions in such a way that if one of a group of cells is stimulated to secrete insulin, the signal is passed through the junctions to the other cells in the cluster, ensuring a coordinated response to the initial signal. Gap junctions allow some nerve cells to be electrically coupled. Heart muscle cells are linked by gap junctions that permit the flow of ions necessary to synchronize contractions.

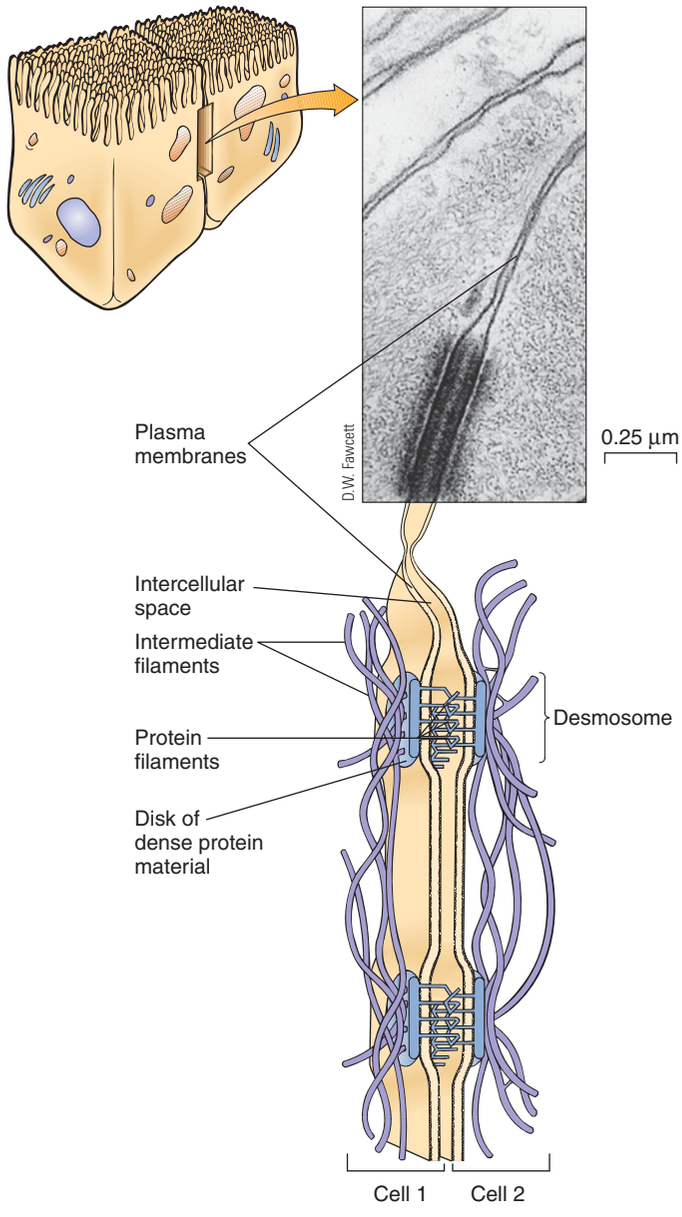

FIGURE **5-22** **Desmosomes.**

The dense structure in the TEM is a desmosome. Each desmosome consists of a pair of button-like discs associated with the plasma membranes of adjacent cells, plus the intercellular protein filaments that connect them. Intermediate filaments in the cells are attached to the discs and are connected to other desmosomes.

Plasmodesmata allow certain molecules and ions to move between plant cells

Plant cells do not need desmosomes for strength because they have cell walls. However, these same walls would isolate the cells,

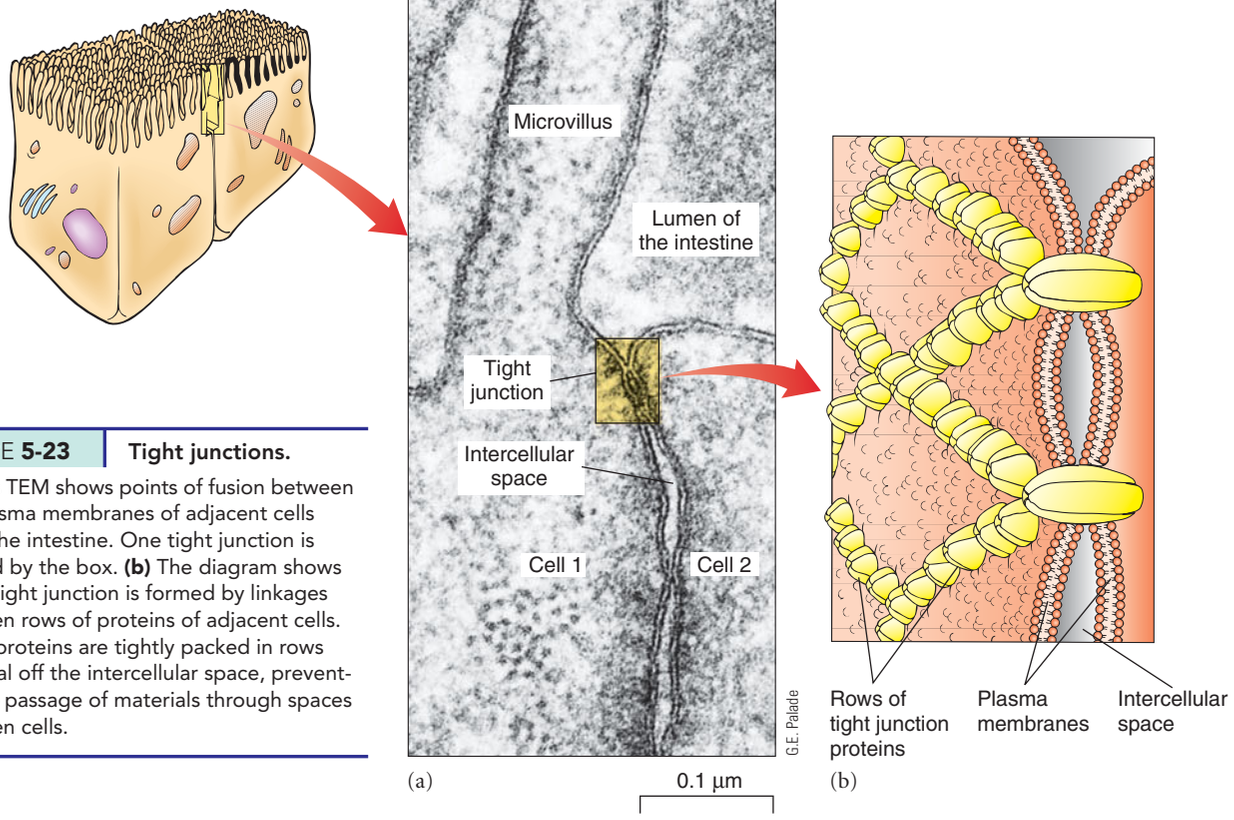

FIGURE **5-23** **Tight junctions.**

(a) This TEM shows points of fusion between the plasma membranes of adjacent cells lining the intestine. One tight junction is marked by the box. **(b)** The diagram shows that a tight junction is formed by linkages between rows of proteins of adjacent cells. These proteins are tightly packed in rows that seal off the intercellular space, preventing the passage of materials through spaces between cells.

FIGURE **5-24** **Gap junctions.**

These connections allow the transfer of small molecules and ions between adjacent cells. **(a)** A TEM of a gap junction *(between the arrows).* **(b)** This model of a gap junction is based on electron microscopic and x-ray diffraction data. The two membranes contain cylinders composed of six connexin molecules. Two cylinders from opposite membranes join to form a channel connecting the cytoplasmic compartments of the two cells. **(d)** This model shows how a gap junction pore might open and close.

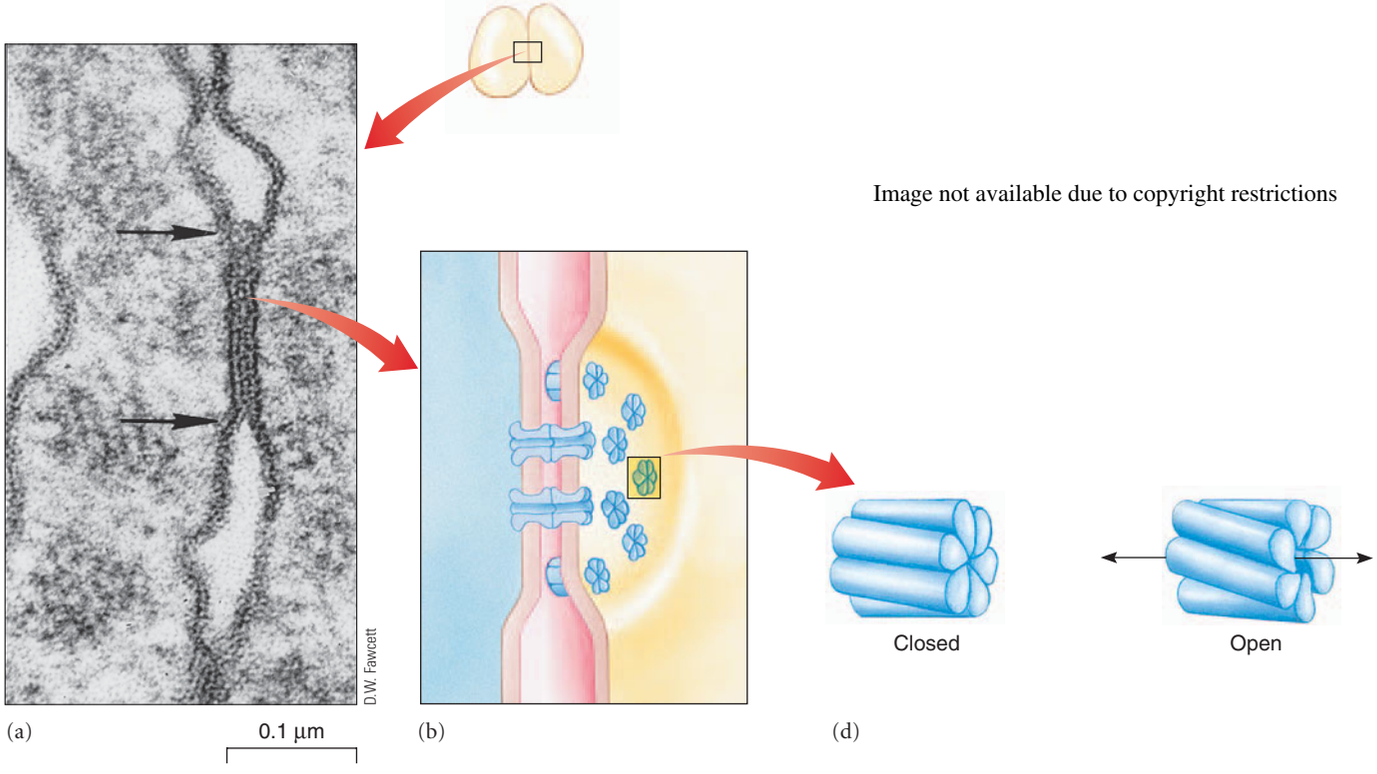

Image not available due to copyright restrictions

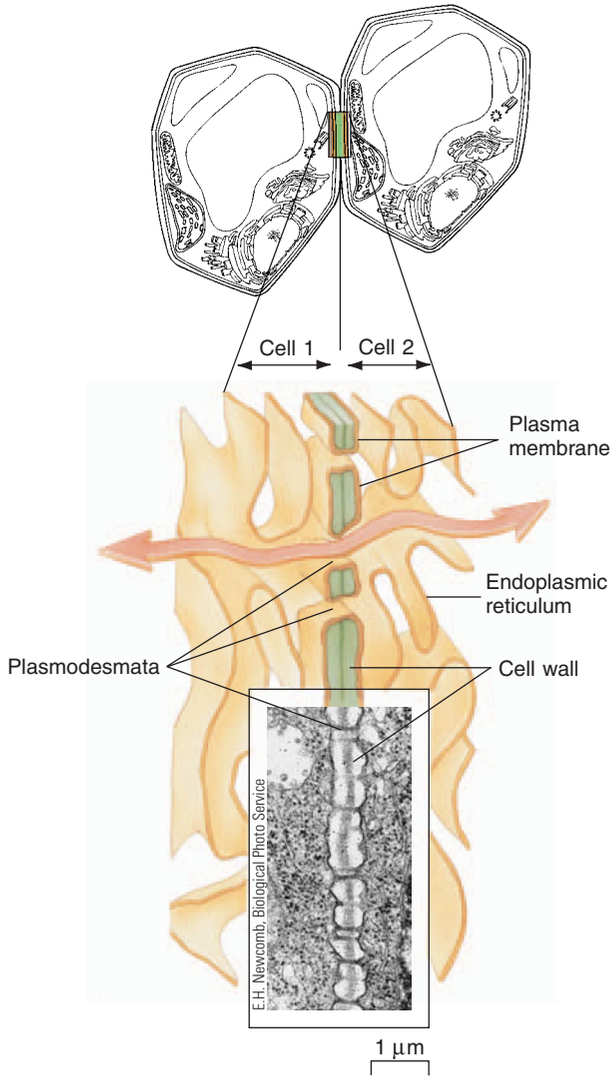
FIGURE **5-25** **Plasmodesmata.**

TEM and line art of cytoplasmic channels through the cell walls of adjacent plant cells *(wide arrows)* that allow passage of water, ions, and small molecules. The channels are lined with the fused plasma membranes of the two adjacent cells. Desmotubules are not shown.



preventing them from communicating. For this reason, plant cells require connections that are functionally equivalent to the gap junctions of some animal cells. **Plasmodesmata** (sing., *plasmodesma*) are channels, 20- to 40-nm wide, through adjacent cell walls, connecting the cytoplasm of neighboring cells (Fig. 5-25). The plasma membranes of adjacent cells are continuous with each other through the plasmodesmata. Most plasmodesmata contain a cylindrical membranous structure, called the *desmotubule,* which also runs through the opening and connects the ER of the two adjacent cells.

Plasmodesmata generally allow molecules and ions, but not organelles, to pass through the openings from cell to cell. The movement of ions through the plasmodesmata allows for a very slow type of electrical signaling in plants. Whereas the channels of gap junctions have a fixed diameter, plants cells can dilate the plasmodesmata channels.

Review

- How are desmosomes and tight junctions functionally similar? How do they differ?
- What is the justification for considering gap junctions and plasmodesmata to be functionally similar? How do they differ structurally?

Biology Now™ Assess your understanding of **cell junctions** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Evaluate the importance of membranes to the homeostasis of the cell, emphasizing their various functions.

- Biological membranes (1) physically separate the interior of the cell from the extracellular environment and (2) form compartments within eukaryotic cells, allowing a variety of separate functions.
- The **plasma membrane** regulates the passage of materials into and out of the cell, participates in and serve as surfaces for biochemical reactions, receives information about changes in the environment, and communicates with other cells.

2 Describe the fluid mosaic model of cell membrane structure.

- According to the **fluid mosaic model,** membranes consist of a fluid phospholipid bilayer in which a variety of proteins are embedded.
- The phospholipid molecules are **amphipathic:** They have hydrophobic and hydrophilic regions. The hydrophilic heads of the phospholipids are at the two surfaces of the bilayer, and their hydrophobic fatty acid chains are in the interior.

3 Explain how the properties of the lipid bilayer govern many of the properties of a cell membrane and of the cell.

- In almost all biological membranes, the lipids of the bilayer are in a fluid or liquid-crystalline state, which allows the molecules to move rapidly in the plane of the membrane. Proteins move within the membrane.
- Lipid bilayers are flexible and self-sealing, and can fuse with other membranes. These properties are the basis for transport of materials from one part of the cell to another in vesicles that bud from various cell membranes and then fuse with some other membrane.

4 Describe how membrane proteins associate with the lipid bilayer, and discuss the functions of membrane proteins.

- **Integral membrane proteins** are embedded in the bilayer with their hydrophilic surfaces exposed to the aqueous environment and their hydrophobic surfaces in contact with the hydrophobic interior of the bilayer. **Transmembrane proteins** are integral proteins that extend completely through the membrane.

- **Peripheral membrane proteins** are associated with the surface of the bilayer, usually bound to exposed regions of integral proteins, and are easily removed without disrupting the structure of the membrane.
- Membrane proteins, lipids, and carbohydrates are asymmetrically positioned with respect to the bilayer so that one side of the membrane has a different composition and structure from the other.
- Membrane proteins have many functions, including transport of materials, acting as enzymes or receptors, cell recognition, and structurally linking cells together.

5 Contrast the physical processes of simple diffusion and osmosis with the carrier-mediated physiological processes by which materials are transported across cell membranes.

- Biological membranes are selectively permeable membranes; that is, they allow the passage of some substances but not others. **Diffusion** is the net movement of a substance down its **concentration gradient** from a region of greater concentration to one of lower concentration.
- Osmosis is a kind of diffusion in which molecules of water pass through a selectively permeable membrane from a region where water has a higher effective concentration to a region where its effective concentration is lower.
- Diffusion and osmosis are physical processes that do not require the cell to directly expend metabolic energy.
- Membrane **transport proteins** facilitate the passage of certain ions and molecules through biological membranes. **Channel proteins** are transport proteins that form passageways through which water and certain ions travel through the membrane. **Carrier proteins** are transport proteins that undergo a series of conformational changes as they bind and transport a specific solute.

6 Solve simple problems involving osmosis; for example, predict whether cells will swell or shrink under various osmotic conditions.

- The concentration of dissolved substances (solutes) in a solution determines its **osmotic pressure.** Cells regulate their internal osmotic pressures to prevent shrinking or bursting.
- An **isotonic** solution has an equal solute concentration compared to another fluid, for example, the fluid within the cell.
- When placed in a **hypertonic** solution, one that has a greater solute concentration than the cell, cells lose water to the surroundings; plant cells undergo **plasmolysis,** a process in which the plasma membrane separates from the cell wall.
- When cells are placed in a **hypotonic** solution, one with a lower concentration of dissolved materials relative to the cell, water enters the cells and causes them to swell.
- Plant cells withstand high internal hydrostatic pressure because their cell walls prevent them from expanding and bursting. When water moves into cells by osmosis, it fills the central vacuoles. The cells swell, building up **turgor pressure** against the rigid cell walls.

7 Differentiate between the processes of facilitated diffusion and active transport, and identify energy sources for each process.

- In **carrier-mediated transport,** specific carrier proteins move ions or molecules across a membrane. **Facilitated diffusion** is a form of carrier-mediated transport that uses the energy of a concentration gradient to transport compounds across a membrane. Facilitated diffusion cannot work against a gradient.
- In **carrier-mediated active transport,** the cell expends metabolic energy to move ions or molecules across a membrane against a concentration gradient. For example, the **sodium-potassium pump** uses ATP to pump sodium ions out of the cell and potassium ions into the cell.
- In **cotransport,** an ATP-powered pump such as the sodium-potassium pump transports ions or some other solute and indirectly powers the transport of other solutes by maintaining a concentration gradient.

8 Compare endocytotic and exocytotic transport mechanisms.

- The cell expends metabolic energy to carry on physiological processes, such as carrier-mediated active transport, exocytosis, and endocytosis.
- In **exocytosis,** the cell ejects waste products or secretes substances such as hormones or mucus by fusion of vesicles with the plasma membrane. In this process, the surface area of the plasma membrane increases.
- In **endocytosis** materials such as food may be moved into the cell; a portion of the plasma membrane envelops the material, enclosing it in a vesicle or vacuole that is then released inside the cell. In this process, the surface area of the plasma membrane decreases. Three types of endocytosis are phagocytosis, pinocytosis, and receptor-mediated endocytosis.
- In **phagocytosis,** the plasma membrane encloses a particle such as a bacterium or protist, forms a vacuole around it, and moves it into the cell.
- In **pinocytosis,** the cell takes in dissolved materials by forming tiny vesicles around droplets of fluid trapped by folds of the plasma membrane.
- In **receptor-mediated endocytosis,** specific receptors in coated pits along the plasma membrane bind **ligands.** These pits, coated by the protein clathrin, form coated vesicles by endocytosis.

9 Describe the generalized process of cell signaling.

- Cells communicate by **cell signaling.** Signaling molecules include neurotransmitters, hormones, and other regulatory molecules. Cell signaling involves synthesis and release of the signaling molecule, transport to target cells, reception of information by target cells, signal transduction, response by the cell, and termination of the signal.

10 Explain how an extracellular signal is converted to an intracellular signal in signal transduction.

- In **signal transduction,** a receptor converts an extracellular signal into an intracellular signal that causes some change in the cell. Signal transduction typically involves a series of molecules that relay information from one to another.
- Signal transduction often involves activation of **G proteins** by binding of a ligand to a receptor; a second messenger such as **cyclic AMP;** and **protein kinases,** enzymes that activate specific proteins by phosphorylating them. The phosphorylated protein then alters some cell functions.

11 Compare the structures and functions of anchoring junctions, tight junctions, gap junctions, and plasmodesmata.

- Cells in close contact with one another may develop intercellular junctions. **Anchoring junctions** include desmosomes and adhering junctions; they are found between cells that form a sheet of tissue. **Desmosomes** spot-weld adjacent animal cells together.

SUMMARY WITH KEY TERMS *(continued)*

Adhering junctions are formed by cadherins that cement cells together.

- **Tight junctions** seal membranes of adjacent animal cells together, preventing substances from moving through the spaces between the cells.
- **Gap junctions,** composed of the protein connexin, form channels, allowing communication between the cytoplasm of adjacent animal cells.
- **Plasmodesmata** are channels connecting adjacent plant cells. Openings in the cell walls allow the plasma membranes and cytoplasm to be continuous; certain molecules and ions pass from cell to cell.

POST-TEST

1. Which of the following statements is *not* true? Biological membranes (a) are composed partly of amphipathic lipids (b) have hydrophobic and hydrophilic regions (c) are typically in a fluid state (d) are made mainly of lipids and of proteins that lie like thin sheets on the membrane surface (e) function in signal transduction
2. According to the fluid mosaic model, membranes consist of (a) a lipid-protein sandwich (b) mainly phospholipids with scattered nucleic acids (c) a fluid phospholipid bilayer in which proteins are embedded (d) a fluid phospholipid bilayer in which carbohydrates are embedded (e) a protein bilayer that behaves as a liquid crystal
3. Transmembrane proteins (a) are peripheral proteins (b) are receptor proteins (c) extend completely through the membrane (d) extend along the surface of the membrane (e) are secreted from the cell
4. Which of the following is *not* a function of the plasma membrane? (a) transports materials (b) helps to structurally link cells together (c) manufactures proteins (d) anchors the cell to the extracellular matrix (e) has receptors that relay signals
5. Which of the following processes requires the cell to expend metabolic energy directly (for example, from ATP)? (a) active transport (b) facilitated diffusion (c) all forms of carrier-mediated transport (d) osmosis (e) simple diffusion
6. Which of the following is an example of carrier-mediated transport? (a) simple diffusion (b) facilitated diffusion (c) movement of water through aquaporins (d) osmosis (e) osmosis when a cell is in a hypertonic solution
7. The action of sodium-potassium pumps is an example of (a) carrier-mediated active transport (b) pinocytosis (c) aquaporin transport (d) exocytosis (e) facilitated diffusion
8. The patch clamp technique (a) cannot be applied to plant cells (b) is mainly used to study exocytosis (c) allows researchers to study single ion channels (d) helped researchers understand signal transduction involving G proteins (e) was developed by Singer and Nicolson
9. A cell takes in dissolved materials by forming tiny vesicles around fluid droplets trapped by folds of the plasma membrane. This process is (a) carrier-mediated active transport (b) pinocytosis (c) receptor-mediated endocytosis (d) exocytosis (e) facilitated diffusion
10. When plant cells are in a hypotonic medium, they (a) undergo plasmolysis (b) build up turgor pressure (c) wilt (d) decrease pinocytosis (e) lose water to the environment
11. After a ligand binds to receptors in coated pit (a) the ligand binds to receptors in coated vesicle (b) a coated vesicle forms by endocytosis (c) a vesicle enters the cytosol by facilitated diffusion (d) lysosomes destroy protein coating of the pit (e) G proteins signal phagocytosis
12. In signal transduction (a) an extracellular signal is converted to an intracellular signal (b) a signal is relayed through a series of molecules in the membrane (c) signal molecules are destroyed before target cells can respond to the signal (d) answers a, b, and c are correct (e) only answers a and b are correct
13. When a ligand binds with a receptor (a) tight junctions develop (b) a third messenger is activated (c) cell signaling is stopped (d) it activates the receptor (e) a G protein is destroyed
14. G proteins (a) relay a message from the activated receptor to an enzyme that activates a second messenger (b) are GTP molecules (c) stop cell signaling (d) directly activate protein kinases (e) are hormones that function as first messengers
15. Anchoring junctions that hold cells together at one point like a spot weld are (a) tight junctions (b) adhering junctions (c) desmosomes (d) gap junctions (e) plasmodesmata
16. Junctions that permit the transfer of water, ions, and molecules between adjacent plant cells are (a) tight junctions (b) adhering junctions (c) desmosomes (d) gap junctions (e) plasmodesmata
17. Junctions that help form the blood–brain barrier are (a) tight junctions (b) adhering junctions (c) desmosomes (d) gap junctions (e) plasmodesmata

CRITICAL THINKING

1. Why can't larger polar molecules and ions diffuse through the plasma membrane? Would it be advantageous to the cell if they could? Explain.
2. Most adjacent plant cells are connected by plasmodesmata, whereas only certain adjacent animal cells are associated through gap junctions. Why?
3. Evaluate the importance of membranes to the cell, discussing their various functions.

Energy and Metabolism

Barbara Gerlach/Visuals Unlimited

Black-tailed prairie dog (*Cynomys ludovicianus*). The chemical energy produced by photosynthesis and stored in seeds and leaves transfers to the black-tailed prairie dog as the animal eats.

CHAPTER OUTLINE

- **Biological Work**
- **The Laws of Thermodynamics**
- **Energy and Metabolism**
- **ATP, The Energy Currency of the Cell**
- **Energy Transfer in Redox Reactions**
- **Enzymes**

All living things require energy to carry out life processes. It may seem obvious that cells need energy to grow and reproduce, but even nongrowing cells need energy simply to maintain themselves. The sun is the ultimate source of almost all the energy that powers life; this *radiant energy* flows from the sun as electromagnetic waves. Plants and other photosynthetic organisms capture about 0.02% of the sun's energy that reaches Earth. In the process of photosynthesis, plants convert radiant energy to *chemical energy* in the bonds of organic molecules. The chemical energy captured by photosynthesis and stored in seeds and leaves is transferred to animals, such as the black-tailed prairie dog in the photograph, when they eat. Plants, animals, and other organisms need the energy stored in these organic molecules, and the process of cellular respiration breaks them apart and converts their energy to more immediately usable forms.

Cells obtain energy in many forms, but that energy can seldom be used directly to power cell processes. For this reason, cells have mechanisms that convert energy from one form to another. Because most components of these energy conversion systems evolved very early in the history of life, many aspects of energy metabolism tend to be similar in a wide range of organisms.

This chapter focuses on some of the basic principles that govern how cells capture, transfer, store, and use energy. We discuss the functions of adenosine triphosphate (ATP) and other molecules used in energy conversions, including those that transfer electrons in oxidation-reduction (redox) reactions. We also pay particular attention to the essential role of enzymes in cell energy dynamics. In Chapter 7 we explore some of the main metabolic pathways used in cellular respiration, and in Chapter 8 we discuss the energy transformations of photosynthesis. The flow of energy in ecosystems is discussed in Chapter 53.

BIOLOGICAL WORK

Learning Objectives

1. Define *energy,* emphasizing how it is related to work and to heat.
2. Use examples to contrast potential energy and kinetic energy.

Energy, one of the most important concepts in biology, can be understood in the context of **matter,** which is anything that has mass and takes up space. **Energy** is defined as the capacity to do work, which is any change in the state or motion of matter. Technically, mass is a form of energy, which is the basis behind the energy generated by the sun and other stars. More than 4 billion kg of matter per second are converted into energy in the sun.

Biologists generally express energy in units of work—**kilojoules (kJ).** It can also be expressed in units of *heat energy*—**kilocalories, kcal**—thermal energy that flows from an object with a higher temperature to an object with a lower temperature. One kcal is equal to 4.184 kJ. Heat energy cannot do cell work, because a cell is too small to have regions that differ in temperature. For that reason, the unit most biologists prefer today is the kilojoule. However, we will use both units because references to the kilocalorie are common in the scientific literature.

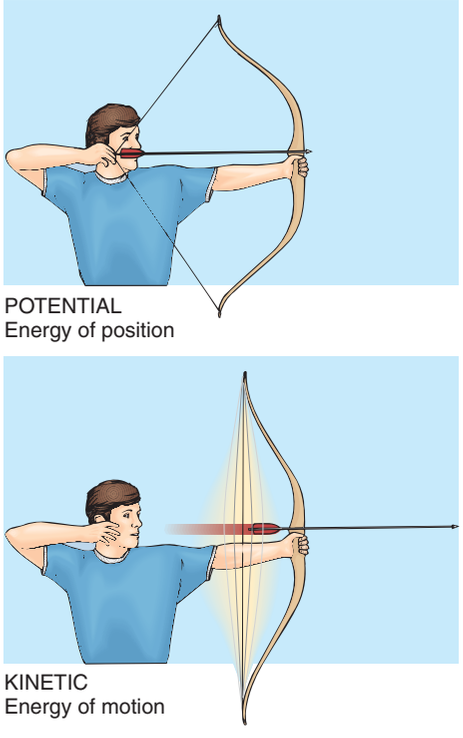

FIGURE **6-1** **Potential versus kinetic energy.**
The potential chemical energy released by cellular respiration is converted to kinetic energy in the muscles, which do the work of drawing the bow. The potential energy stored in the drawn bow is transformed into kinetic energy as the bowstring pushes the arrow toward its target.

Organisms carry out conversions between potential energy and kinetic energy

When an archer draws a bow, **kinetic energy,** the energy of motion, is used and work is performed (Fig. 6-1). The resulting tension in the bow and string represents stored, or potential, energy. **Potential energy** is the capacity to do work owing to position or state. When the string is released, this potential energy is converted to kinetic energy in the motion of the bow, which propels the arrow.

Most actions of an organism involve a complex series of energy transformations that occur as kinetic energy is converted to potential energy or as potential energy is converted to kinetic energy. **Chemical energy,** potential energy stored in chemical bonds, is of particular importance to organisms. In our example, the chemical energy of food molecules is converted to kinetic energy in the muscle cells of the archer. The contraction of the archer's muscles, like many of the activities performed by an organism, is an example of *mechanical energy,* which performs work by moving matter.

Review

- You exert tension on a spring and then release it. How do these actions relate to work, potential energy, and kinetic energy?

THE LAWS OF THERMODYNAMICS

Learning Objective

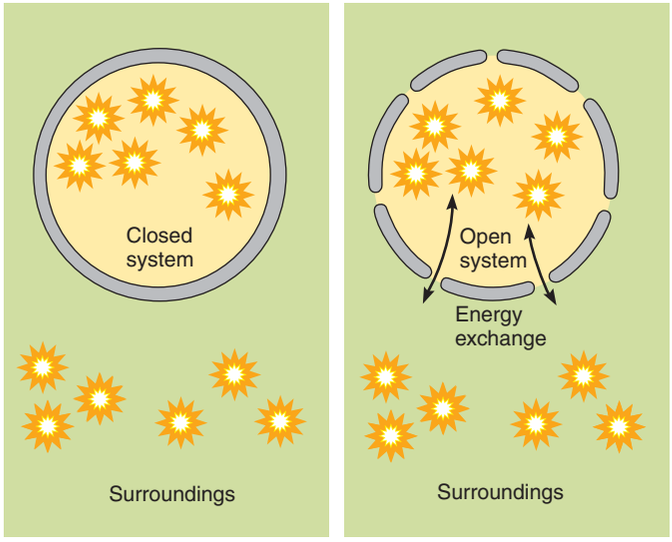
3. State the first and second laws of thermodynamics, and discuss the implications of these laws as they relate to organisms.

Thermodynamics, the study of energy and its transformations, governs all activities of the universe, from the life and death of cells to the life and death of stars. When considering thermodynamics, scientists use the term *system* to refer to an object that they are studying, whether a cell, an organism, or planet Earth. The rest of the universe other than the system being studied constitutes the *surroundings.* A **closed system** does not exchange energy with its surroundings, whereas an **open system** can exchange energy with its surroundings (Fig. 6-2). Biological systems are open systems.

Two laws about energy apply to all things in the universe: the first and second laws of thermodynamics.

The total energy in the universe does not change

According to the **first law of thermodynamics,** energy cannot be created or destroyed, although it can be transferred or converted from one form to another, including conversions between matter and energy. As far as we know, the total mass-energy present in the universe when it formed, almost 14 billion years ago, equals the amount of energy present in the uni-



(a) Closed system (b) Open system

FIGURE **6-2** **Closed and open systems.**

(a) Energy is not exchanged between a closed system and its surroundings. **(b)** Energy is exchanged between an open system and its surroundings.

verse today. This is all the energy that can ever be present in the universe. Similarly, the energy of any system plus its surroundings is constant. A system may absorb energy from its surroundings, or it may give up some energy to its surroundings, but the total energy content of that system plus its surroundings is always the same.

As specified by the first law of thermodynamics, then, organisms cannot create the energy they require in order to live. Instead, they must capture energy from the environment and transform it to a form that can be used for biological work.

The entropy of the universe is increasing

The **second law of thermodynamics** is as follows: When energy is converted from one form to another, some usable energy—that is, energy available to do work—is converted into heat that disperses into the surroundings (see Fig. 53-1). As you learned in Chapter 2, **heat** is the kinetic energy of randomly moving particles. Unlike *heat energy,* which flows from an object with a higher temperature to one with a lower temperature, this random motion cannot perform work. As a result, the amount of usable energy available to do work in the universe decreases over time.

It is important to understand that the second law of thermodynamics is consistent with the first law; that is, the total amount of energy in the universe is *not* decreasing with time. However, the total amount of energy in the universe that is available to do work is decreasing over time.

Less usable energy is more diffuse, or disorganized. **Entropy** (***S***) is a measure of this disorder, or randomness; organized, usable energy has a low entropy, whereas disorganized energy, such as heat, has a high entropy.

Entropy is continuously increasing in the universe in all natural processes. Maybe at some time, billions of years from now, all energy will exist as heat uniformly distributed throughout the universe. If that happens, the universe will cease to operate, because no work will be possible. Everything will be at the same temperature, so there will be no way to convert the thermal energy of the universe into usable mechanical energy.

As a consequence of the second law of thermodynamics, no process requiring an energy conversion is ever 100% efficient, because much of the energy is dispersed as heat, increasing entropy. For example, an automobile engine, which converts the chemical energy of gasoline to mechanical energy, is between 20% and 30% efficient. Thus only 20% to 30% of the original energy stored in the chemical bonds of the gasoline molecules is actually transformed into mechanical energy; the other 70% to 80% dissipates as waste heat. Energy use in your cells is about 40% efficient, with the remaining energy given to the surroundings as heat.

Organisms have a high degree of organization, and at first glance they appear to refute the second law of thermodynamics. As organisms grow and develop, they maintain a high level of order and do not appear to become more disorganized. However, organisms maintain their degree of order over time only with the constant input of energy from their surroundings. That is why plants must photosynthesize and animals must eat. Although the order within organisms may tend to increase temporarily, the total entropy of the universe (organisms plus surroundings) always increases over time.

Review

- What is the first law of thermodynamics? The second law?
- Life is sometimes described as a constant struggle against the second law of thermodynamics. How do organisms succeed in this struggle without violating the second law?

BiologyNow™ Assess your understanding of the **laws of thermodynamics** by taking the pretest on your BiologyNow CD-ROM.

ENERGY AND METABOLISM

Learning Objectives

4 Discuss how changes in free energy in a reaction are related to changes in entropy and enthalpy.

5 Distinguish between exergonic and endergonic reactions, and give examples of how they may be coupled.

6 Compare the energy dynamics of a reaction at equilibrium with the dynamics of a reaction not at equilibrium.

The chemical reactions that enable an organism to carry on its activities—to grow, move, maintain and repair itself, reproduce, and respond to stimuli—together make up its metabolism. Recall from Chapter 1 that **metabolism** is the sum of all the chemical activities taking place in an organism. An organism's metabolism consists of many intersecting series of chemical reactions, or pathways, which are of two main types: anabolism and catabolism. **Anabolism** includes the various pathways in which complex molecules are synthesized from simpler sub-

stances, such as in the linking of amino acids to form proteins. **Catabolism** includes the pathways in which larger molecules are broken down into smaller ones, such as in the degradation of starch to form monosaccharides.

As you will see, these changes involve not only alterations in the arrangement of atoms but also various energy transformations. Catabolism and anabolism are complementary processes; catabolic pathways involve an overall release of energy, some of which powers anabolic pathways, which have an overall energy requirement. In the following sections we discuss how to predict whether a particular chemical reaction requires energy or releases it.

Enthalpy is the total potential energy of a system

In the course of any chemical reaction, including the metabolic reactions of a cell, chemical bonds break, and new and different bonds may form. Every specific type of chemical bond has a certain amount of *bond energy,* defined as the energy required to break that bond. The total bond energy is essentially equivalent to the total potential energy of the system, a quantity known as **enthalpy (*H*).**

Free energy is available to do cell work

Entropy and enthalpy are related by a third type of energy, termed **free energy (*G*),** which is the amount of energy available to do work under the conditions of a biochemical reaction. (*G,* also known as "Gibbs free energy," is named for J.W. Gibbs, a Yale professor who was one of the founders of the science of thermodynamics.) Free energy, the only kind of energy that can do cell work, is the aspect of thermodynamics of greatest interest to a biologist.

Enthalpy, free energy, and entropy are related by the following equation:

$$H = G + TS$$

in which H is enthalpy, G is free energy, S is entropy, and T is the absolute temperature of the system, expressed in degrees Kelvin. Disregarding temperature (T) for the moment, enthalpy (the total energy of a system) is equal to free energy (the usable energy) plus entropy (the unusable energy).

A rearrangement of the equation shows that as entropy increases, the amount of free energy decreases:

$$G = H - TS$$

If we assume that entropy is zero, the free energy is simply equal to the total potential energy (enthalpy); an increase in entropy reduces the amount of free energy.

What is the significance of the temperature (T)? Remember that as the temperature increases, the increase in random molecular motion contributes to disorder and multiplies the effect of the entropy term.

Chemical reactions involve changes in free energy

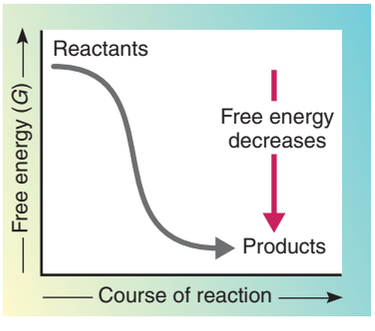
Biologists analyze the role of energy in the many biochemical reactions of metabolism. Although the total free energy of a system (G) cannot be effectively measured, the equation $G = H - TS$ can be extended to predict whether a particular chemical reaction will release energy or require an input of energy. This is because *changes* in free energy can be measured. Scientists use the Greek capital letter delta (Δ) to denote any change that occurs in the system between its initial state before the reaction and its final state after the reaction. To express what happens with respect to energy in a chemical reaction, the equation becomes

$$\Delta G = \Delta H - T\Delta S$$

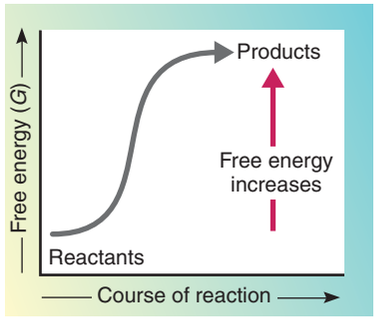
Notice that the temperature does not change; it is held constant during the reaction. Thus the change in free energy (ΔG) during the reaction is equal to the change in enthalpy (ΔH) minus the product of the absolute temperature (T) multiplied by the change in entropy (ΔS). Scientists express ΔG and ΔH in kilojoules or kilocalories per mole; they express ΔS in kilojoules or kilocalories per degree.

Free energy decreases during an exergonic reaction

An **exergonic reaction** releases energy and is said to be a spontaneous or a "downhill" reaction, from higher to lower free energy (Fig. 6-3a). Because the total free energy in its final state is less than the total free energy in its initial state, ΔG is a negative number for exergonic reactions.



(a) Exergonic reaction (spontaneous; energy-releasing)



(b) Endergonic reaction (not spontaneous; energy-requiring)

FIGURE **6-3**

(a) In an exergonic reaction, there is a net loss of free energy. The products have less free energy than was present in the reactants, and the reaction proceeds spontaneously. **(b)** In an endergonic reaction, there is a net gain have more free energy than was present in the reactants. An endergonic reaction occurs only if energy is supplied by an exergonic reaction.

The term *spontaneous* may give the false impression that such reactions are always instantaneous. In fact, spontaneous reactions do not necessarily occur readily; some are extremely slow. This is because energy, known as *activation energy,* is required to initiate every reaction, even a spontaneous one. We discuss activation energy later in the chapter.

Free energy increases during an endergonic reaction

An **endergonic reaction** is a reaction in which there is a gain of free energy (Fig. 6-3b). Because the free energy of the products is greater than the free energy of the reactants, ΔG has a positive value. Such a reaction cannot take place in isolation. Instead, it must occur in such a way that energy can be supplied from the surroundings. Of course, many energy-requiring reactions take place in cells, and as you will see, metabolic mechanisms have evolved that supply the energy needed to "drive" these nonspontaneous cell reactions in a particular direction.

Diffusion is an exergonic process

In Chapter 5, you saw that randomly moving particles diffuse down their own concentration gradient (Fig. 6-4). Although the movements of the individual particles are random, net movement of the group of particles seems to be directional. What provides energy for this apparently directed process? A **concentration gradient,** with a region of higher concentration and another region of lower concentration, is an orderly state. A cell must expend energy to produce a concentration gradient. Because work is done to produce this order, a concentration gradient is a form of potential energy. As the particles move about randomly, the gradient becomes degraded. Thus free energy decreases as entropy increases.

In cellular respiration and photosynthesis, the potential energy stored in a concentration gradient of hydrogen ions (H^+) is transformed into chemical energy in adenosine triphosphate (ATP) as the hydrogen ions pass through a membrane down their concentration gradient. This important concept, known as *chemiosmosis,* is discussed in detail in Chapters 7 and 8.

Free energy changes depend on the concentrations of reactants and products

According to the second law of thermodynamics, any process that increases entropy can do work. As we have discussed, differences in the concentration of a substance, such as between two different parts of a cell, represent a more orderly state than when the substance is diffused homogeneously throughout the cell. Free energy changes in any chemical reaction depend mainly on the difference in bond energies (enthalpy, *H*) between reactants and products. Free energy also depends on *concentrations* of both reactants and products. The change in molecules from a more concentrated to a less concentrated state increases entropy because it is movement from a more orderly to a less orderly state.

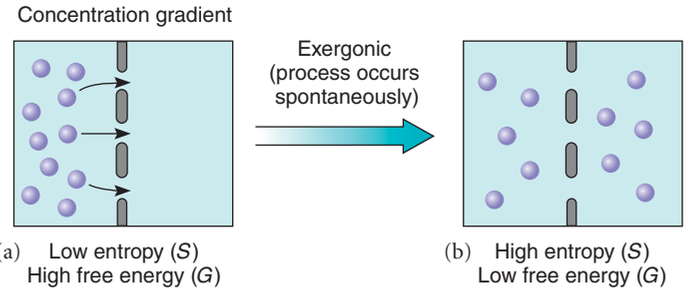


FIGURE **6-4** **Entropy and diffusion.**
The tendency of entropy to increase can be used to produce work, in this case, diffusion. **(a)** A concentration gradient is a form of potential energy. **(b)** When molecules are evenly distributed, they have high entropy.

In most biochemical reactions there is little intrinsic free energy difference between reactants and products. Such reactions are reversible, indicated by drawing double arrows ($\rightleftharpoons$).

$$A \rightleftharpoons B$$

At the beginning of a reaction, only the reactant molecules (A) may be present. As the reaction proceeds, the concentration of the reactant molecules decreases, and the concentration of the product molecules (B) increases. As the concentration of the product molecules increases, they may have enough free energy to initiate the reverse reaction. The reaction thus proceeds in both directions simultaneously; if undisturbed, it eventually reaches a state of **dynamic equilibrium,** in which the rate of the reverse reaction equals the rate of the forward reaction. At equilibrium there is no net change in the system; a reverse reaction balances every forward reaction.

At a given temperature and pressure, each reaction has its own characteristic equilibrium. For any given reaction, chemists can perform experiments and calculations to determine the relative concentrations of reactants and products present at equilibrium. If the reactants have much greater intrinsic free energy than the products, the reaction goes almost to completion; that is, it reaches equilibrium at a point at which most of the reactants have been converted to products. Reactions in which the reactants have much less intrinsic free energy than the products reach equilibrium at a point where very few of the reactant molecules have been converted to products.

If you increase the initial concentration of A, then the reaction will "shift to the right," and more A will be converted to B. A similar effect can be obtained if B is removed from the reaction mixture. The reaction always shifts in the direction that reestablishes equilibrium, so that the proportions of reactants and products characteristic of that reaction at equilibrium are restored. The opposite effect occurs if the concentration of B increases or if A is removed; here the system "shifts to the left." The actual free energy change that occurs during a reaction is defined mathematically to include these effects, which stem from the relative initial concentrations of reactants and products.

Cells manipulate the relative concentrations of reactants and products of almost every reaction. Cell reactions are virtu-

ally never at equilibrium. By displacing their reactions far from equilibrium, cells supply energy to endergonic reactions and direct their metabolism according to their needs.

Cells drive endergonic reactions by coupling them to exergonic reactions

Many metabolic reactions, such as protein synthesis, are anabolic and endergonic. Because an endergonic reaction cannot take place without an input of energy, endergonic reactions are coupled to exergonic reactions. In **coupled reactions,** the thermodynamically favorable exergonic reaction provides the energy required to drive the thermodynamically unfavorable endergonic reaction. The endergonic reaction proceeds only if it absorbs free energy released by the exergonic reaction to which it is coupled.

Consider the free energy change, ΔG, in the following reaction:

$$(1)\ A \longrightarrow B \qquad \Delta G = +20.9 \text{ kJ/mol } (+5 \text{ kcal/mol})$$

Because ΔG has a positive value, you know that the product of this reaction has more free energy than the reactant. This is an endergonic reaction. It is not spontaneous and does not take place without an energy source.

By contrast, consider the following reaction:

$$(2)\ C \longrightarrow D \qquad \Delta G = -33.5 \text{ kJ/mol } (-8 \text{ kcal/mol})$$

The negative value of ΔG tells you that the free energy of the reactant is greater than the free energy of the product. This exergonic reaction proceeds spontaneously.

You can sum up reactions 1 and 2 as follows:

(1) $A \longrightarrow B$	$\Delta G = +20.9$ kJ/mol (+5 kcal/mol)
(2) $C \longrightarrow D$	$\Delta G = -33.5$ kJ/mol (−8 kcal/mol)
Overall	$\Delta G = -12.6$ kJ/mol (−3 kcal/mol)

Because thermodynamics considers the overall changes in these two reactions, which show a net negative value of ΔG, the two reactions taken together are exergonic.

The fact that scientists can write reactions this way is a useful bookkeeping device, but it does not mean that an exergonic reaction mysteriously transfers energy to an endergonic "bystander" reaction. However, these reactions are coupled if their pathways are altered so a common intermediate links them. Reactions 1 and 2 might be coupled by an intermediate (I) in the following way:

(3) $A + C \longrightarrow I$	$\Delta G = -8.4$ kJ/mol (−2 kcal/mol)
(4) $I \longrightarrow B + D$	$\Delta G = -4.2$ kJ/mol (−1 kcal/mol)
Overall	$\Delta G = -12.6$ kJ/mol (−3 kcal/mol)

Note that reactions 3 and 4 are sequential. Thus the reaction pathways have changed, but overall the reactants (A and C) and products (B and D) are the same, and the free energy change is the same.

Generally, for each endergonic reaction occurring in a living cell there is a coupled exergonic reaction to drive it. Often the exergonic reaction involves the breakdown of ATP. Now let's examine specific examples of the role of ATP in energy coupling.

Review

- Consider the free energy change in a reaction in which enthalpy decreases and entropy increases. Is ΔG zero, or does it have a positive value or a negative value? Is the reaction endergonic or exergonic?
- Why can't a reaction at equilibrium do work?

BiologyNow™ Assess your understanding of **energy and metabolism** by taking the pretest on your BiologyNow CD-ROM.

ATP, THE ENERGY CURRENCY OF THE CELL

Learning Objective

7 Explain how the chemical structure of ATP allows it to transfer a phosphate group. Discuss the central role of ATP in the overall energy metabolism of the cell.

In all living cells, energy is temporarily packaged within a remarkable chemical compound called **adenosine triphosphate (ATP),** which holds readily available energy for very short periods. We may think of ATP as the energy currency of the cell. When you work to earn money, you might say your energy is symbolically stored in the money you earn. The energy the cell requires for immediate use is temporarily stored in ATP, which is like cash. When you earn extra money, you may deposit some in the bank; similarly, a cell may deposit energy in the chemical bonds of lipids, starch, or glycogen. Moreover, just as you dare not make less money than you spend, the cell must avoid energy bankruptcy, which would mean its death. Finally, just as you probably don't keep money you make very long, the cell continuously spends its ATP, which must be replaced immediately.

ATP is a nucleotide consisting of three main parts: adenine, a nitrogen-containing organic base; ribose, a five-carbon sugar; and three phosphate groups, identifiable as phosphorus atoms surrounded by oxygen atoms (Fig. 6-5). Notice that the phosphate groups are bonded to the end of the molecule in a series, rather like three cars behind a locomotive, and, like the cars of a train, they can be attached and detached.

ATP donates energy through the transfer of a phosphate group

When the terminal phosphate is removed from ATP, the remaining molecule is **adenosine diphosphate (ADP)** (see Fig. 6-5). If the phosphate group is not transferred to another molecule, it is released as inorganic phosphate (P_i). This is an exergonic reaction. ATP is sometimes called a "high-energy" compound because the hydrolysis reaction that releases a phosphate has a relatively large negative value of ΔG. (Calculations of the free energy of ATP hydrolysis vary somewhat, but range between about −28 and −37 kJ/mol, or −6.8 to −8.7 kcal/mol.)

$$(5)\ ATP + H_2O \longrightarrow ADP + P_i \qquad \Delta G = -32 \text{ kJ/mol (or } -7.6 \text{ kcal/mol)}$$

Reaction 5 can be coupled to endergonic reactions in cells. Consider the following endergonic reaction, in which two

monosaccharides, glucose and fructose, form the disaccharide sucrose.

(6) Glucose + fructose $\longrightarrow$ sucrose + H_2O

$\Delta G = +27$ kJ/mol (or +6.5 kcal/mol)

With a free energy change of −32 kJ/mol (−7.6 kcal/mol), the hydrolysis of ATP in reaction 5 can drive reaction 6, but only if the reactions are coupled through a common intermediate.

The following series of reactions is a simplified version of an alternative pathway that some bacteria use:

(7) Glucose + ATP $\longrightarrow$ glucose-P + ADP

(8) Glucose-P + fructose $\longrightarrow$ sucrose + P_i

Reaction 7 is a **phosphorylation reaction,** one in which a phosphate group is transferred to some other compound. Glucose is phosphorylated to form glucose phosphate (glucose-P), the intermediate that links the two reactions. Glucose-P, which corresponds to I in reactions 3 and 4, reacts exergonically with fructose to form sucrose. For energy coupling to work in this way, reactions 7 and 8 must occur in sequence.

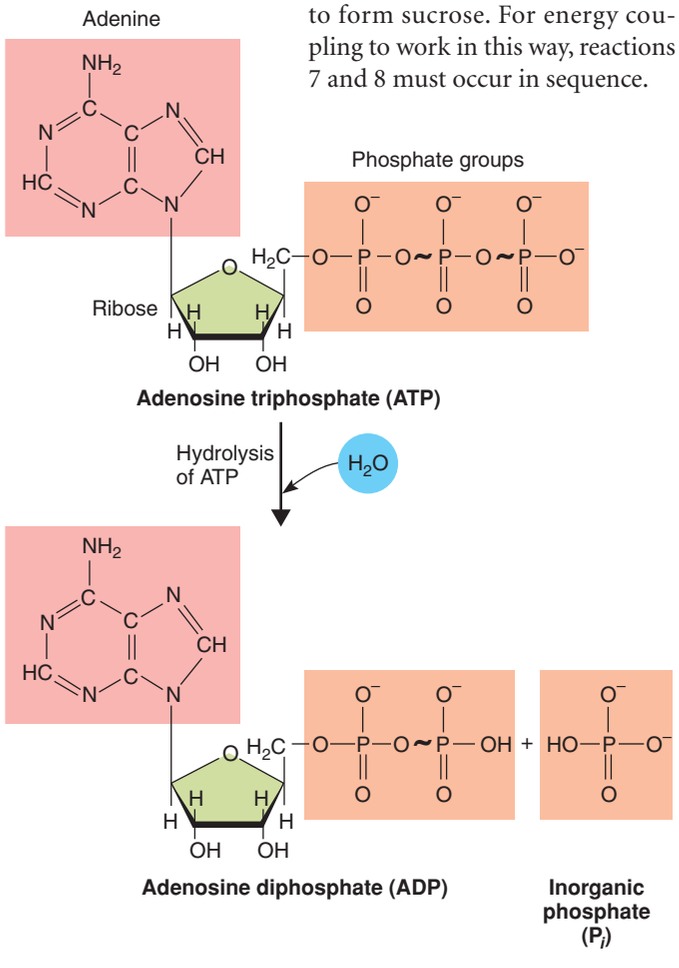

FIGURE **6-5** **ATP and ADP.**

The energy currency of all living things, ATP consists of adenine, ribose, and three phosphate groups. The hydrolysis of ATP, an exergonic reaction, yields ADP and inorganic phosphate. (The black wavy lines indicate unstable bonds. These bonds allow the phosphates to be transferred to other molecules, making them more reactive.)

It's convenient to summarize the reactions thus:

(9) Glucose + fructose + ATP $\longrightarrow$ sucrose + ADP + P_i

$\Delta G = -5$ kJ/mol (−1.2 kcal/mol)

When you encounter an equation written in this way, remember that it is actually a summary of a series of reactions and that transitory intermediate products (in this case, glucose-P) are sometimes not shown.

ATP links exergonic and endergonic reactions

We have just discussed how the transfer of a phosphate group from ATP to some other compound is coupled to endergonic reactions in the cell. Conversely, adding a phosphate group to adenosine monophosphate, or AMP (forming ADP) or to ADP (forming ATP) requires coupling to exergonic reactions in the cell.

AMP + P_i + energy $\longrightarrow$ ADP

ADP + P_i + energy $\longrightarrow$ ATP

Thus ATP occupies an intermediate position in the metabolism of the cell and is an important link between exergonic reactions, which are generally components of *catabolic pathways,* and endergonic reactions, which are generally part of *anabolic pathways* (Fig. 6-6).

The cell maintains a very high ratio of ATP to ADP

The cell maintains a ratio of ATP to ADP far from the equilibrium point. ATP constantly forms from ADP and inorganic

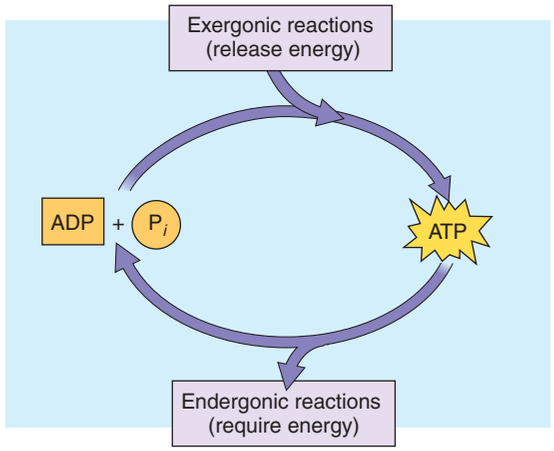

FIGURE **6-6** **ATP links exergonic and endergonic reactions.**

Exergonic reactions in catabolic pathways (*top*) supply energy to drive the endergonic formation of ATP from ADP. Conversely, the exergonic hydrolysis of ATP supplies energy to endergonic reactions in anabolic pathways (*bottom*).

phosphate as nutrients break down in cellular respiration or as photosynthesis traps the radiant energy of sunlight. At any time, a typical cell contains more than 10 ATP molecules for every ADP molecule. The fact that the cell maintains the ATP concentration at such a high level (relative to the concentration of ADP) makes its hydrolysis reaction even more strongly exergonic and more able to drive the endergonic reactions to which it is coupled.

Although the cell maintains a high ratio of ATP to ADP, the cell cannot store large quantities of ATP. The concentration of ATP is always very low, less than 1 mmol/L. In fact, studies suggest a bacterial cell has no more than a 1-second supply of ATP. Thus it uses ATP molecules almost as quickly as they are produced. A healthy adult human at rest uses about 45 kg (100 lb) of ATP each day, but the amount present in the body at any given moment is less than 1 g (0.035 oz). Every second in every cell, an estimated 10 million molecules of ATP are made from ADP and phosphate, and an equal number of ATPs transfer their phosphate groups, along with their energy, to whatever chemical reactions need them.

Review

- Why do coupled reactions typically have common intermediates? Give a generalized example involving ATP, distinguishing between the exergonic and endergonic reactions.
- Why is the ATP concentration in a cell about 10 times the concentration of ADP?

BiologyNow™ Assess your understanding of **ATP** by taking the pretest on your BiologyNow CD-ROM.

ENERGY TRANSFER IN REDOX REACTIONS

Learning Objective

8 Relate the transfer of electrons (or hydrogen atoms) to the transfer of energy.

You have seen that cells transfer energy through the transfer of a phosphate group from ATP. Energy is also transferred through the transfer of electrons. As discussed in Chapter 2, **oxidation** is the chemical process in which a substance loses electrons, whereas **reduction** is the complementary process in which a substance gains electrons. Because electrons released during an oxidation reaction cannot exist in the free state in living cells, every oxidation reaction must be accompanied by a reduction reaction, in which the electrons are accepted by another atom, ion, or molecule. Oxidation and reduction reactions are often called **redox reactions,** because they occur simultaneously. The substance that becomes oxidized gives up energy as it releases electrons, and the substance that becomes reduced receives energy as it gains electrons.

Redox reactions often occur in a series as electrons are transferred from one molecule to another. These electron transfers, which are equivalent to energy transfers, are an essential part of cellular respiration, photosynthesis, and many other chemical reactions. Redox reactions, for example, release the energy stored in food molecules so that ATP can be synthesized using that energy.

Most electron carriers transfer hydrogen atoms

Generally it is not easy to remove one or more electrons from a covalent compound; it is much easier to remove a whole atom. For this reason, redox reactions in cells usually involve the transfer of a hydrogen atom rather than just an electron. A hydrogen atom contains an electron, plus a proton that does not participate in the oxidation-reduction reaction.

When an electron, either singly or as part of a hydrogen atom, is removed from an organic compound, it takes with it some of the energy stored in the chemical bond of which it was a part. That electron, along with its energy, is transferred to an acceptor molecule. An electron progressively loses free energy as it is transferred from one acceptor to another.

One of the most frequently encountered acceptor molecules is **nicotinamide adenine dinucleotide (NAD^+).** When NAD^+ becomes reduced, it temporarily stores large amounts of free energy. Here is a generalized equation showing the transfer of hydrogen from a compound we call X, to NAD^+:

$$XH_2 + NAD^+ \longrightarrow X + NADH + H^+$$

Oxidized Reduced

Notice that the NAD^+ becomes reduced when it combines with hydrogen. NAD^+ is an ion with a net charge of + 1. When 2 electrons and 1 proton are added, the charge is neutralized and the reduced form of the compound, **NADH,** is produced (Fig. 6-7). (Although the correct way to write the reduced form of NAD^+ is NADH + H^+, for simplicity we present the reduced form as NADH in this book.) Some energy stored in the bonds holding the hydrogen atoms to molecule X has been transferred by this redox reaction and is temporarily held by NADH. When NADH transfers the electrons to some other molecule, some of their energy is transferred. This energy is usually then transferred through a series of reactions that ultimately result in the formation of ATP (see Chapter 7).

Nicotinamide adenine dinucleotide phosphate ($NADP^+$) is a hydrogen acceptor that is chemically similar to NAD^+ but has an extra phosphate group. Unlike NADH, the reduced form of $NADP^+$, abbreviated **NADPH,** is not involved in ATP synthesis. Instead, the electrons of NADPH are used more directly to provide energy for certain reactions, including certain essential reactions of photosynthesis (see Chapter 8).

Other important hydrogen acceptors or electron acceptors are FAD and the cytochromes. **Flavin adenine dinucleotide (FAD)** is a nucleotide that accepts hydrogen atoms and their electrons; its reduced form is **$FADH_2$.** The **cytochromes** are proteins that contain iron; the iron component accepts electrons from hydrogen atoms and then transfers these electrons to some other compound. Like NAD^+ and $NADP^+$, FAD and the cytochromes are electron transfer agents. Each exists in a *reduced state,* in which it has more free energy, or in an *oxidized state,* in which it has less. Each is an essential component of many redox reaction sequences in cells.

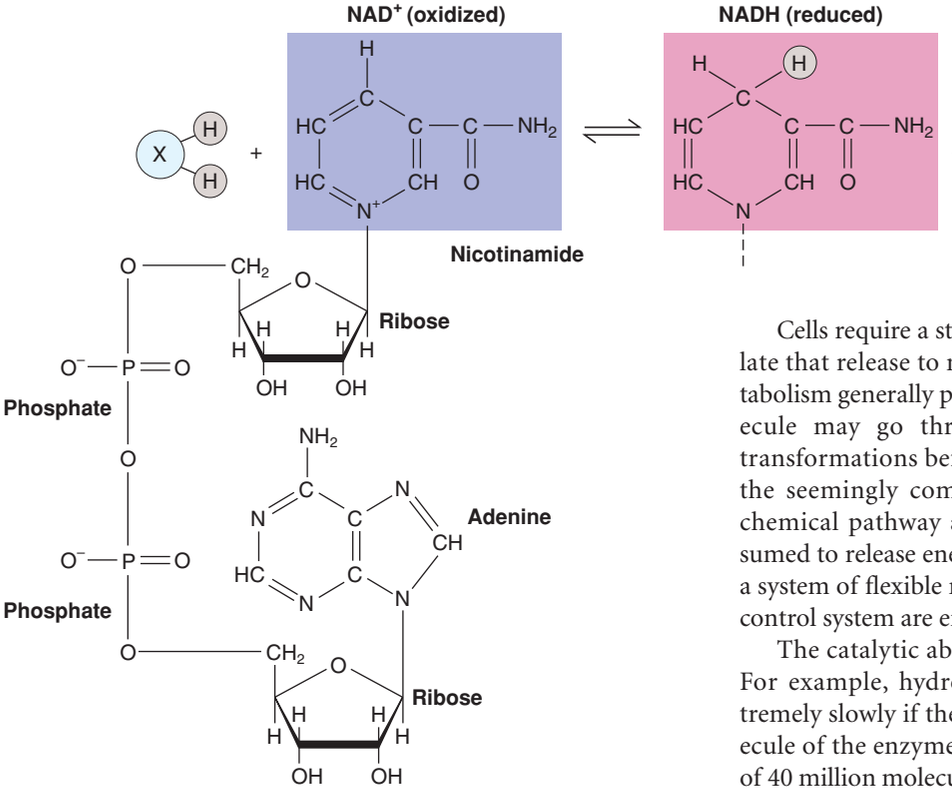

FIGURE **6-7** **NAD+.**

NAD^+ consists of two nucleotides, one with adenine and one with nicotinamide, that are joined at their phosphate groups. The oxidized form (NAD^+, *purple screen at top*) becomes reduced (NADH, *pink screen*) by the transfer of 2 electrons and 1 proton from another organic compound (XH_2), which becomes oxidized (to X) in the process.

ENZYMES

Learning Objectives

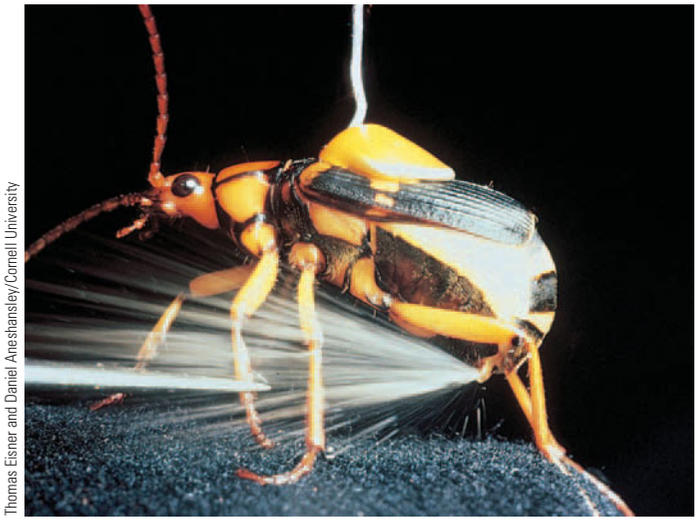
9 Explain how an enzyme lowers the required energy of activation for a reaction.

10 Describe specific ways enzymes are regulated.

The principles of thermodynamics help us predict whether a reaction can occur, but they tell us nothing about the speed of the reaction. The breakdown of glucose, for example, is an exergonic reaction, yet a glucose solution stays unchanged virtually indefinitely in a bottle if it is kept free of bacteria and molds and not subjected to high temperatures or strong acids or bases. Cells cannot wait for centuries for glucose to break down, nor can they use extreme conditions to cleave glucose molecules. Cells regulate the rates of chemical reactions with **enzymes,** which are biological **catalysts** that increase the speed of a chemical reaction without being consumed by the reaction. Although most enzymes are proteins, scientists have learned that some types of RNA molecules have catalytic activity as well (see Chapter 12).

Cells require a steady release of energy, and they must regulate that release to meet metabolic energy requirements. Metabolism generally proceeds by a series of steps such that a molecule may go through as many as 20 or 30 chemical transformations before it reaches some final state. Even then, the seemingly completed molecule may enter yet another chemical pathway and become totally transformed or consumed to release energy. The changing needs of the cell require a system of flexible metabolic control. The key directors of this control system are enzymes.

The catalytic ability of some enzymes is truly impressive. For example, hydrogen peroxide (H_2O_2) breaks down extremely slowly if the reaction is uncatalyzed, but a single molecule of the enzyme **catalase** brings about the decomposition of 40 million molecules of hydrogen peroxide per second! Catalase has the highest catalytic rate known for any enzyme. It protects cells by destroying hydrogen peroxide, a poisonous substance produced as a byproduct of some cell reactions. The bombardier beetle uses the enzyme catalase as a defense mechanism (Fig. 6-8).



Thomas Eisner and Daniel Aneshansley/Cornell University

FIGURE **6-8** **Catalase as a defense mechanism.**

When threatened, a bombardier beetle (*Stenaptinus insignis*) uses the enzyme catalase to decompose hydrogen peroxide. The oxygen gas formed in the decomposition ejects water and other chemicals with explosive force. Because the reaction releases a great deal of heat, the water comes out as steam. (A wire attached by a drop of adhesive to the beetle's back immobilizes it. The researcher prodded its leg with the dissecting needle on the left to trigger the ejection.)

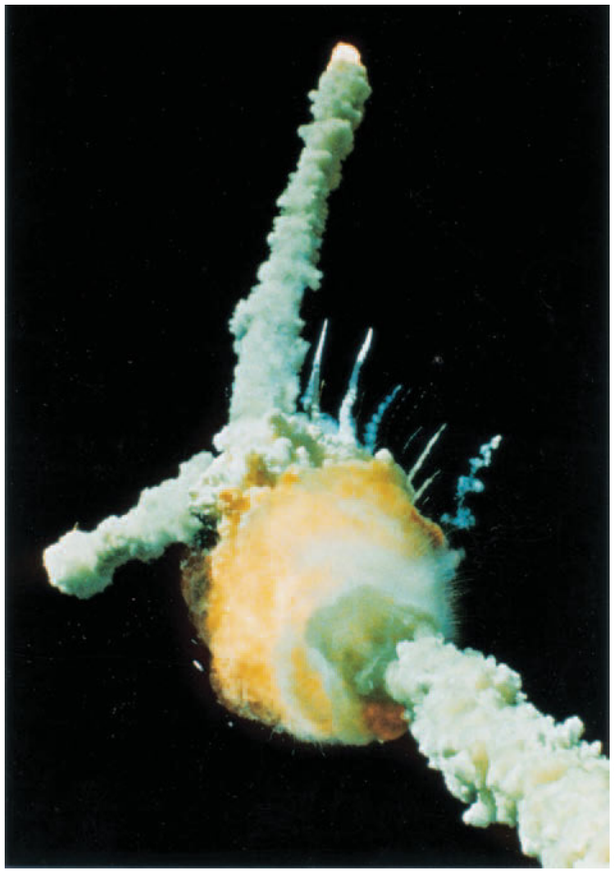
All reactions have a required energy of activation

All reactions, whether exergonic or endergonic, have an energy barrier known as the **energy of activation (E_A),** or **activation energy,** which is the energy required to break the existing bonds and begin the reaction. In a population of molecules of any kind, some have a relatively high kinetic energy, whereas others have a lower energy content. Only molecules with a relatively high kinetic energy are likely to react to form the product.

Even a strongly exergonic reaction, one that releases a substantial quantity of energy as it proceeds, may be prevented from proceeding by the activation energy required to begin the reaction. For example, molecular hydrogen and molecular oxygen can react explosively to form water:

$$2\ H_2 + O_2 \longrightarrow 2\ H_2O$$

This reaction is spontaneous, yet hydrogen and oxygen can be safely mixed as long as all sparks are kept away. This is because the required activation energy for this particular reaction is relatively high. A tiny spark provides the activation energy that allows a few molecules to react. Their reaction liberates so much heat that the rest react, producing an explosion. Such an explosion occurred on the space shuttle *Challenger* on January 28, 1986 (Fig. 6-9). The failure of a rubber O-ring to properly seal caused the liquid hydrogen in the tank attached to the shuttle to leak and start burning. When the hydrogen tank ruptured a few seconds later, the resulting force burst the nearby oxygen tank as well, mixing hydrogen and oxygen and igniting a huge explosion.



AP/Wide World Photos

FIGURE **6-9** **The space shuttle *Challenger* explosion.**
This disaster resulted from an explosive exergonic reaction between hydrogen and oxygen. All seven crew members died in the accident on January 28, 1986.

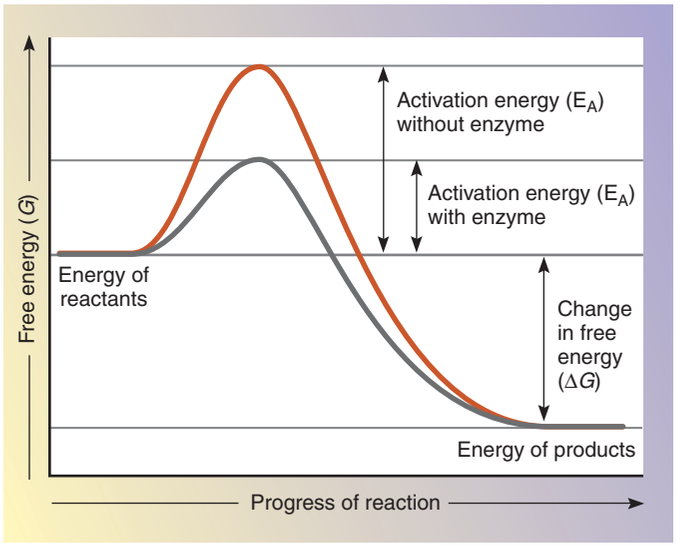
An enzyme lowers a reaction's activation energy

Like all catalysts, enzymes affect the rate of a reaction by lowering the activation energy (E_A) necessary to initiate a chemical reaction (Fig. 6-10). If molecules need less energy to react because the activation barrier is lowered, a larger fraction of the reactant molecules reacts at any one time. As a result, the reaction proceeds more quickly.

Although an enzyme lowers the activation energy for a reaction, it has no effect on the overall free energy change; that is, an enzyme can only promote a chemical reaction that could proceed without it. If the reaction goes to equilibrium, no catalyst can cause a reaction to proceed in a thermodynamically unfavorable direction, or can influence the final concentrations of reactants and products. Enzymes simply speed up reaction rates.

An enzyme works by forming an enzyme-substrate complex

An uncatalyzed reaction depends on random collisions among reactants. Because of its ordered structure, an enzyme reduces this reliance on random events and thereby controls the reaction. The enzyme accomplishes this by forming an unstable intermediate complex with the **substrate,** the substance on which it acts. When the **enzyme-substrate complex,** or **ES complex,**



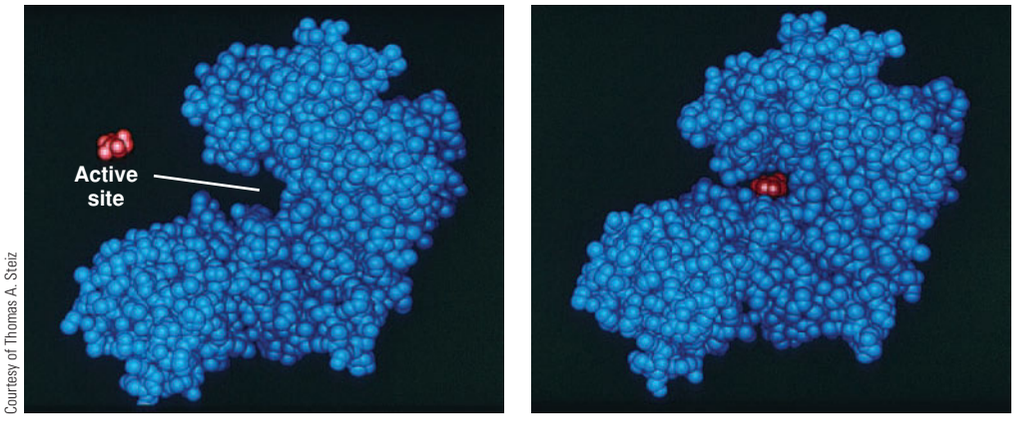
ACTIVE FIGURE **6-10** **Activation energy and enzymes.**
An enzyme speeds up a reaction by lowering its activation energy (E_a). In the presence of an enzyme, reacting molecules require less kinetic energy to complete a reaction.

BiologyNow™ Learn more about **activation energy** by clicking on this figure on your BiologyNow CD-ROM.

FIGURE **6-11**

An enzyme-substrate complex.

This computer graphic model shows the enzyme hexokinase (*blue*) and its substrate, glucose (*red*). **(a)** Prior to forming an ES complex, the enzyme's active site is the furrow where glucose will bind. **(b)** The binding of glucose to the active site induces a changes in the enzyme's active site.



(a) (b)

breaks up, the product is released; the original enzyme molecule is regenerated and is free to form a new ES complex:

$$\text{Enzyme} + \text{substrate(s)} \longrightarrow \text{ES complex}$$
$$\text{ES complex} \longrightarrow \text{enzyme} + \text{product(s)}$$

The enzyme itself is not permanently altered or consumed by the reaction and can be reused.

As shown in Figure 6-11a, every enzyme contains one or more **active sites,** regions to which the substrate binds, forming the ES complex. The active sites of some enzymes are grooves or cavities in the enzyme molecule, formed by amino acid side chains. The active sites of most enzymes are located close to the surface. During the course of a reaction, substrate molecules occupying these sites are brought close together and react with one another.

The shape of the enzyme does not seem exactly complementary to that of the substrate. When the substrate binds to the enzyme molecule, it causes a change, known as **induced fit,** in the shape of the enzyme (Fig. 6-11b). Usually the shape of the substrate also changes slightly, in a way that may distort its chemical bonds. The proximity and orientation of the reactants, together with strains in their chemical bonds, facilitate the breakage of old bonds and the formation of new ones. Thus the substrate is changed into a product, which moves away from the enzyme. The enzyme is then free to catalyze the reaction of more substrate molecules to form more product molecules.

Scientists usually name enzymes by adding the suffix *-ase* to the name of the substrate. The enzyme sucrase, for example, splits sucrose into glucose and fructose. A few enzymes retain traditional names that do not end in *-ase;* some of these end in *-zyme.* For example, lysozyme (from the Greek *lysis,* "a loosening") is an enzyme found in tears and saliva; it breaks down bacterial cell walls. Other examples of enzymes with traditional names are pepsin and trypsin, which break peptide bonds in proteins.

Enzymes are specific

Enzymes catalyze virtually every chemical reaction that takes place in an organism. Because the shape of the active site is closely related to the shape of the substrate, most enzymes are highly specific. Most catalyze only a few closely related chemical reactions or, in many cases, only one particular reaction. For example, the enzyme urease, which decomposes urea to ammonia and carbon dioxide, attacks no other substrate. The enzyme sucrase splits only sucrose; it does not act on other disaccharides, such as maltose or lactose. A few enzymes are specific only to the extent that they require the substrate to have a certain kind of chemical bond. For example, lipase, secreted by the pancreas, splits the ester linkages connecting the glycerol and fatty acids of a wide variety of fats.

Scientists classify into groups enzymes that catalyze similar reactions, although each particular enzyme in the group may catalyze only one specific reaction. Table 6-1 describes the six classes of enzymes that biologists recognize. Each class is divided into many subclasses. For example, sucrase, mentioned earlier, is called a glycosidase, because it cleaves a glycosidic linkage (see Chapter 3). Glycosidases are a subclass of the hydrolases.

Many enzymes require cofactors

Some enzymes consist only of protein. For example, the enzyme pepsin, which is secreted by the animal stomach and digests dietary protein by breaking certain peptide bonds, is exclusively a protein molecule. Other enzymes have two components: a protein called the *apoenzyme* and an additional chemical component called a **cofactor.** Neither the apoenzyme nor the cofactor alone has catalytic activity; only when the two are combined

TABLE **6-1** Important Classes of Enzymes

Enzyme Class	Function
Oxidoreductases	Catalyze oxidation-reduction reactions
Transferases	Catalyze the transfer of a functional group from a donor molecule to an acceptor molecule
Hydrolases	Catalyze hydrolysis reactions
Isomerases	Catalyze conversion of a molecule from one isomeric form to another
Ligases	Catalyze certain reactions in which two molecules join in a process coupled to the hydrolysis of ATP
Lyases	Catalyze certain reactions in which double bonds form or break

does the enzyme function. A cofactor may be inorganic, or it may be an organic molecule.

Some enzymes require a specific metal ion as a cofactor. Two very common inorganic cofactors are magnesium ions and calcium ions. Most of the trace elements, such as iron, copper, zinc, and manganese, all of which organisms require in very small amounts, function as cofactors.

An organic, nonpolypeptide compound that binds to the apoenzyme and serves as a cofactor is called a **coenzyme.** Most coenzymes are carrier molecules that transfer electrons or part of a substrate from one molecule to another. We have already introduced some examples of coenzymes in this chapter. NADH, NADPH, and $FADH_2$ are coenzymes; they transfer electrons. ATP functions as a coenzyme; it is responsible for transferring phosphate groups. Yet another coenzyme, **coenzyme A,** is involved in the transfer of groups derived from organic acids. Most vitamins, which are organic compounds that an organism requires in small amounts but cannot synthesize itself, are coenzymes or components of coenzymes (see Table 45-3).

(b)

FIGURE **6-12** **The effect of temperature and pH on enzyme activity.**

Substrate and enzyme concentrations are held constant in the reactions illustrated. **(a)** Generalized curves for the effect of temperature on enzyme activity. As temperature increases, enzyme activity increases until it reaches an optimal temperature. Enzyme activity abruptly falls after it exceeds the optimal temperature because the enzyme, being a protein, denatures. **(b)** Enzyme activity is very sensitive to pH. Pepsin is a protein-digesting enzyme in the very acidic stomach juice. Trypsin, secreted by the pancreas into the slightly basic small intestine, digests polypeptides.

Enzymes are most effective at optimal conditions

Enzymes generally work best under certain narrowly defined conditions, such as appropriate temperature, pH, and ion concentration. Any departure from optimal conditions adversely affects enzyme activity.

Each enzyme has an optimal temperature

Most enzymes have an optimal temperature, at which the rate of reaction is fastest. For human enzymes, the temperature optima are near the human body temperature (35° to 40°C). Enzymatic reactions occur slowly or not at all at low temperatures. As the temperature increases, molecular motion increases, resulting in more molecular collisions. The rates of most enzyme-controlled reactions therefore increase as the temperature increases, within limits (Fig. 6-12a). High temperatures rapidly denature most enzymes. The molecular conformation (3-D shape) of the protein becomes altered as the hydrogen bonds responsible for its secondary, tertiary, and quaternary structures are broken. Because this inactivation is usually not reversible, activity is not regained when the enzyme is cooled.

Most organisms are killed by even a short exposure to high temperature; their enzymes are denatured, and they are unable to continue metabolism. There are a few stunning exceptions to this rule. Certain species of archaea (see Chapter 1) can survive in the waters of hot springs, such as those in Yellowstone Park, where the temperature is almost 100°C; these organisms are responsible for the brilliant colors in the terraces of the hot springs (Fig. 6-13). Still other archaea live at temperatures much above that of boiling water, near deep-sea vents, where the

The world's third largest spring, about 61 m (200 ft) in diameter, the Grand Prismatic Spring teems with heat-tolerant bacteria. The rings around the perimeter, where the water is slightly cooler, get their distinctive colors from the various kinds of bacteria living there.

extreme pressure keeps water in its liquid state (see Chapter 23; see also Chapter 53, *Focus On: Life Without the Sun*).

Each enzyme has an optimal pH

Most enzymes are active only over a narrow pH range and have an optimal pH, at which the rate of reaction is fastest. The optimal pH for most human enzymes is between 6 and 8. (Recall from Chapter 2 that buffers minimize pH changes in cells so that the pH is maintained within a narrow limit.) Pepsin, a protein-digesting enzyme secreted by cells lining the stomach, is an exception; it works only in a very acidic medium, optimally at pH 2 (Fig. 6-12b). In contrast, trypsin, a protein-splitting enzyme secreted by the pancreas, functions best under the slightly basic conditions found in the small intestine.

The activity of an enzyme may be markedly changed by any alteration in pH, which in turn alters electrical charges on the enzyme. Changes in charge affect the ionic bonds that contribute to tertiary and quaternary structure, thereby changing the protein's conformation and activity. Many enzymes become inactive, and usually irreversibly denatured, when the medium is made very acidic or very basic.

Enzymes are organized into teams in metabolic pathways

Enzymes play an essential role in reaction coupling because they usually work in sequence, with the product of one enzyme-controlled reaction serving as the substrate for the next. You can picture the inside of a cell as a factory with many different assembly (and disassembly) lines operating simultaneously. An assembly line consists of a number of enzymes. Each enzyme carries out one step, such as changing molecule A into molecule B. Then molecule B is passed along to the next enzyme, which converts it into molecule C, and so on. Such a series of reactions is called a **metabolic pathway.**

$$A \xrightarrow{\text{Enzyme 1}} B \xrightarrow{\text{Enzyme 2}} C$$

Theoretically, each of these reactions is reversible, and that an enzyme catalyzes it does not change that fact. An enzyme does not itself determine the direction of the reaction it catalyzes. However, the overall reaction sequence is portrayed as proceeding from left to right. Recall that if there is little intrinsic free energy difference between the reactants and products for a particular reaction, its direction is determined mainly by the relative concentrations of reactants and products.

In biological pathways, both intermediate and final products are often removed and converted to other chemical compounds. Such removal drives the sequence of reactions in a particular direction. Let's assume that reactant A is continually supplied and that its concentration remains constant. Enzyme 1 converts reactant A to product B. The concentration of B is always lower than the concentration of A, because B is removed as it is converted to C in the reaction catalyzed by enzyme 2. If C is removed as quickly as it is formed (perhaps by leaving the cell), the entire reaction pathway is "pulled" toward C.

The cell regulates enzymatic activity

Enzymes regulate the chemistry of the cell, but what controls the enzymes? One regulatory mechanism depends simply on controlling the amount of enzyme produced. A specific gene directs the synthesis of each type of enzyme. The gene, in turn, may be switched on by a signal from a hormone or by some other type of cell product. When the gene is switched on, the enzyme is synthesized. The total amount of enzyme present then influences the overall cell reaction rate.

If the pH and temperature are kept constant (as they are in most cells), the rate of the reaction can be affected by the substrate concentration or by the enzyme concentration. If an excess of substrate is present, the enzyme concentration is the rate-limiting factor. The initial rate of the reaction is then directly proportional to the enzyme concentration (Fig. 6-14a).

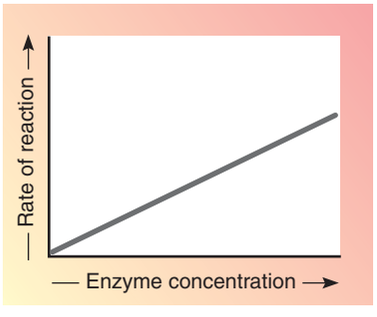
If the enzyme concentration is kept constant, the rate of an enzymatic reaction is proportional to the concentration of substrate present. Substrate concentration is the rate-limiting factor at lower concentrations; the rate of the reaction is therefore directly proportional to the substrate concentration. However, at higher substrate concentrations, the enzyme molecules become saturated with substrate; that is, substrate molecules are bound to all available active sites of enzyme molecules. In this situation, increasing the substrate concentration does not increase the net reaction rate (Fig. 6-14b).

The product of one enzymatic reaction may control the activity of another enzyme, especially in a com-

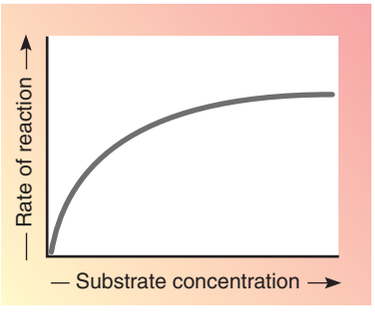
FIGURE **6-14**

The effect of enzyme concentration and substrate concentration on the rate of a reaction.

(a) In this example, the rate of reaction is measured at different enzyme concentrations, with an excess of substrate present. (Temperature and pH are constant.) The rate of the reaction is directly proportional to the enzyme concentration. **(b)** In this example, the rate of the reaction is measured at different substrate concentrations, and enzyme concentration, temperature, and pH are constant. If the substrate concentration is relatively low, the reaction rate is directly proportional to substrate concentration. However, higher substrate concentrations do not increase the reaction rate, because the enzymes become saturated with substrate.



(a)



(b)

plex sequence of enzymatic reactions. For example, consider the following metabolic pathway:

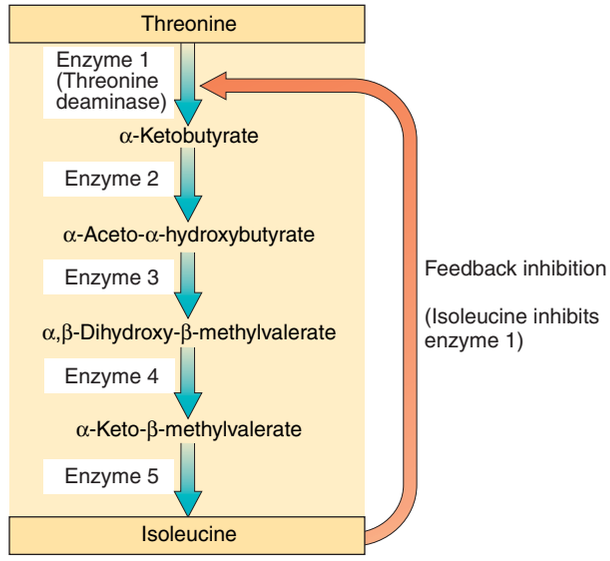
$$A \xrightarrow{\text{Enzyme 1}} B \xrightarrow{\text{Enzyme 2}} C \xrightarrow{\text{Enzyme 3}} D \xrightarrow{\text{Enzyme 4}} E$$

A different enzyme catalyzes each step, and the final product E may inhibit the activity of enzyme 1. When the concentration of E is low, the sequence of reactions proceeds rapidly. However, an increasing concentration of E serves as a signal for enzyme 1 to slow down and eventually to stop functioning. Inhibition of enzyme 1 stops the entire reaction sequence. This type of enzyme regulation, in which the formation of a product inhibits an earlier reaction in the sequence, is called **feedback inhibition** (Fig. 6-15).

Another important method of enzymatic control focuses on the activation of enzyme molecules. In their inactive form, the active sites of the enzyme are inappropriately shaped, so that the substrates do not fit. Among the factors that influence the shape of the enzyme are pH, the concentration of certain ions, and the addition of phosphate groups to certain amino acids in the enzyme.

Some enzymes have a receptor site, called an **allosteric site,** on some region of the enzyme molecule other than the active site. (The word *allosteric* means "another space.") When a substance binds to an enzyme's allosteric site, the conformation of the enzyme's active site changes, thereby modifying the enzyme's activity. Substances that affect enzyme activity by binding to allosteric sites are called **allosteric regulators.** Some allosteric regulators are allosteric inhibitors that keep the enzyme in its inactive shape. Conversely, the activities of allosteric activators result in an enzyme with a functional active site.

The enzyme *cyclic AMP-dependent protein kinase* is an allosteric enzyme regulated by a protein that binds reversibly to the allosteric site and inactivates the enzyme. Protein kinase is in this inactive form most of the time (Fig. 6-16). When protein kinase activity is needed, the compound cyclic AMP (cAMP; see Fig. 3-25) contacts the enzyme-inhibitor complex and removes the inhibitory protein, thereby activating the protein kinase. Activation of protein kinases by cAMP is an important aspect of the mechanism of action of certain hormones (see Chapters 5 and 47).



ACTIVE FIGURE **6-15** **Feedback inhibition.**

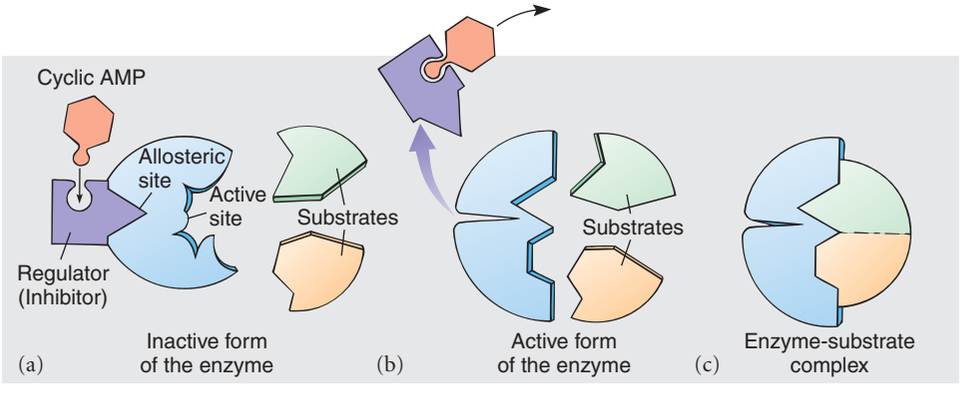
Bacteria synthesize the amino acid isoleucine from the amino acid threonine. The isoleucine pathway involves five steps, each catalyzed by a different enzyme. When enough isoleucine accumulates in the cell, the isoleucine inhibits threonine deaminase, the enzyme that catalyzes the first step in this pathway.

BiologyNow™ Learn more about **feedback inhibition** by clicking on this figure on your BiologyNow CD-ROM.

Enzymes are inhibited by certain chemical agents

Most enzymes are inhibited or even destroyed by certain chemical agents. Enzyme inhibition may be reversible or irreversible. **Reversible inhibition** occurs when an inhibitor forms weak chemical bonds with the enzyme. Reversible inhibition can be competitive or noncompetitive.

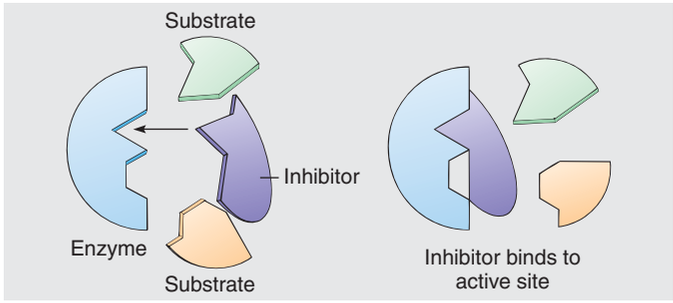
In **competitive inhibition,** the inhibitor competes with the normal substrate for binding to the active site of the enzyme (Fig. 6-17a). Usually a competitive inhibitor is structurally similar to the normal substrate and fits into the active site and combines with the enzyme. However, it is not similar enough to substitute fully for the normal substrate in the chemical reaction, and the enzyme cannot con-



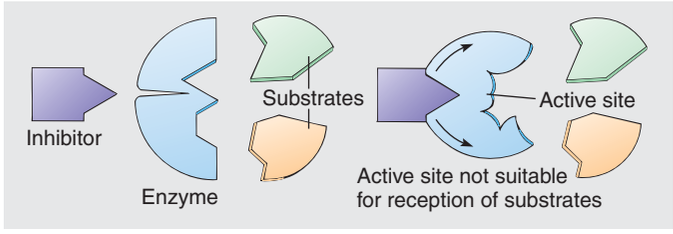
ACTIVE FIGURE **6-16** **An allosteric enzyme**

(a) The enzyme protein kinase is inhibited by a regulatory protein that binds reversibly to its allosteric site. When the enzyme is in this inactive form, the shape of the active site is modified so that the substrate cannot combine with it. **(b)** Cyclic AMP removes the allosteric inhibitor and activates the enzyme. **(c)** The substrate can then combine with the active site.

BiologyNow™ Learn more about **allosteric enzymes** by clicking on this figure on your BiologyNow CD-ROM.



(a) Competitive inhibition



(b) Noncompetitive inhibition

FIGURE **6-17** **Competitive and noncompetitive inhibition.**

(a) In competitive inhibition, the inhibitor competes with the normal substrate for the active site of the enzyme. A competitive inhibitor occupies the active site only temporarily. **(b)** In noncompetitive inhibition, the inhibitor binds with the enzyme at a site other than the active site, altering the shape of the enzyme and thereby inactivating it.

vert it to product molecules. A competitive inhibitor occupies the active site only temporarily and does not permanently damage the enzyme. In competitive inhibition, an active site is occupied by the inhibitor part of the time and by the normal substrate part of the time. If the concentration of the substrate is increased relative to the concentration of the inhibitor, the active site is usually occupied by the substrate. Scientists demonstrate competitive inhibition experimentally by showing that increasing the substrate concentration reverses competitive inhibition.

In **noncompetitive inhibition,** the inhibitor binds with the enzyme at a site other than the active site (Fig. 6-17b). Such an inhibitor inactivates the enzyme by altering its shape so that the active site cannot bind with the substrate. Many important noncompetitive inhibitors are metabolic substances that regulate enzyme activity by combining reversibly with the enzyme. Noncompetitive inhibition has some features in common with allosteric inhibition.

In **irreversible inhibition,** an inhibitor permanently inactivates or destroys an enzyme when it combines with one of its functional groups, either at the active site or elsewhere. Many poisons are irreversible enzyme inhibitors. For example, heavy metals such as mercury and lead bind irreversibly to and denature many proteins, including enzymes. Certain nerve gases poison the enzyme acetylcholinesterase, which is important for the functioning of nerves and muscles. Cytochrome oxidase, one of the enzymes that transports electrons in cellular respiration, is especially sensitive to cyanide. Death results from cyanide

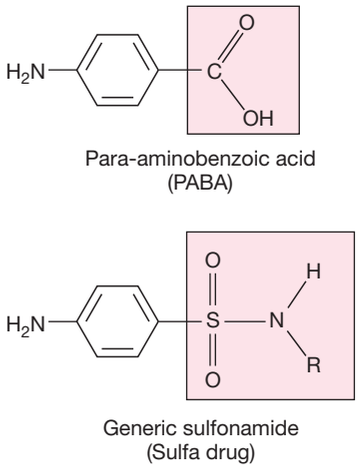


FIGURE **6-18** **Para-aminobenzoic acid and sulfonamides.**

Sulfa drugs inhibit an enzyme in bacteria necessary for the synthesis of folic acid, an important vitamin required for growth. (Note the unusual structure of the sulfonamide molecule, in which sulfur, which commonly forms two covalent bonds, forms six instead.)

poisoning because cytochrome oxidase is irreversibly inhibited and no longer transfers electrons from its substrate to oxygen.

Some drugs are enzyme inhibitors

Physicians treat many bacterial infections with drugs that directly or indirectly inhibit bacterial enzyme activity. For example, sulfa drugs have a chemical structure similar to that of the nutrient *para-aminobenzoic acid (PABA)* (Fig. 6-18). When PABA is available, microorganisms can synthesize the vitamin *folic acid,* which is necessary for growth. Humans do not synthesize folic acid from PABA, and that's why sulfa drugs selectively affect bacteria. When a sulfa drug is present, the drug competes with PABA for the active site of the bacterial enzyme. When bacteria use the sulfa drug instead of PABA, they synthesize a compound that cannot be used to make folic acid. Therefore, the bacterial cells are unable to grow.

Penicillin and related antibiotics irreversibly inhibit a bacterial enzyme called *transpeptidase.* This enzyme establishes some of the chemical linkages in the bacterial cell wall. Susceptible bacteria cannot produce properly constructed cell walls and are prevented from multiplying effectively. Human cells do not have cell walls and therefore do not use this enzyme. Thus, except for individuals allergic to it, penicillin is harmless to humans. Unfortunately, during the years since it was introduced, many bacterial strains have evolved resistance to penicillin. The resistant bacteria fight back with an enzyme of their own, penicillinase, which breaks down the penicillin and renders it ineffective. Because bacteria evolve at such a rapid rate, drug resistance is a growing problem in medical practice.

Review

- What effect does an enzyme have on the required activation energy of a reaction?
- How does the function of the active site of an enzyme differ from that of an allosteric site?
- How are temperature and pH optima of an enzyme related to its structure and function?
- Is allosteric inhibition competitive or noncompetitive?

Biology Now™ Assess your understanding of **enzymes** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Define *energy,* emphasizing how it is related to work and to heat.

- **Energy** is the capacity to do work (expressed in **kilojoules, kJ**).
- Energy can be conveniently measured as **heat energy,** thermal energy that flows from an object with a higher temperature to an object with a lower temperature; the unit of heat energy is the **kilocalorie (kcal),** which is equal to 4.184 kilojoules. Heat energy cannot do cell work.

2 Use examples to contrast potential energy and kinetic energy.

- **Potential energy** is stored energy; **kinetic energy** is energy of motion.
- All life depends on a continuous input of energy. All forms of energy are interconvertible. For example, photosynthetic organisms capture radiant energy and convert some of it to **chemical energy,** a form of potential energy that powers many life processes.

3 State the first and second laws of thermodynamics, and discuss the implications of these laws as they relate to organisms.

- A **closed system** does not exchange energy with its surroundings. Organisms are **open systems.**
- The **first law of thermodynamics** states that energy cannot be created or destroyed but can be transferred and changed in form. The first law explains why organisms cannot produce energy, but as open systems they continuously capture it from the surroundings.
- The **second law of thermodynamics** states that disorder (entropy) in the universe, a closed system, is continuously increasing. No energy transfer is 100% efficient; some energy is dissipated as **heat,** random motion that contributes to **entropy** or disorder. Organisms maintain their ordered states at the expense of their surroundings.

4 Discuss how changes in free energy in a reaction are related to changes in entropy and enthalpy.

- As entropy increases, the amount of f**ree energy** decreases, as shown in the equation $G = H - TS$, in which G is the free energy, H is the **enthalpy** (total potential energy of the system), T is the absolute temperature (expressed in degrees Kelvin), and S is entropy.
- The equation $\Delta G = \Delta H - TS$ indicates that the change in free energy (ΔG) during a chemical reaction is equal to the change in enthalpy (ΔH) minus the product of the absolute temperature (T) multiplied by the change in entropy (ΔS).

5 Distinguish between exergonic and endergonic reactions, and give examples of how they may be coupled.

- An **exergonic reaction** has a negative value of ΔG; that is, free energy decreases. Such a reaction is spontaneous; it released free energy that can perform work.
- Free energy increases in an **endergonic reaction.** Such a reaction has a positive value of ΔG, and is nonspontaneous. In a **coupled reaction,** the input of free energy required to drive an endergonic reaction is supplied by an exergonic reaction.

6 Compare the energy dynamics of a reaction at equilibrium with the dynamics of a reaction not at equilibrium.

- When a chemical reaction is in a state of **dynamic equilibrium,** the rate of change in one direction is exactly the same as the rate of change in the opposite direction; the system can do no work because the free energy difference between the reactants and products is zero.
- When the concentration of reactant molecules is increased, the reaction shifts to the right, and more product molecules are formed until equilibrium is re-established.

7 Explain how the chemical structure of ATP allows it to transfer a phosphate group. Discuss the central role of ATP in the overall energy metabolism of the cell.

- **Adenosine triphosphate, ATP,** is the immediate energy currency of the cell. It donates energy by means of its terminal phosphate group, which is easily transferred to an acceptor molecule. ATP is formed by the **phosphorylation** of **adenosine diphosphate, ADP,** an endergonic process that requires an input of energy.
- ATP is the common link between exergonic and endergonic reactions and between **catabolism** (degradation of large complex molecules into smaller, simpler molecules) and **anabolism** (synthesis of complex molecules from simpler molecules)

8 Relate the transfer of electrons (or hydrogen atoms) to the transfer of energy.

- Energy is transferred in **oxidation-reduction (redox) reactions.** A substance becomes oxidized as it gives up one or more electrons to a substance that has become reduced. Electrons are typically transferred as part of hydrogen atoms.
- NAD^+ and $NADP^+$ accept electrons as part of hydrogen atoms and become reduced to form **NADH** and **NADPH,** respectively. These electrons (along with some of their energy) can be transferred to other acceptors.

9 Explain how an enzyme lowers the required energy of activation for a reaction.

- An **enzyme** is a biological **catalyst;** it greatly increases the speed of a chemical reaction without being consumed.
- An enzyme works by lowering the **activation energy,** the kinetic energy necessary to get a reaction going. The **active site** of an enzyme is a 3-D region where **substrates** come into close contact and thereby react more readily. When a substrate binds to an active site, an **enzyme-substrate complex** forms in which the shapes of the enzyme and substrate change slightly. This **induced fit** facilitates the breaking of bonds and formation of new ones.

10 Describe specific ways enzymes are regulated.

- Enzymes work best at specific temperature and pH conditions.
- A cell can regulate enzymatic activity by controlling the amount of enzyme produced and by regulating metabolic conditions that influence the shape of the enzyme.
- Some enzymes have **allosteric sites,** noncatalytic sites to which an **allosteric regulator** binds, changing the enzyme's activity. Some allosteric enzymes are subject to **feedback inhibition,** in which the formation of an end product inhibits an earlier reaction in the **metabolic pathway.**
- **Reversible inhibition** occurs when an inhibitor forms weak chemical bonds with the enzyme. Reversible inhibition may be **competitive,** in which the inhibitor competes with the substrate for the active site, or **noncompetitive,** in which the inhibitor binds with the enzyme at a site other than the active site. **Irreversible** inhibition occurs when an inhibitor combines with an enzyme and permanently inactivates it.

2. According to the second law of thermodynamics (a) energy may be changed from one form to another but is neither created nor destroyed (b) much of the work an organism does is mechanical work (c) the disorder of the universe is increasing (d) free energy is available to do cell work (e) a cell is in a state of dynamic equilibrium
3. In thermodynamics, _____ is a measure of the amount of disorder in the system. (a) bond energy (b) catabolism (c) entropy (d) enthalpy (e) work
4. The _____ energy of a system is that part of the total energy available to do cell work. (a) activation (b) bond (c) kinetic (d) free (e) heat
5. A reaction that requires a net input of free energy is described as (a) exergonic (b) endergonic (c) spontaneous (d) both a and c (e) both b and c
6. A reaction that releases energy is described as (a) exergonic (b) endergonic (c) spontaneous (d) both a and c (e) both b and c
7. A spontaneous reaction is one in which the change in free energy (ΔG) has a _____ value. (a) positive (b) negative (c) positive or negative (d) none of these (ΔG has no measurable value)
8. To drive a reaction that requires an input of energy (a) an enzyme-substrate complex must form (b) the concentration of ATP must be decreased (c) the activation energy must be increased (d) some reaction that yields energy must be coupled to it (e) some reaction that requires energy must be coupled to it
9. Which of the following reactions could be coupled to an endergonic reaction with $\Delta G = +3.56$ kJ/mol? (a) A $\longrightarrow$ B, $\Delta G = +6.08$ kJ/mol (b) C $\longrightarrow$ D, $\Delta G = +3.56$ kJ/mol (c) E $\longrightarrow$ F, $\Delta G = 0$ kJ/mol (d) G $\longrightarrow$ H, $\Delta G = -1.22$ kJ/mol (e) I $\longrightarrow$ J, $\Delta G = -5.91$ kJ/mol
10. Consider this reaction: Glucose + 6 O_2 $\longrightarrow$ 6 CO_2 + 6 H_2O ($\Delta G = -2880$ kJ/mol). Which of the following statements about this reaction is *not* true? (a) the reaction is spontaneous in a thermodynamic sense (b) a small amount of energy (activation energy) must be supplied to start the reaction, which then proceeds with a release of energy (c) the reaction is exergonic (d) the reaction can be coupled to an endergonic reaction (e) the reaction must be coupled to an exergonic reaction
11. The kinetic energy required to initiate a reaction is called (a) activation energy (b) bond energy (c) potential energy (d) free energy (e) heat energy
12. A biological catalyst that affects the rate of a chemical reaction without being consumed by the reaction is a(an) (a) product (b) cofactor (c) coenzyme (d) substrate (e) enzyme
13. The region of an enzyme molecule that combines with the substrate is the (a) allosteric site (b) reactant (c) active site (d) coenzyme (e) product
14. Which inhibitor binds to the active site of an enzyme? (a) noncompetitive inhibitor (b) competitive inhibitor (c) irreversible inhibitor (d) allosteric regulator (e) PABA
15. In the following reaction series, which enzyme(s) is/are most likely to have an allosteric site to which the end product E binds?

$$A \xrightarrow{\text{Enzyme 1}} B \xrightarrow{\text{Enzyme 2}} C \xrightarrow{\text{Enzyme 3}} D \xrightarrow{\text{Enzyme 4}} E$$

(a) enzyme 1 (b) enzyme 2 (c) enzyme 3 (d) enzyme 4 (e) enzymes 3 and 4

CRITICAL THINKING

1. Reactions 1 and 2 happen to have the same free energy change: $\Delta G = -41.8$ kJ/mol (-10 kcal/mol). Reaction 1 is at equilibrium, but reaction 2 is far from equilibrium. Is either reaction capable of performing work? If so, which one?
2. Let's say you are performing an experiment in which you are measuring the rate at which succinate is converted to fumarate by the enzyme succinic dehydrogenase. You decide to add a little malonate to make things interesting. You observe that the reaction rate slows markedly and hypothesize that malonate is inhibiting the reaction. Design an experiment that will help you decide whether malonate is acting as a competitive inhibitor or a noncompetitive inhibitor.
3. Given what you have learned in this chapter, explain why an extremely high fever (body temperature above 105°F or 40°C) is often fatal.

How Cells Make ATP: Energy-Releasing Pathways

Renee Lynn/Photo Researchers, Inc.

Female gerenuks. Gerenuks (*Litocranius walleri*) live in the dry brush country of East Africa, where they browse on leaves, fruits, and flowers of thorny trees and shrubs.

CHAPTER OUTLINE

- Redox Reactions
- The Four Stages of Aerobic Respiration
- Energy Yield of Nutrients Other Than Glucose
- Anaerobic Respiration and Fermentation

Cells are tiny factories that process materials on the molecular level, through thousands of metabolic reactions. Cells exist in a dynamic state and are continuously building up and breaking down the many different cell constituents. As you learned in Chapter 6, metabolism has two complementary components: **catabolism,** which releases energy by splitting complex molecules into smaller components, and **anabolism,** the synthesis of complex molecules from simpler building blocks. Anabolic reactions produce proteins, nucleic acids, lipids, polysaccharides, and other complex molecules that help maintain the cell or the organism. Most anabolic reactions are endergonic and require ATP or some other energy source to drive them.

Every organism must extract energy from the organic food molecules that it either manufactures by photosynthesis or captures from the environment. The gerenuks in the photograph, for example, obtain organic molecules when they eat the leaves of thorny shrubs and trees. How do they obtain energy from these organic molecules? First the complex food molecules are broken down by digestion into simpler components that are absorbed into the blood and transported to all the cells. The catabolic processes that convert the energy in the chemical bonds of nutrients to chemical energy stored in ATP then occur inside cells, usually through a process known as **cellular respiration.** (The term *cellular respiration* is used to distinguish it from *organismic respiration,* the exchange of oxygen and carbon dioxide with the environment by animals that have special organs, such as lungs or gills, for gas exchange.)

Cellular respiration may be either aerobic or anaerobic. **Aerobic** respiration requires molecular oxygen (O_2), whereas **anaerobic** pathways, which include anaerobic respiration and fermentation, do not require oxygen. A steady supply of oxygen enables your cells to capture energy through aerobic respiration, which is by far the most common pathway and the main subject of this chapter. All three pathways—aerobic respiration, anaerobic respiration, and fermentation—are exergonic and release free energy. ■

REDOX REACTIONS

Learning Objective

1 Write a summary reaction for aerobic respiration, showing which reactant becomes oxidized and which becomes reduced.

Most eukaryotes and prokaryotes carry out **aerobic respiration,** a form of cellular respiration requiring oxygen. During aerobic respiration, nutrients are catabolized to carbon dioxide and water. Most cells use aerobic respiration to obtain energy from glucose, which enters the cell though a specific transport protein in the plasma membrane (see discussion of facilitated diffusion in Chapter 5). The overall reaction pathway for the aerobic respiration of glucose is summarized as follows:

$$C_6H_{12}O_6 + 6\ O_2 + 6\ H_2O \longrightarrow 6\ CO_2 + 12\ H_2O + \text{energy (in the chemical bonds of ATP)}$$

Note that water is shown on both sides of the equation; this is because it is a reactant in some reactions and a product in others.

For purposes of discussion, the equation for aerobic respiration can be simplified to indicate that there is a net yield of water:

$$\underset{\text{Oxidation}}{\overset{\text{Reduction}}{C_6H_{12}O_6 + 6\ O_2 \rightarrow 6\ CO_2 + 6\ H_2O}} + \text{energy (in the chemical bonds of ATP)}$$

If we analyze this summary reaction, it appears CO_2 is produced by the removal of hydrogen atoms from glucose. Conversely, water seems to be formed as oxygen accepts the hydrogen atoms. Because the transfer of hydrogen atoms is equivalent to the transfer of electrons, this is a **redox reaction** in which glucose becomes **oxidized** and oxygen becomes **reduced** (see Chapters 2 and 6).

The products of the reaction would be the same if the glucose were simply placed in a test tube and burned in the presence of oxygen. However, if a cell were to burn glucose its energy would be released all at once as heat, which not only would be unavailable to the cell but also would actually destroy it. For this reason, cells do not transfer hydrogen atoms directly from glucose to oxygen. Aerobic respiration includes a series of redox reactions in which electrons associated with the hydrogen atoms in glucose are transferred to oxygen in a series of steps (Fig. 7-1). During this process, the free energy of the electrons is coupled to ATP synthesis.

Review

THE FOUR STAGES OF AEROBIC RESPIRATION

Learning Objectives

2 List and give a brief overview of the four stages of aerobic respiration.

3 Indicate where each stage of aerobic respiration takes place in a eukaryotic cell.

4 Add up the energy captured (as ATP, NADH, and $FADH_2$) in each stage of aerobic respiration.

5 Define *chemiosmosis,* and explain how a gradient of protons is established across the inner mitochondrial membrane.

6 Describe the process by which the proton gradient drives ATP synthesis in chemiosmosis.

The chemical reactions of the aerobic respiration of glucose are grouped into four stages (Fig. 7-2, Table 7-1; see also the summary equations at the end of the chapter). In eukaryotes, the first stage (glycolysis) takes place in the cytosol, and the remaining stages take place inside mitochondria. Most bacteria and archaea also carry out these processes, but because prokaryotic cells lack mitochondria the reactions of aerobic respiration occur in the cytosol and in association with the plasma membrane.

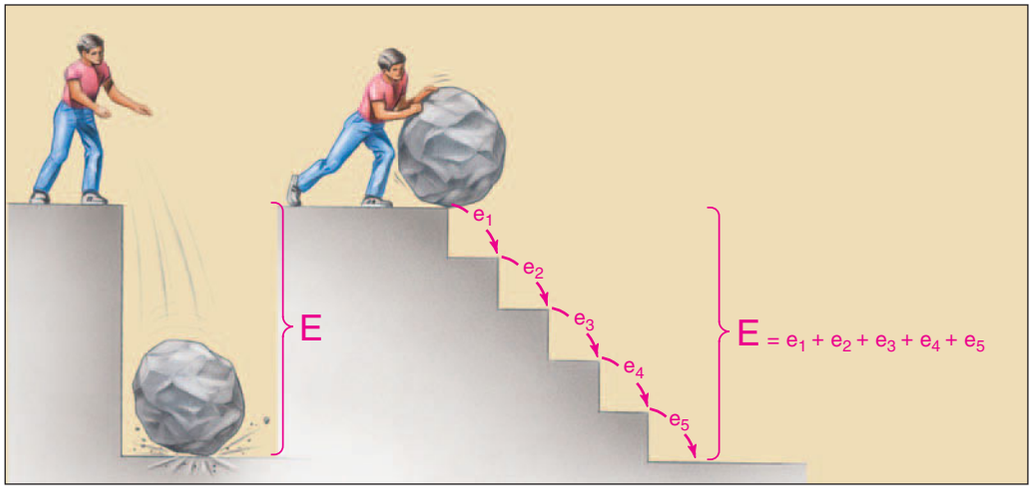

FIGURE **7-1**

Changes in free energy.

The release of energy from a glucose molecule is analogous to the liberation of energy by a falling object. The total energy released (*E*) is the same whether it occurs all at once or in a series of steps.

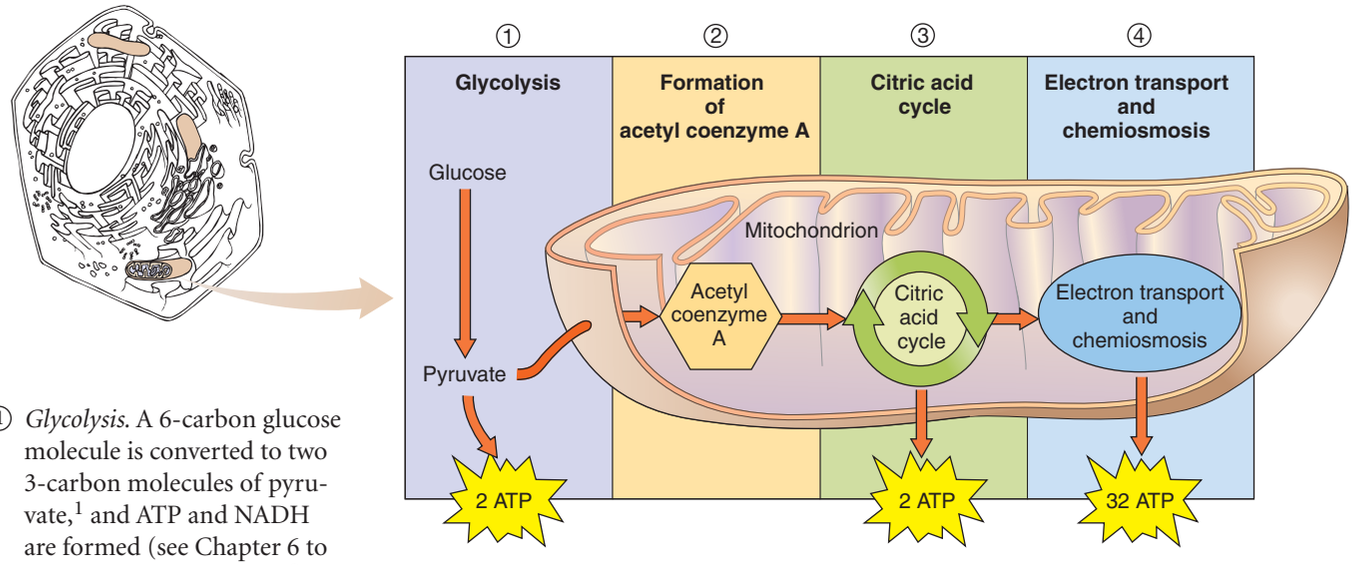

FIGURE 7-2 The four stages of aerobic respiration.
① Glycolysis, the first stage of aerobic respiration, occurs in the cytosol. ② Pyruvate, the product of glycolysis, enters a mitochondrion, where cellular respiration continues with the formation of acetyl CoA, ③ the citric acid cycle, and ④ electron transport/chemiosmosis. Most ATP is synthesized by chemiosmosis.

① *Glycolysis.* A 6-carbon glucose molecule is converted to two 3-carbon molecules of pyruvate,[1] and ATP and NADH are formed (see Chapter 6 to review ATP and NADH).[2]

② *Formation of acetyl coenzyme A.* Each pyruvate enters a mitochondrion and is oxidized to a 2-carbon group (acetate) that combines with coenzyme A, forming acetyl coenzyme A. NADH is produced, and carbon dioxide is released as a waste product.

③ *The citric acid cycle.* The acetate group of acetyl coenzyme A combines with a four-carbon molecule (oxaloacetate) to form a 6-carbon molecule (citrate). In the course of the cycle, citrate is recycled to oxaloacetate, and carbon dioxide is released as a waste product. Energy is captured as ATP and the reduced, high-energy compounds NADH and $FADH_2$ (see Chapter 6 to review $FADH_2$).

[1] Pyruvate and many other compounds in cellular respiration exist as anions at the pH found in the cell. They sometimes associate with H^+ to form acids. For example, pyruvate forms pyruvic acid. In some textbooks these compounds are presented in the acid form.

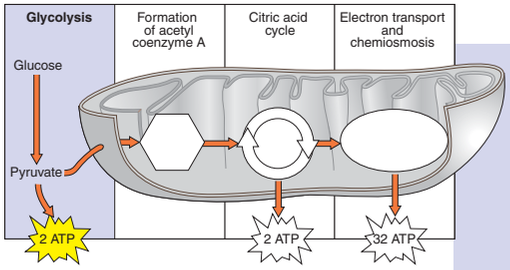
[2] Although the correct way to write the reduced form of NAD^+ is NADH + H^+, for simplicity we present the reduced form as NADH throughout the book.

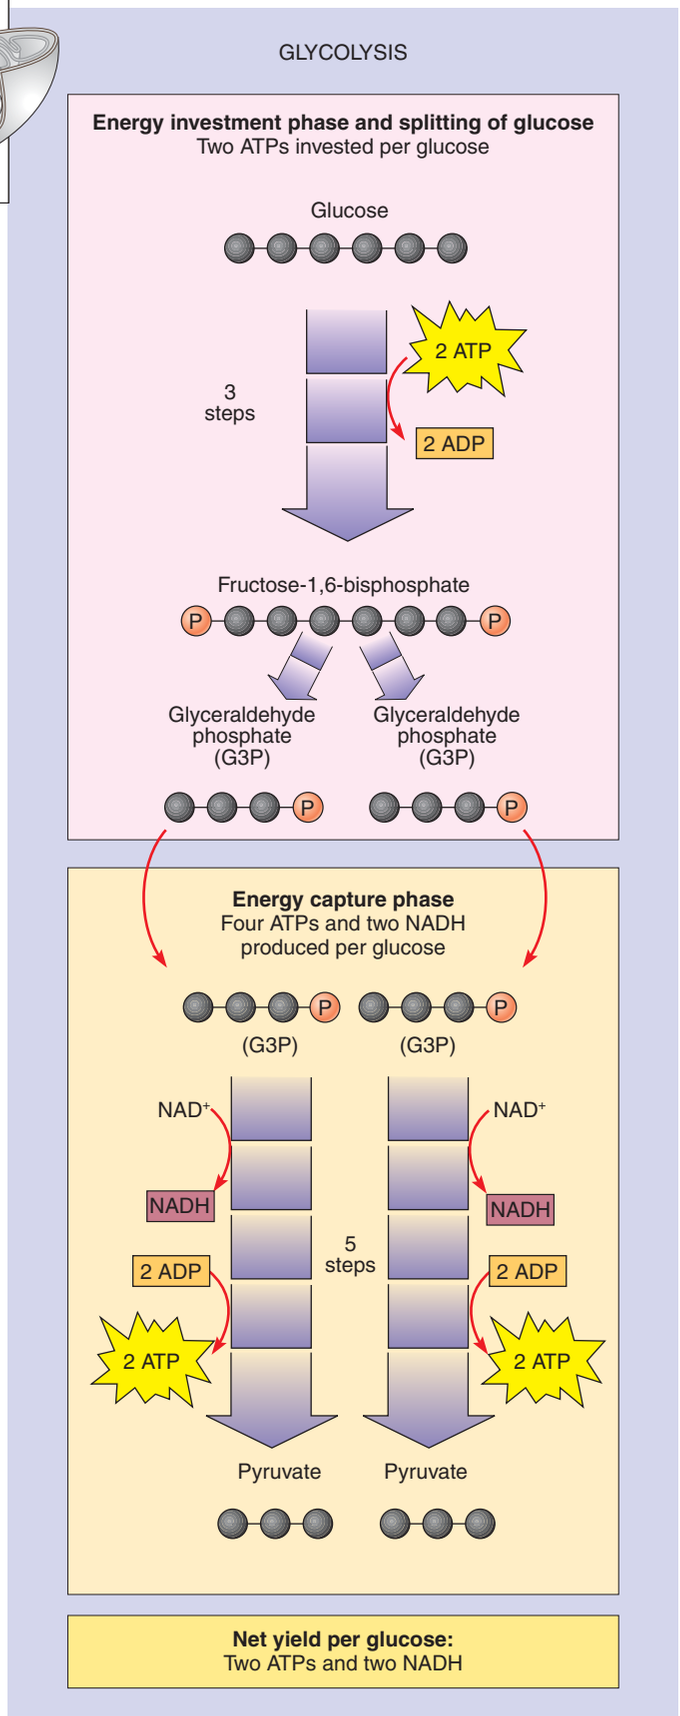
④ *The electron transport chain and chemiosmosis.* The electrons removed from glucose during the preceding stages are transferred from NADH and $FADH_2$ to a chain of electron acceptor compounds. As the electrons are passed from one electron acceptor to another, some of their energy is used to transport hydrogen ions (protons) across the inner mitochondrial membrane, forming a proton gradient. In a process known as *chemiosmosis* (described later), the energy of this proton gradient is used to produce ATP.

Most reactions involved in aerobic respiration are one of three types: dehydrogenations, decarboxylations, and those we infor-

TABLE 7-1 Summary of Aerobic Respiration

Stage	Summary	Some Starting Materials	Some End Products
1. Glycolysis (in cytosol)	Series of reactions in which glucose is degraded to pyruvate; net profit of 2 ATPs; hydrogen atoms are transferred to carriers; can proceed anaerobically	Glucose, ATP, NAD^+, ADP, P_i	Pyruvate, ATP, NADH
2. Formation of acetyl CoA (in mitochondria)	Pyruvate is degraded and combined with coenzyme A to form acetyl CoA; hydrogen atoms are transferred to carriers; CO_2 is released	Pyruvate, coenzyme A, NAD^+	Acetyl CoA, CO_2, NADH
3. Citric acid cycle (in mitochondria)	Series of reactions in which the acetyl portion of acetyl CoA is degraded to CO_2; hydrogen atoms are transferred to carriers; ATP is synthesized	Acetyl CoA, H_2O, NAD^+, FAD, ADP, P_i	CO_2 NADH, $FADH_2$, ATP
4. Electron transport and chemiosmosis (in mitochondria)	Chain of several electron transport molecules; electrons are passed along chain; released energy is used to form a proton gradient; ATP is synthesized as protons diffuse down the gradient; oxygen is final electron acceptor	NADH, $FADH_2$, O_2, ADP, P_i	ATP, H_2O, NAD^+, FAD





ACTIVE FIGURE **7-3** **An overview of glycolysis.**

The black spheres represent carbon atoms. The energy investment phase of glycolysis leads to the splitting of sugar; ATP and NADH are produced during the energy capture phase. During glycolysis, each glucose molecule is converted to two pyruvates, with a net yield of two ATP molecules and two NADH molecules.

Biology Now™ See the process of **glycolysis** unfold by clicking on this figure on your BiologyNow CD-ROM.

mally categorize as preparation reactions. **Dehydrogenations** are reactions in which two hydrogen atoms (actually, 2 electrons plus 1 or 2 protons) are removed from the substrate and transferred to NAD^+ or FAD. **Decarboxylations** are reactions in which part of a carboxyl group (—COOH) is removed from the substrate as a molecule of CO_2. The carbon dioxide you exhale with each breath is derived from decarboxylations that occur in your cells. The rest of the reactions are preparation reactions in which molecules undergo rearrangements and other changes so that they can undergo further dehydrogenations or decarboxylations. As you examine the individual reactions of aerobic respiration, you will encounter many examples of these three basic types.

In following the reactions of aerobic respiration, it helps to do some bookkeeping as you go along. Because glucose is the starting material, it is useful to express changes on a per glucose basis. We will pay particular attention to changes in the number of carbon atoms per molecule and to steps in which some type of energy transfer takes place.

In glycolysis, glucose yields two pyruvates

The word **glycolysis** comes from Greek words meaning "sugar splitting," which refers to the fact that the sugar glucose is metabolized. Glycolysis does not require oxygen and proceeds under aerobic or anaerobic conditions. Figure 7-3 shows a simplified overview of glycolysis, in which a glucose molecule consisting of six carbons is converted to two molecules of **pyruvate,** a three-carbon molecule. Some of the energy in the glucose is captured; there is a net yield of two ATP molecules and two NADH molecules. The reactions of glycolysis take place in the cytosol, where the necessary reactants, such as ADP, NAD^+, and inorganic phosphates, float freely and are used as needed.

The glycolysis pathway consists of a series of reactions, each of which is catalyzed by a specific enzyme (Fig. 7-4). Glycolysis is divided into two major phases: The first includes endergonic reactions that require ATP, and the second includes exergonic reactions that yield ATP and NADH.

The first phase of glycolysis requires an investment of ATP

The first phase of glycolysis is sometimes called the *energy investment phase* (Fig. 7-4, steps ① – ⑤). Glucose is a relatively stable molecule and is not easily broken down. In two separate **phosphorylation reactions,** a phosphate group is transferred from ATP to the sugar. The resulting phosphorylated sugar (fructose-1,6-bisphosphate) is less stable and is broken enzymatically into two 3-carbon molecules, dihydroxyacetone phosphate and glyceraldehyde-3-phosphate (G3P). The dihydroxyacetone phosphate is enzymatically converted to G3P, so the products at this point in glycolysis are two molecules of G3P. We can summarize this portion of glycolysis as follows:

$$\underset{\text{Six-carbon compound}}{\text{Glucose}} + 2\ \text{ATP} \longrightarrow 2\ \underset{\text{Three-carbon compound}}{\text{G3P}} + 2\ \text{ADP}$$

The second phase of glycolysis yields NADH and ATP

The second phase of glycolysis is sometimes called the *energy capture phase* (Fig. 7-4, steps ⑥ – ⑩). Each G3P is converted to pyruvate. In the first step of this process, each G3P is oxidized by the removal of 2 electrons (as part of two hydrogen atoms). These immediately combine with the hydrogen carrier molecule, NAD^+:

$$\underset{\text{Oxidized}}{NAD^+} + \underset{\text{(From G3P)}}{2\ H} \longrightarrow \underset{\text{Reduced}}{NADH} + H^+$$

Because there are two G3P molecules for every glucose, two NADH are formed. The energy of the electrons carried by NADH is used to form ATP later. This process is discussed in conjunction with the electron transport chain.

In two of the reactions leading to the formation of pyruvate, ATP forms when a phosphate group is transferred to ADP from a phosphorylated intermediate (see Fig. 7-4). This process is called **substrate-level phosphorylation.** Note that in the energy investment phase of glycolysis two molecules of ATP are consumed, but in the energy capture phase four molecules of ATP are produced. Thus glycolysis yields a net energy profit of *two* ATPs per glucose.

We can summarize the energy capture phase of glycolysis as follows:

$$2\ \text{G3P} + 2\ NAD^+ + 4\ \text{ADP} \longrightarrow 2\ \text{pyruvate} + 2\ \text{NADH} + 4\ \text{ATP}$$

Pyruvate is converted to acetyl CoA

In eukaryotes, the pyruvate molecules formed in glycolysis enter the mitochondria, where they are converted to **acetyl coenzyme A (acetyl CoA).** These reactions occur in the cytosol of aerobic prokaryotes. In this series of reactions, pyruvate undergoes a process known as **oxidative decarboxylation.** First, a carboxyl group is removed as carbon dioxide, which diffuses out of the cell (Fig. 7-5). Then the remaining two-carbon fragment is oxidized, and NAD^+ accepts the electrons removed during the oxidation. Finally, the oxidized two-carbon fragment, an acetyl group, becomes attached to **coenzyme A,** yielding acetyl CoA. *Pyruvate dehydrogenase,* the enzyme that catalyzes these reactions, is an enormous multienzyme complex consisting of 72 polypeptide chains!

Recall from Chapter 6 that coenzyme A transfers groups derived from organic acids. In this case, coenzyme A transfers an acetyl group, which is related to acetic acid. Coenzyme A is manufactured in the cell from one of the B vitamins, pantothenic acid.

The overall reaction for the formation of acetyl coenzyme A is

$$2\ \text{Pyruvate} + 2\ NAD^+ + 2\ \text{CoA} \longrightarrow 2\ \text{Acetyl CoA} + 2\ \text{NADH} + 2\ CO_2$$

Note that the original glucose molecule has now been partially oxidized, yielding two acetyl groups and two CO_2 molecules. The electrons removed have reduced NAD^+ to NADH. At this point in aerobic respiration, four NADH molecules have been formed as a result of the catabolism of a single glucose molecule: two during glycolysis and two during the formation of acetyl CoA from pyruvate. Keep in mind that these NADH molecules will be used later (during electron transport) to form additional ATP molecules.

The citric acid cycle oxidizes acetyl CoA

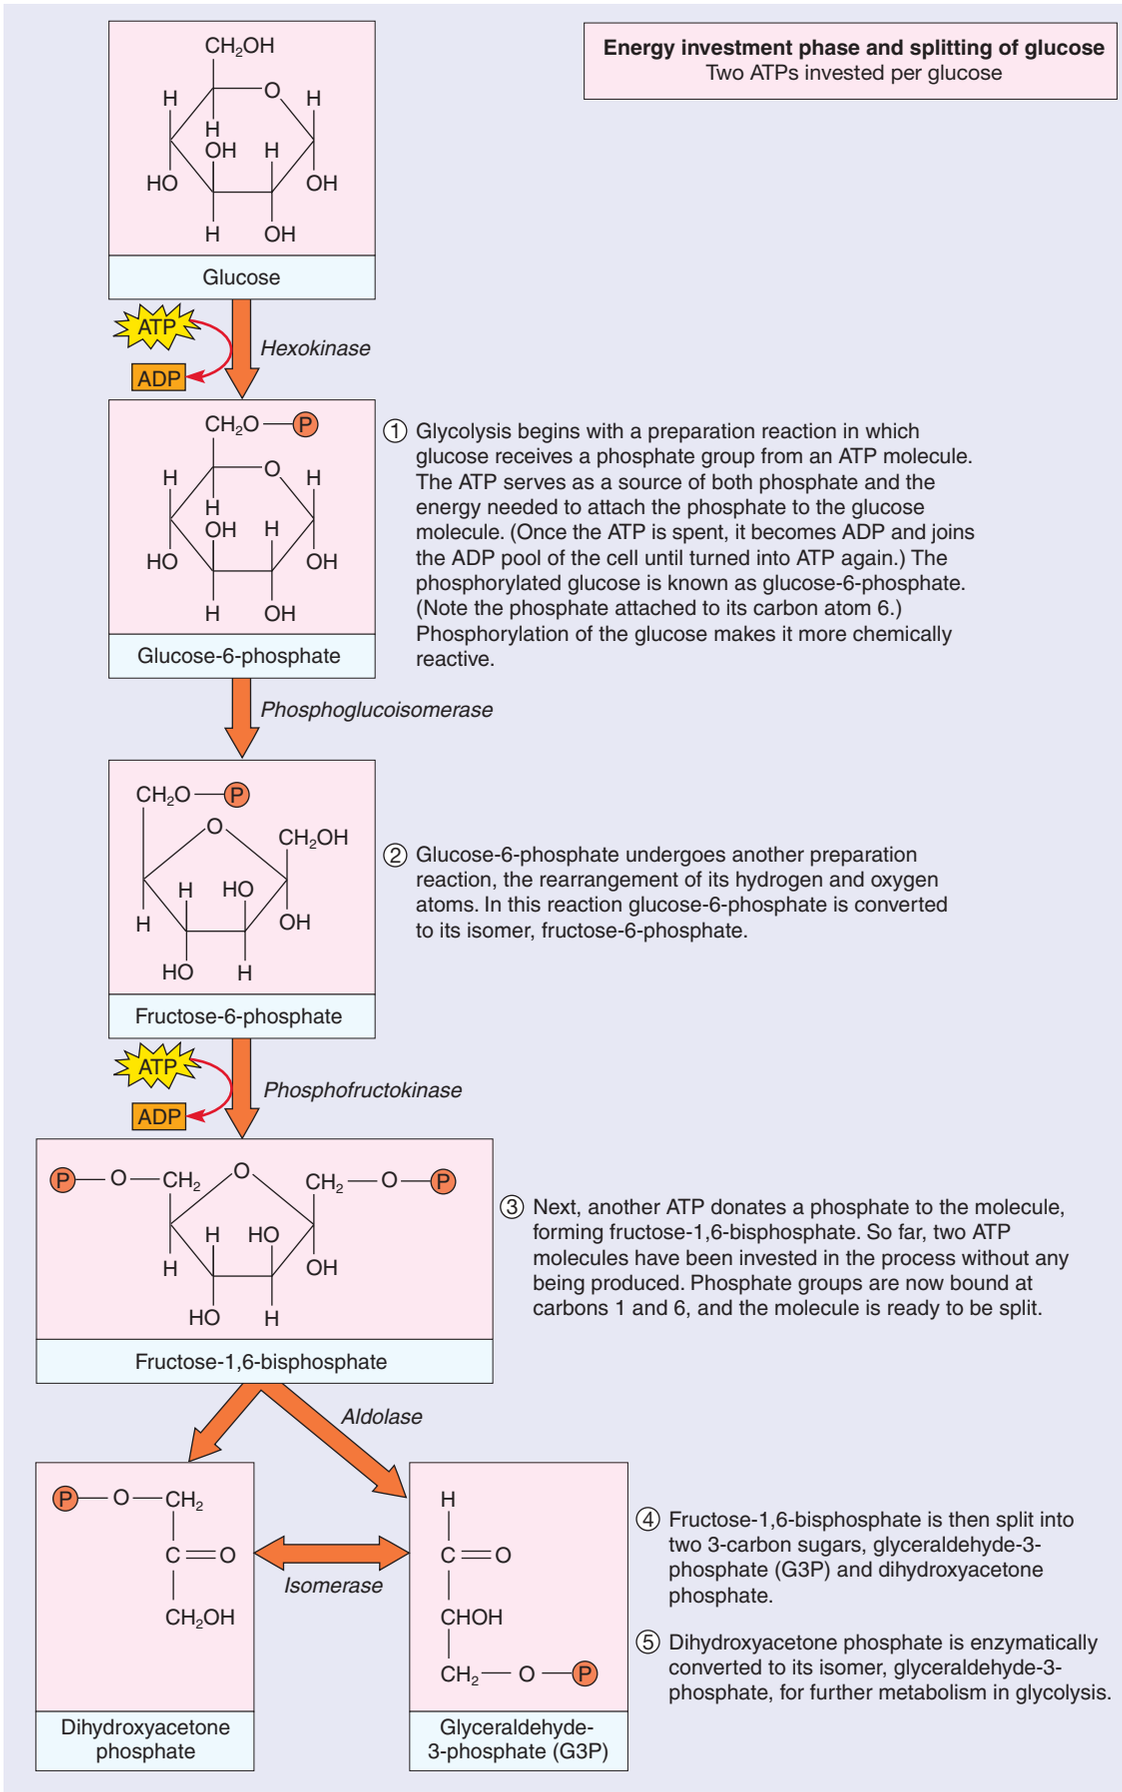
The **citric acid cycle** is also known as the **tricarboxylic acid (TCA) cycle** and the **Krebs cycle,** after Hans Krebs, the German biochemist who assembled the accumulated contributions of many scientists and worked out the details of the cycle in the 1930s. He received the Nobel Prize for Medicine in 1953 for this contribution. A simplified overview of the citric acid cycle, which takes place in the matrix of the mitochondria, is given in Figure 7-6. The eight steps of the citric acid cycle are shown in Figure 7-7. A specific enzyme catalyzes each reaction.

The first reaction of the cycle occurs when acetyl CoA transfers its two-carbon acetyl group to the four-carbon acceptor compound **oxaloacetate,** forming **citrate,** a six-carbon compound (step ①):

$$\underset{\text{Four-carbon compound}}{\text{Oxaloacetate}} + \underset{\text{Two-carbon compound}}{\text{acetyl CoA}} \longrightarrow \underset{\text{Six-carbon compound}}{\text{citrate}} + \text{CoA}$$

The citrate then goes through a series of chemical transformations, losing first one and then a second carboxyl group as CO_2 (steps ②, ③, and ④). Most of the energy made available by the oxidative steps of the cycle is transferred as energy-rich electrons to NAD^+, forming NADH. For each acetyl group that enters the citric acid cycle, three molecules of NADH are produced (steps ③, ④, and ⑧). Electrons are also transferred to the electron acceptor FAD, forming $FADH_2$ (step ⑥).

In the course of the citric acid cycle, two molecules of CO_2 and the equivalent of eight hydrogen atoms (8 protons and 8 electrons) are removed, forming three NADH and one $FADH_2$. You may wonder why more hydrogen is generated by these reactions than entered the cycle with the acetyl CoA molecule. These hydrogen atoms come from water molecules that are added during the reactions of the cycle. The CO_2 produced



Energy investment phase and splitting of glucose
Two ATPs invested per glucose
Glucose
ATP
ADP
Hexokinase
Glucose-6-phosphate
① Glycolysis begins with a preparation reaction in which glucose receives a phosphate group from an ATP molecule. The ATP serves as a source of both phosphate and the energy needed to attach the phosphate to the glucose molecule. (Once the ATP is spent, it becomes ADP and joins the ADP pool of the cell until turned into ATP again.) The phosphorylated glucose is known as glucose-6-phosphate. (Note the phosphate attached to its carbon atom 6.) Phosphorylation of the glucose makes it more chemically reactive.
Phosphoglucoisomerase
Fructose-6-phosphate
② Glucose-6-phosphate undergoes another preparation reaction, the rearrangement of its hydrogen and oxygen atoms. In this reaction glucose-6-phosphate is converted to its isomer, fructose-6-phosphate.
ATP
ADP
Phosphofructokinase
Fructose-1,6-bisphosphate
③ Next, another ATP donates a phosphate to the molecule, forming fructose-1,6-bisphosphate. So far, two ATP molecules have been invested in the process without any being produced. Phosphate groups are now bound at carbons 1 and 6, and the molecule is ready to be split.
Aldolase
Isomerase
Dihydroxyacetone phosphate
Glyceraldehyde-3-phosphate (G3P)
④ Fructose-1,6-bisphosphate is then split into two 3-carbon sugars, glyceraldehyde-3-phosphate (G3P) and dihydroxyacetone phosphate.
⑤ Dihydroxyacetone phosphate is enzymatically converted to its isomer, glyceraldehyde-3-phosphate, for further metabolism in glycolysis.

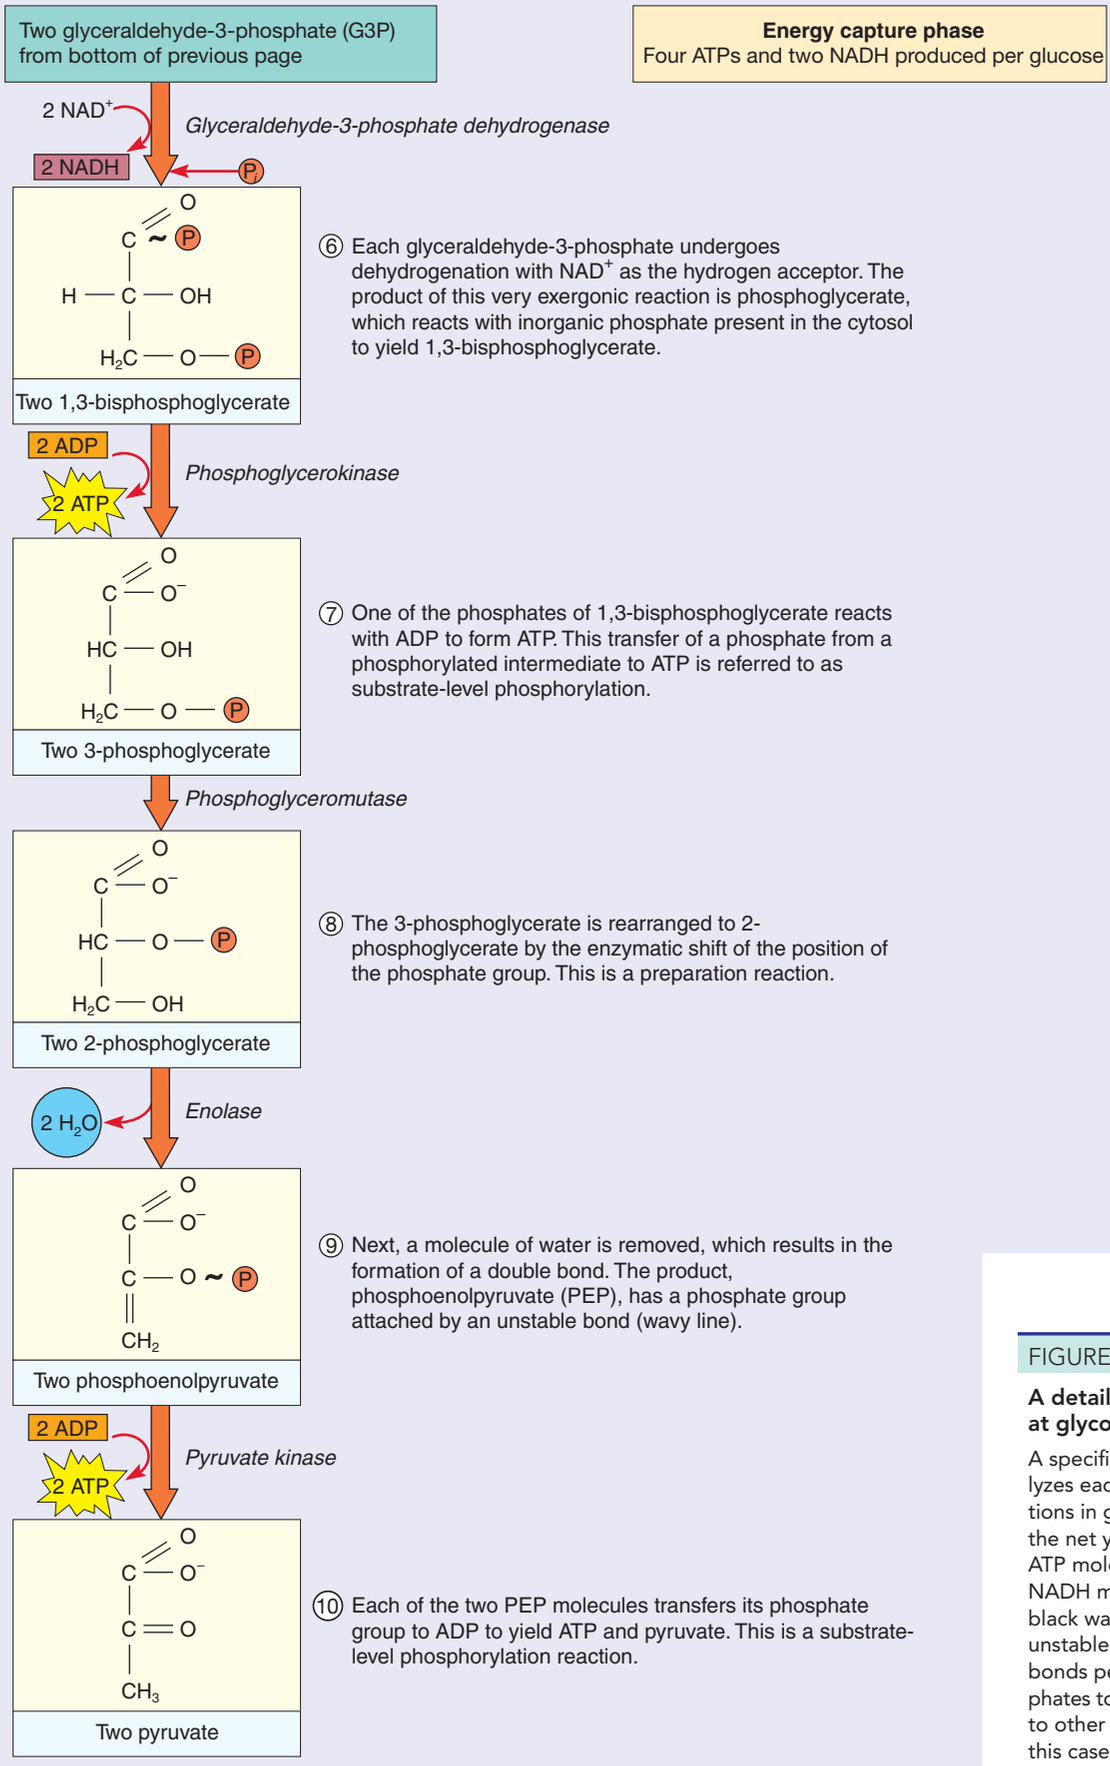


FIGURE **7-4**

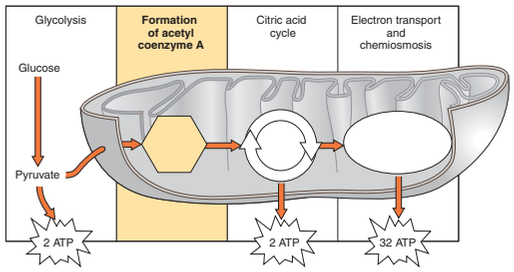
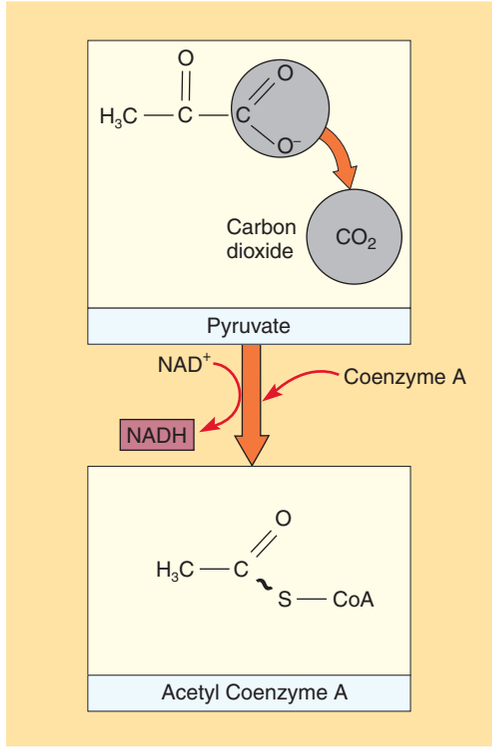
A detailed look at glycolysis.

A specific enzyme catalyzes each of the reactions in glycolysis. Note the net yield of two ATP molecules and two NADH molecules. (The black wavy lines indicate unstable bonds. These bonds permit the phosphates to be transferred to other molecules, in this case ADP.)

FIGURE 7-5 The formation of acetyl CoA.

This series of reactions is catalyzed by the enzyme pyruvate dehydrogenase. Pyruvate, a three-carbon molecule that is the end product of glycolysis, enters the mitochondrion and undergoes oxidative decarboxylation. First, the carboxyl group is split off as carbon dioxide. Then the remaining two-carbon fragment is oxidized, and its electrons are transferred to NAD^+. Finally, the oxidized two-carbon group, an acetyl group, is attached to coenzyme A. CoA has a sulfur atom that forms a very unstable bond, shown as a black wavy line, with the acetyl group.

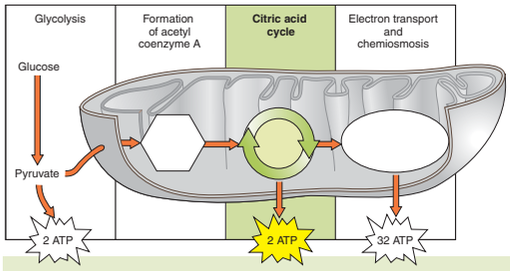


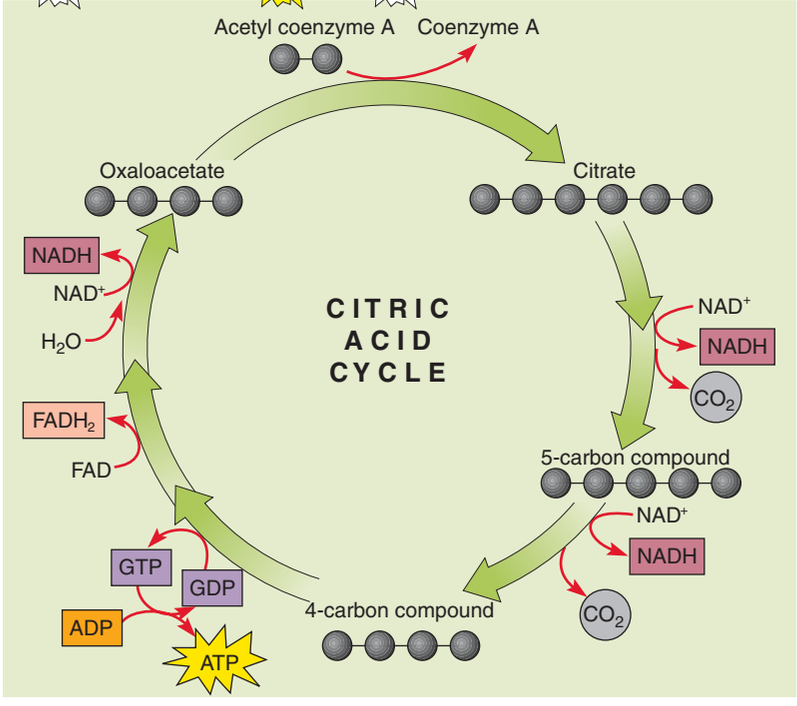


accounts for the two carbon atoms of the acetyl group that entered the citric acid cycle. At the end of each cycle, the four-carbon oxaloacetate has been regenerated (step ⑧), and the cycle continues.

Because two acetyl CoA molecules are produced from each glucose molecule, two cycles are required per glucose molecule. After two turns of the cycle, the original glucose has lost all its carbons and may be regarded as having been completely consumed. To summarize, the citric acid cycle yields 4 CO_2, 6 NADH, 2 $FADH_2$, and 2 ATP per glucose molecule.

At this point in aerobic respiration, only four molecules of ATP have been formed per glucose by substrate-level phosphorylation: two during glycolysis and two during the citric acid cycle (step ⑤). Most of the energy of the original glucose molecule is in the form of high-energy electrons in NADH and $FADH_2$. Their energy will be used to synthesize additional ATP through the electron transport chain and chemiosmosis.





The electron transport chain is coupled to ATP synthesis

Let's consider the fate of all the electrons removed from a molecule of glucose during glycolysis, acetyl

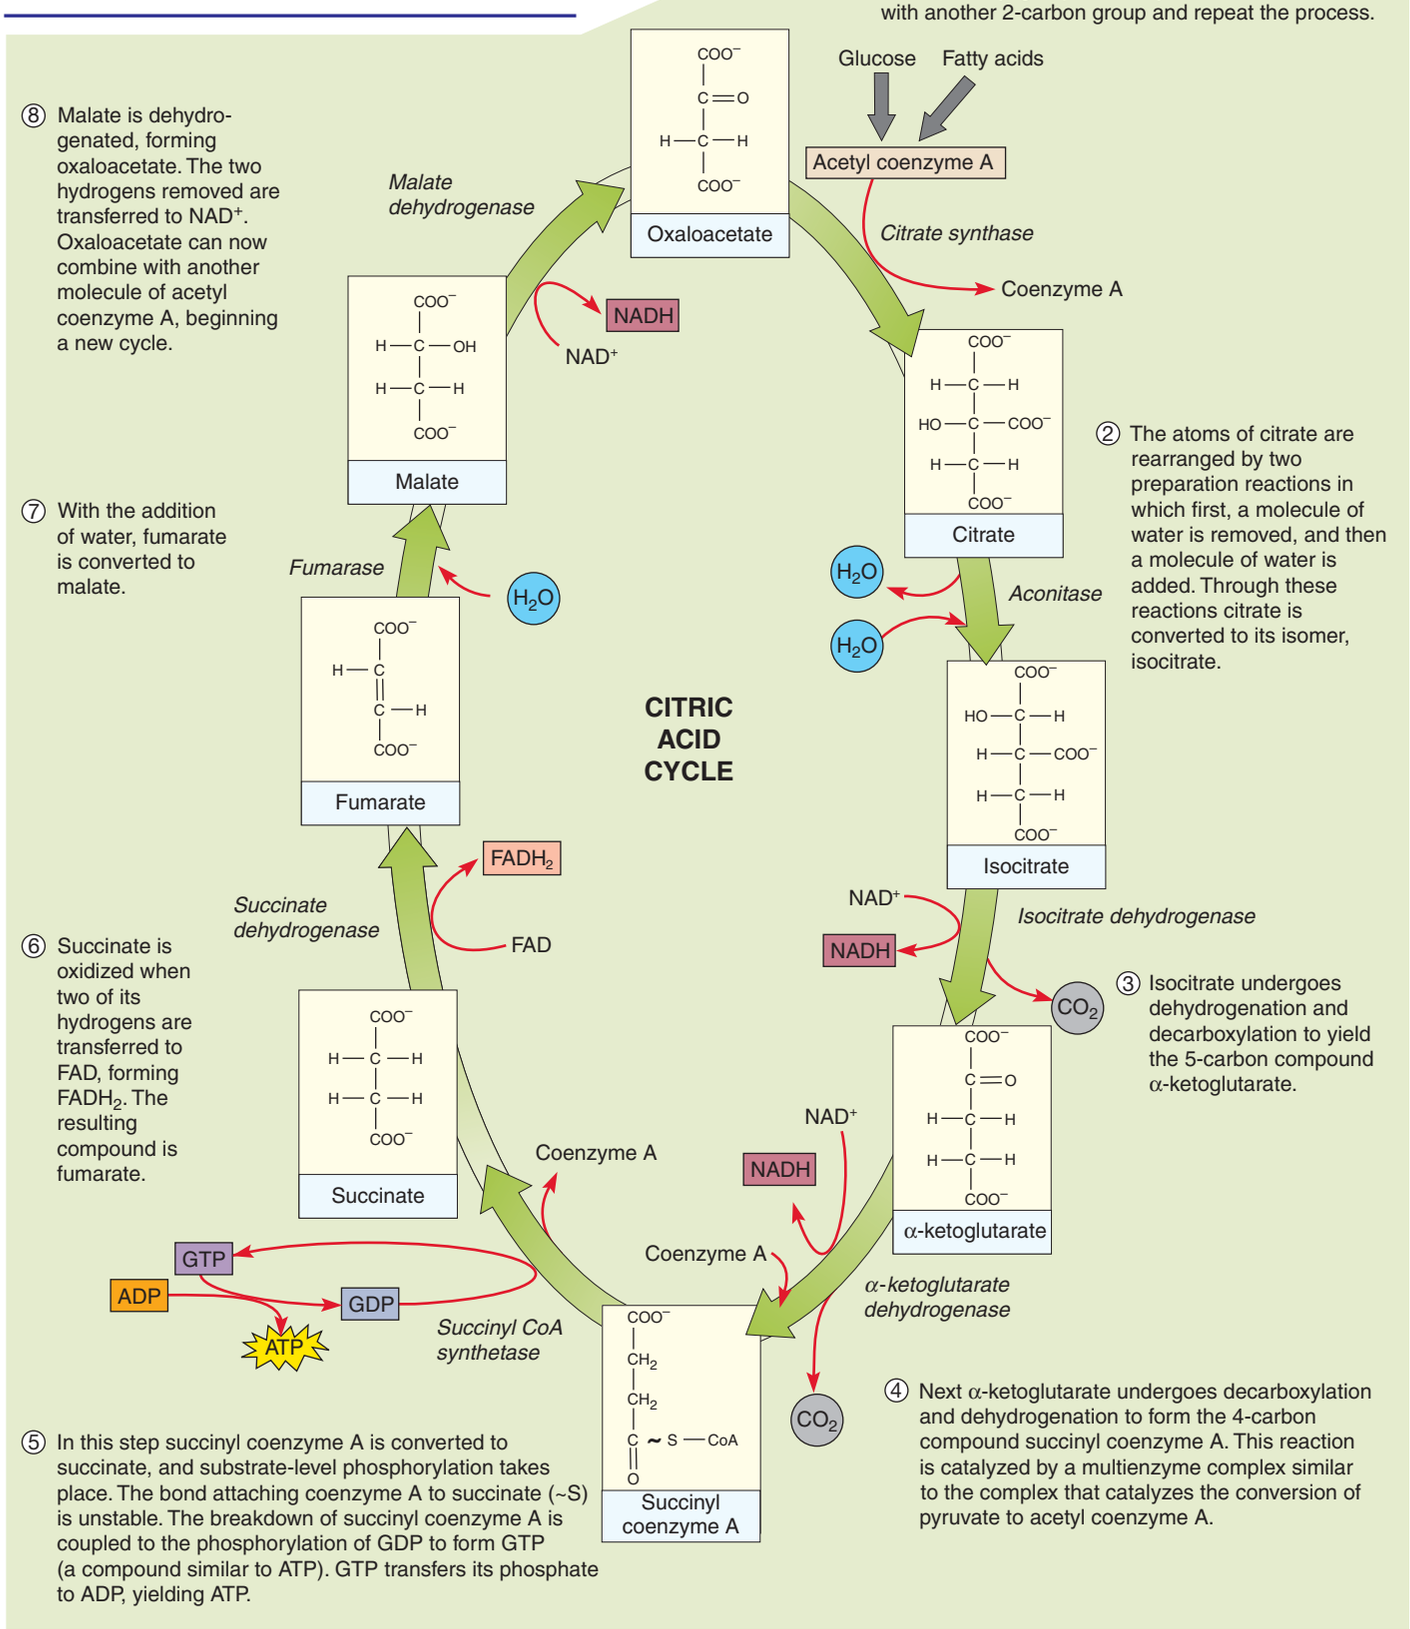
ACTIVE FIGURE 7-6 Overview of the citric acid cycle.

For every glucose, two acetyl groups enter the citric acid cycle *(top)*. Each two-carbon acetyl group combines with a four-carbon compound, oxaloacetate, to form the six-carbon compound citrate. Two CO_2 molecules are removed, and energy is captured as one ATP, three NADH, and one $FADH_2$ per acetyl group (or two ATPs, six NADH, and two $FADH_2$ per glucose molecule).

BiologyNow™ Interact with the **citric acid cycle** by clicking on this figure on your BiologyNow CD-ROM.

FIGURE **7-7** **A detailed look at the citric acid cycle.**

Begin with step (1), in the upper right corner, where acetyl coenzyme A attaches to oxaloacetate. During the citric acid cycle, the entry of a two-carbon acetyl group is balanced by the release of two molecules of CO_2. Electrons are transferred to NAD^+ or FAD, yielding NADH and $FADH_2$, respectively, and ATP is formed by substrate-level phosphorylation.



CoA formation, and the citric acid cycle. Recall that these electrons were transferred as part of hydrogen atoms to the acceptors NAD^+ and FAD, forming NADH and $FADH_2$. These reduced compounds now enter the **electron transport chain,** where the high-energy electrons of their hydrogen atoms are shuttled from one acceptor to another. As the electrons are passed along in a series of exergonic redox reactions, some of their energy is used to drive the synthesis of ATP, which is an endergonic process. Because ATP synthesis (by phosphorylation of ADP) is coupled to the redox reactions in the electron transport chain, the entire process is known as **oxidative phosphorylation.**

The electron transport chain transfers electrons from NADH and $FADH_2$ to oxygen

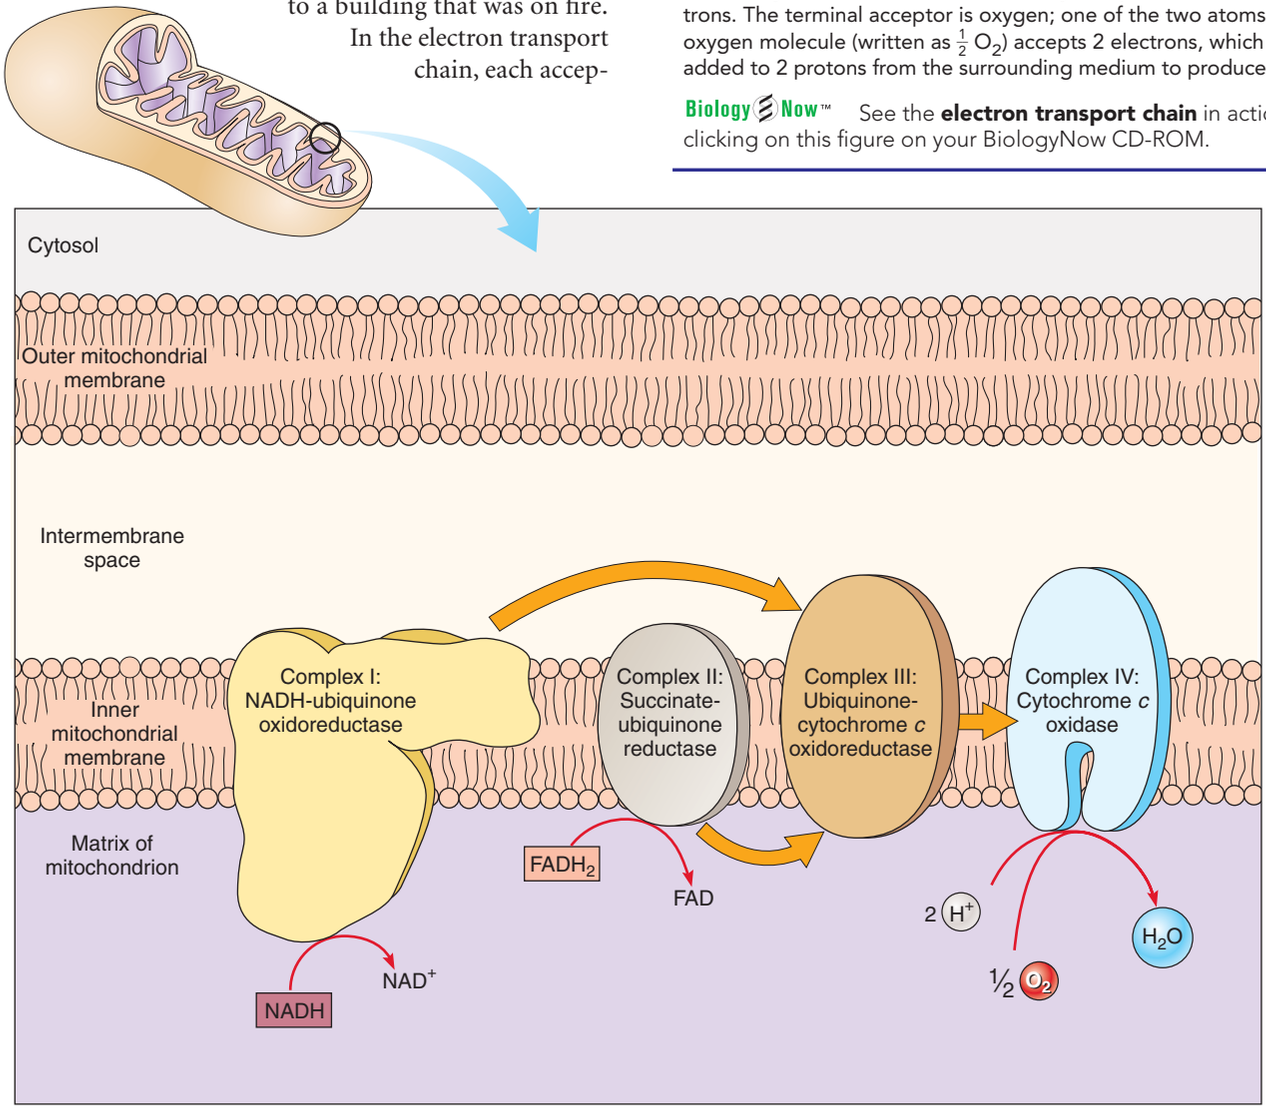
The electron transport chain is a series of electron carriers embedded in the inner mitochondrial membrane of eukaryotes and in the plasma membrane of aerobic prokaryotes. Like NADH and $FADH_2$, each carrier exists in an oxidized form or a reduced form. Electrons pass down the electron transport chain in a series of redox reactions that works much like a bucket brigade, the old-time chain of people who passed buckets of water from a stream to each other, to a building that was on fire. In the electron transport chain, each acceptor molecule becomes alternately reduced as it accepts electrons and oxidized as it gives them up. The electrons entering the electron transport chain have a relatively high energy content. They lose some of their energy at each step as they pass along the chain of electron carriers (just as some of the water spills out of the bucket as it is passed from one person to another).

Members of the electron transport chain include the flavoprotein *flavin mononucleotide (FMN),* the lipid *ubiquinone* (also called *coenzyme Q* or *CoQ*), several *iron-sulfur proteins,* and a group of closely related iron-containing proteins called *cytochromes* (Fig. 7-8). Each electron carrier has a different mechanism for accepting and passing electrons. As cytochromes accept and donate electrons, for example, the charge on the iron atom, which is the electron carrier portion of the cytochromes, alternates between Fe^{2+} (reduced) and Fe^{3+} (oxidized).

ACTIVE FIGURE **7-8** **An overview of the electron transport chain.**

Electrons fall to successively lower energy levels as they are passed along the four complexes of the electron transport chain located in the inner mitochondrial membrane. (The orange arrows indicate the pathway of electrons.) The carriers within each complex become alternately reduced and oxidized as they accept and donate electrons. The terminal acceptor is oxygen; one of the two atoms of an oxygen molecule (written as $\frac{1}{2}\ O_2$) accepts 2 electrons, which are added to 2 protons from the surrounding medium to produce water.

Biology Now™ See the **electron transport chain** in action by clicking on this figure on your BiologyNow CD-ROM.



What is the source of our body heat? Essentially, it is a byproduct of various exergonic reactions, especially those involving the electron transport chains in our mitochondria. Some cold-adapted animals, hibernating animals, and newborn animals produce unusually large amounts of heat by uncoupling electron transport from ATP production. These animals have **adipose tissue** (tissue in which fat is stored) that is brown. The brown color comes from the large number of mitochondria found in the brown adipose tissue cells. The inner mitochondrial membranes of these mitochondria contain an *uncoupling protein* that produces a passive proton channel through which protons flow into the mitochondrial matrix. As a consequence, most of the energy of glucose is converted to heat rather than to chemical energy in ATP.

Certain plants, which are not generally considered "warm" organisms, also have the ability to produce large amounts of heat. Skunk cabbage (*Symplocarpus foetidus*), for example, lives in North American swamps and wet woodlands and generally flowers during February and March when the ground is still covered with snow (see figure). Its uncoupled mitochondria generate large amounts of heat, enabling the plant to melt the snow and attract insect pollinators by vaporizing certain odiferous molecules into the surrounding air. The flower temperature of skunk cabbage is 15° to 22°C (59° to 72°F) when the air surrounding it is −15° to 10°C (5° to 50°F). Skunk cabbage flowers maintain this temperature for two weeks or more. Other plants, such as splitleaf philodendron (*Philodendron selloum*) and sacred lotus (*Nelumbo nucifera*), also generate heat when they bloom and maintain their temperatures within precise limits.

Leonard Lee Rue III/Earth Scenes

Skunk cabbage (*Symplocarpus foetidus*).
This plant not only produces a significant amount of heat when it flowers but also regulates its temperature within a specific range.

Some plants generate as much or more heat per gram of tissue than animals in flight, which have long been considered the greatest heat producers in the living world. The European plant lords-and-ladies (*Arum maculatum*), for example, produces 0.4 joules (0.1 cal) of heat per second per gram of tissue, whereas a hummingbird in flight produces 0.24 J (0.06 cal) per second per gram of tissue.

The electron transport chain has been isolated and purified from the inner mitochondrial membrane as four large, distinct protein complexes, or groups, of acceptors. *Complex I (NADH-ubiquinone oxidoreductase)* accepts electrons from NADH molecules that were produced during glycolysis, the formation of acetyl CoA, and the citric acid cycle. *Complex II (succinate-ubiquinone reductase)* accepts electrons from $FADH_2$ molecules that were produced during the citric acid cycle. Complexes I and II both produce the same product, reduced ubiquinone, which is the substrate of *complex III (ubiquinone-cytochrome* c *oxidoreductase)*. That is, complex III accepts electrons from reduced ubiquinone and passes them on to cytochrome *c*. *Complex IV (cytochrome* c *oxidase)* accepts electrons from cytochrome *c* and uses these electrons to reduce molecular oxygen, forming water in the process. The electrons simultaneously unite with protons from the surrounding medium to form hydrogen, and the chemical reaction between hydrogen and oxygen produces water.

Because oxygen is the final electron acceptor in the electron transport chain, organisms that respire aerobically require oxygen. What happens when cells that are strict aerobes are deprived of oxygen? When no oxygen is available to accept them, the last cytochrome in the chain is stuck with its electrons. When that occurs, each acceptor molecule in the chain remains stuck with electrons (each is reduced), and the entire chain is blocked all the way back to NADH. Because oxidative phosphorylation is coupled to electron transport, no further ATPs are produced by way of the electron transport chain. Most cells of multicellular organisms cannot live long without oxygen, because the small amount of ATP they produce by glycolysis alone is insufficient to sustain life processes.

Lack of oxygen is not the only factor that interferes with the electron transport chain. Some poisons, including cyanide, inhibit the normal activity of the cytochromes. Cyanide binds tightly to the iron in the last cytochrome in the electron transport chain (cytochrome a_3), making it unable to transport electrons to oxygen. This blocks the further passage of electrons through the chain, halting ATP production.

Although the flow of electrons in electron transport is usually tightly coupled to the production of ATP, some organisms uncouple the two processes to produce heat (see *Focus On: Electron Transport and Heat*).

The chemiosmotic model explains the coupling of ATP synthesis to electron transport in aerobic respiration

PROCESS OF SCIENCE

For decades, scientists were aware that oxidative phosphorylation occurs in mitochondria, and many experiments had shown

that the transfer of 2 electrons from each NADH to oxygen (via the electron transport chain) usually results in the production of up to three ATP molecules. However, for a long time, the connection between ATP synthesis and electron transport remained a mystery.

In 1961 Peter Mitchell, a British biochemist, proposed the *chemiosmotic model,* based on his experiments with bacteria. Because the respiratory electron transport chain is located in the plasma membrane of an aerobic bacterial cell, the bacterial plasma membrane can be considered comparable to the inner mitochondrial membrane. Mitchell demonstrated that if bacterial cells are placed in an acidic environment (that is, an environment with a high hydrogen ion, or proton, concentration), the cells synthesized ATP even if electron transport was not taking place. On the basis of these and other experiments, Mitchell proposed that electron transport and ATP synthesis are coupled by means of a proton gradient across the inner mitochondrial membrane in eukaryotes (or across the plasma membrane in bacteria). His model was so radical it was not immediately accepted. By 1978 so much evidence had accumulated in support of **chemiosmosis** that Peter Mitchell was awarded a Nobel Prize for Chemistry.

The electron transport chain establishes the proton gradient; some of the energy released as electrons pass down the electron transport chain is used to move protons (H^+) across a membrane. In eukaryotes the protons are moved across the inner mitochondrial membrane into the intermembrane space (Fig. 7-9). Hence the inner mitochondrial membrane separates a space with a higher concentration of protons (the intermembrane space) from a space with a lower concentration of protons (the mitochondrial matrix).

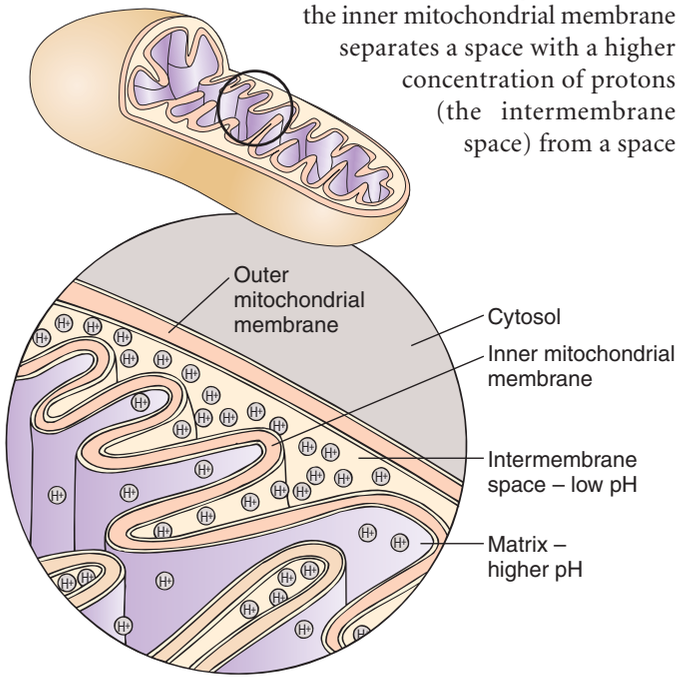


FIGURE **7-9** **The accumulation of protons (H^+) within the intermembrane space.**

As electrons move down the electron transport chain, the electron transport complexes move protons (H^+) from the matrix to the intermembrane space, creating a proton gradient. The high concentration of H^+ in the intermembrane space lowers the pH.

Protons are moved across the inner mitochondrial membrane by three of the four electron transport complexes (complexes I, III, and IV) (Fig. 7-10a). Like water behind a dam, the resulting proton gradient is a form of potential energy that can be harnessed to provide the energy for ATP synthesis.

Diffusion of protons from the intermembrane space, where they are highly concentrated, through the inner mitochondrial membrane to the matrix of the mitochondrion is limited to specific channels formed by a fifth enzyme complex, **ATP synthase,** a transmembrane protein. Portions of these complexes project from the inner surface of the membrane (the surface that faces the matrix) and are visible by electron microscopy (Fig. 7-10b). Diffusion of the protons down their gradient, through the ATP synthase complex, is exergonic because the entropy of the system increases. This exergonic process provides the energy for ATP production, although the exact mechanism by which ATP synthase catalyzes the phosphorylation of ADP is still not completely understood. In 1997, Paul Boyer of the University of California at Los Angeles and John Walker, of the Medical Research Council Laboratory of Molecular Biology, Cambridge, United Kingdom, shared the Nobel Prize for chemistry for the discovery that ATP synthase functions in an unusual way. Experimental evidence strongly suggests ATP synthase acts like a highly efficient molecular motor: During the production of ATP from ADP and inorganic phosphate, a central structure of ATP synthase rotates, possibly in response to the force of protons moving through the enzyme complex. The rotation apparently alters the conformation of the catalytic subunits in a way that allows ATP synthesis.

Chemiosmosis is a fundamental mechanism of energy coupling in cells; it allows exergonic redox reactions to drive the endergonic reaction in which ATP is produced by phosphorylating ADP. In photosynthesis (see Chapter 8), ATP is produced by a comparable process.

Aerobic respiration of one glucose yields a maximum of 36–38 ATPs

Let's now review where biologically useful energy is captured in aerobic respiration and calculate the total energy yield from the complete oxidation of glucose. Figure 7-11 summarizes the arithmetic involved.

1. In glycolysis, glucose is activated by the addition of phosphates from 2 ATP molecules and converted ultimately to 2 pyruvates + 2 NADH + 4 ATPs, yielding a net profit of 2 ATPs.
2. The 2 pyruvates are metabolized to 2 acetyl CoA + 2 CO_2 + 2 NADH.
3. In the citric acid cycle the 2 acetyl CoA molecules are metabolized to 4 CO_2 + 6 NADH + 2 $FADH_2$ + 2 ATPs.

   Because the oxidation of NADH in the electron transport chain yields up to 3 ATPs per molecule, the total of 10

(b)

FIGURE **7-10** **A detailed look at electron transport and chemiosmosis.**

(a) The electron transport chain in the inner mitochondrial membrane includes three proton pumps that are located in three of the four electron transport complexes. (The orange arrows indicate the pathway of electrons, and the black arrows the pathway of protons.) The energy released during electron transport is used to transport protons (H^+) from the mitochondrial matrix to the intermembrane space, where a high concentration of protons accumulates. The protons cannot diffuse back into the matrix except through special channels in ATP synthase in the inner membrane. The flow of the protons through ATP synthase provides the energy for generating ATP from ADP and P_i. In the process, the inner part of ATP synthase rotates *(thick red arrows)* like a motor. **(b)** This TEM shows hundreds of projections of ATP synthase complexes along the surface of the inner mitochondrial membrane.

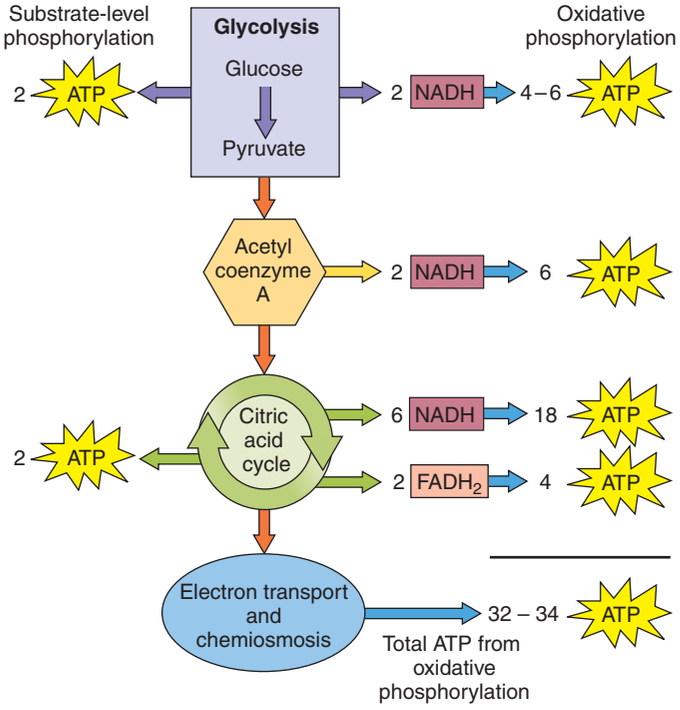

FIGURE **7-11** **Energy yield from the complete oxidation of glucose by aerobic respiration.**

A maximum of 36 to 38 ATPs are produced per glucose molecule. Of these ATPs, four are produced by substrate-level phosphorylation, and the remainder by oxidative phosphorylation (that is, electron transport and chemiosmosis).

NADH molecules can yield up to 30 ATPs. The 2 NADH molecules from glycolysis, however, yield either 2 or 3 ATPs each. This is because certain types of eukaryotic cells must expend energy to shuttle the NADH produced by glycolysis across the mitochondrial membrane (to be discussed shortly). Prokaryotic cells lack mitochondria; hence they have no need to shuttle NADH molecules. For this reason, bacteria are able to generate 3 ATPs for every NADH, even those produced during glycolysis. Thus, the maximum number of ATPs formed using the energy from NADH is 28 to 30.

The oxidation of $FADH_2$ yields 2 ATPs per molecule (recall that $FADH_2$ enters the electron transport chain at a different location from NADH), so the 2 $FADH_2$ molecules produced in the citric acid cycle yield 4 ATPs.

4. Summing all the ATPs (2 from glycolysis, 2 from the citric acid cycle, and 32 to 34 from electron transport and chemiosmosis), you can see that the complete aerobic metabolism of one molecule of glucose yields a maximum of 36 to 38 ATPs. Note that most of the ATPs are generated by oxidative phosphorylation, which involves the electron transport chain and chemiosmosis. Only 4 ATPs are formed by substrate-level phosphorylation in glycolysis and the citric acid cycle.

We can analyze the efficiency of the overall process of aerobic respiration by comparing the free energy captured as ATP to the total free energy in a glucose molecule. Recall from Chapter 6 that, although heat energy cannot power biological reactions, it is convenient to measure energy as heat. This is done through the use of a calorimeter, an instrument that measures the heat of a reaction. A sample is placed in a compartment surrounded by a chamber of water. As the sample burns (becomes oxidized), the temperature of the water rises, providing a measure of the heat released during the reaction.

When 1 mol of glucose is burned in a calorimeter, some 686 kcal (2870 kJ) are released as heat. The free energy temporarily held in the phosphate bonds of ATP is about 7.6 kcal (31.8 kJ) per mole. When 36 to 38 ATPs are generated during the aerobic respiration of glucose, the free energy trapped in ATP amounts to 7.6 kcal/mol × 36, or about 274 kcal (1146 kJ) per mole. Thus the efficiency of aerobic respiration is 274/686, or about 40%. (By comparison, a steam power plant has an efficiency of 35% to 36% in converting its fuel energy into electricity.) The remainder of the energy in the glucose is released as heat.

Mitochondrial shuttle systems harvest the electrons of NADH produced in the cytosol

The inner mitochondrial membrane is not permeable to NADH, which is a large molecule. Therefore, the NADH molecules produced in the cytosol during glycolysis cannot diffuse into the mitochondria to transfer their electrons to the electron transport chain. Unlike ATP and ADP, NADH does not have a carrier protein to transport it across the membrane. Instead, several systems have evolved to transfer just the *electrons* of NADH, not the NADH molecules themselves, into the mitochondria.

In liver, kidney, and heart cells, a special shuttle system transfers the electrons from NADH through the inner mitochondrial membrane to an NAD^+ molecule in the matrix. These electrons are transferred to the electron transport chain in the inner mitochondrial membrane, and up to three molecules of ATP are produced per pair of electrons.

In skeletal muscle, brain, and some other types of cells, another type of shuttle operates. Because this shuttle requires more energy than the shuttle in liver, kidney, and heart cells, the electrons are at a lower energy level when they enter the electron transport chain. They are accepted by ubiquinone rather than by NAD^+ and so generate a maximum of 2 ATP molecules per pair of electrons. This is why the number of ATPs produced by aerobic respiration of 1 molecule of glucose in skeletal muscle cells is 36 rather than 38.

Review

ENERGY YIELD OF NUTRIENTS OTHER THAN GLUCOSE

Learning Objective

7 Summarize how the products of protein and lipid catabolism enter the same metabolic pathway that oxidizes glucose.

Many organisms, including humans, depend on nutrients other than glucose as a source of energy. In fact, you usually obtain more of your energy by oxidizing fatty acids than by oxidizing glucose. Amino acids derived from protein digestion are also used as fuel molecules. Such nutrients are transformed into one of the metabolic intermediates that are fed into glycolysis or the citric acid cycle (Fig. 7-12).

Amino acids are metabolized by reactions in which the amino group (—NH_2) is first removed, a process called **deamination.** In mammals and some other animals, the amino group is converted to urea (see Fig. 46-1) and excreted, but the carbon chain is metabolized and eventually is used as a reactant in one of the steps of aerobic respiration. The amino acid alanine, for example, undergoes deamination to become pyruvate, the amino acid glutamate is converted to α-ketoglutarate, and the amino acid aspartate yields oxaloacetate. Pyruvate enters aerobic respiration as the end product of glycolysis, and α-ketoglutarate and oxaloacetate both enter aerobic respiration as intermediates in the citric acid cycle. Ultimately, the carbon chains of all the amino acids are metabolized in this way.

Each gram of lipid in the diet contains 9 kcal (38 kJ), more than twice as much energy as 1 g of glucose or amino acids, which have about 4 kcal (17 kJ) per gram. Lipids are rich in energy because they are highly reduced; that is, they have many hydrogen atoms and few oxygen atoms. When completely oxidized in aerobic respiration, a molecule of a six-carbon fatty acid generates up to 44 ATPs (compared with 36 to 38 ATPs for a molecule of glucose, which also has 6 carbons).

Both the glycerol and fatty acid components of a triacylglycerol (see Chapter 3) are used as fuel; phosphate is added to glycerol, converting it to G3P or another compound that enters glycolysis. Fatty acids are oxidized and split enzymatically into two-carbon acetyl groups that are bound to coenzyme A; that is, fatty acids are converted to acetyl CoA. This process, which occurs in the mitochondrial matrix, is called **beta-oxidation,** or **β-oxidation.** Acetyl CoA molecules formed by β-oxidation enter the citric acid cycle.

ANAEROBIC RESPIRATION AND FERMENTATION

Learning Objective

8 Compare and contrast anaerobic respiration and fermentation; include the mechanism of ATP formation, the final electron acceptor, and the end products.

Anaerobic respiration, which does not use oxygen as the final electron acceptor, is performed by some prokaryotes that live in anaerobic environments such as waterlogged soil, stagnant ponds, or animal intestines. As in aerobic respiration, electrons are transferred in anaerobic respiration from glucose to NADH; they then pass down an electron transport chain that is coupled to ATP synthesis by chemiosmosis. However, an inorganic substance such as nitrate (NO_3^-) or sulfate (SO_4^{2-}) replaces molecular oxygen as the terminal electron acceptor. The end products of this type of anaerobic respiration are carbon dioxide,

one or more reduced inorganic substances, and ATP. One representative type of anaerobic respiration, which is part of the biogeochemical cycle known as the **nitrogen cycle** (see Chapter 53) is summarized below.

$$C_6H_{12}O_6 + 12\ KNO_3 \longrightarrow 6\ CO_2 + 6\ H_2O + 12\ KNO_2 + \text{energy}$$

Potassium nitrate: $12\ KNO_3$. Potassium nitrite: $12\ KNO_2$. Energy: (in the chemical bonds of ATP)

Certain other bacteria, as well as some fungi, regularly use **fermentation,** an anaerobic pathway that does not involve an electron transport chain. During fermentation only two ATPs are formed per glucose (by substrate-level phosphorylation during glycolysis). One might expect that a cell that obtains energy from glycolysis would produce pyruvate, the end product of glycolysis. However, this cannot happen because every cell has a limited supply of NAD^+, and NAD^+ is required for glycolysis to continue. If virtually all NAD^+ becomes reduced to NADH during glycolysis, then glycolysis stops, and no more ATP is produced.

In fermentation, NADH molecules transfer their hydrogen atoms to organic molecules, thus regenerating the NAD^+ needed to keep glycolysis going. The resulting relatively reduced organic molecules (commonly alcohol or lactate) tend to be toxic to the cells and are essentially waste products.

Table 7-2 compares the three processes: aerobic respiration, anaerobic respiration, and fermentation.

Alcohol fermentation and lactate fermentation are inefficient

Yeasts are **facultative anaerobes** that carry out aerobic respiration when oxygen is available but switch to **alcohol fermentation** when deprived of oxygen (Fig. 7-13a). These eukaryotic, unicellular fungi have enzymes that decarboxylate pyruvate, releasing carbon dioxide and forming a two-carbon compound called *acetaldehyde.* NADH produced during glycolysis transfers hydrogen atoms to acetaldehyde, reducing it to *ethyl alcohol* (Fig. 7-13b). Alcohol fermentation is the basis for the production of beer, wine, and other alcoholic beverages. Yeast cells are also used in baking to produce the carbon dioxide that causes dough to rise; the alcohol evaporates during baking.

Certain fungi and bacteria perform **lactate (lactic acid) fermentation.** In this alternative pathway, NADH produced during glycolysis transfers hydrogen atoms to pyruvate, reducing it to *lactate* (Fig. 7-13c). The ability of some bacteria to produce lactate is exploited by humans, who use these bacteria to make yogurt and to ferment cabbage for sauerkraut.

Lactate is also produced by muscle cells. Exercise can cause fatigue and muscle cramps possibly due to insufficient oxygen, the depletion of fuel molecules, and the accumulation of lactate during strenuous activity. This buildup of lactate occurs because muscle cells shift briefly to lactate fermentation if the amount of oxygen delivered to muscle cells is insufficient to support aerobic respiration. The shift is only temporary, however, and oxygen is required for sustained work. About 80% of the lactate is eventually exported to the liver, where it is used to regenerate more glucose for the muscle cells. The remaining 20% of the lactate is metabolized in muscle cells in the presence of oxygen. This explains why you continue to breathe heavily after you have stopped exercising: The additional oxygen is needed to oxidize lactate, thereby restoring the muscle cells to their normal state.

Although humans use lactate fermentation to produce ATP for only a few minutes, a few animals can live without oxygen for much longer periods. The red-eared slider, a freshwater turtle, remains under water for as long as two weeks. During this time, it is relatively inactive and therefore does not expend a great deal of energy. It relies on lactate fermentation for ATP production.

Both alcohol fermentation and lactate fermentation are highly inefficient, because the fuel is only partially oxidized. Alcohol, the end product of fermentation by yeast cells, can be burned and is even used as automobile fuel; obviously, it contains a great deal of energy that the yeast cells cannot extract using anaerobic methods. Lactate, a three-carbon compound, contains even more energy than the two-carbon alcohol. In contrast, all available energy is removed during aerobic respiration, because the fuel molecules become completely oxidized to CO_2. A net profit of only 2 ATPs is produced by the fermentation of one molecule of glucose, compared with up to 36 to 38 ATPs when oxygen is available.

The inefficiency of fermentation necessitates a large supply of fuel. To perform the same amount of work, a cell engaged in fermentation must consume up to 20 times more glucose or other carbohydrate per second than a cell using aerobic respi-

TABLE 7-2 A Comparison of Aerobic Respiration, Anaerobic Respiration, and Fermentation

	Aerobic Respiration	Anaerobic Respiration	Fermentation
Immediate Fate of Electrons in NADH	Transferred to electron transport chain	Transferred to electron transport chain	Transferred to organic molecule
Terminal Electron Acceptor of Electron Transport Chain	O_2	Inorganic substances such as NO_3^- or SO_4^{2-}	No electron transport chain
Reduced Product(s) Formed	Water	Relatively reduced inorganic substances	Relatively reduced organic compounds (commonly, alcohol or lactate)
Mechanism of ATP Synthesis	Oxidative phosphorylation/ chemiosmosis; also substrate-level phosphorylation	Oxidative phosphorylation/chemiosmosis; also substrate-level phosphorylation	Substrate-level phosphorylation only (during glycolysis)

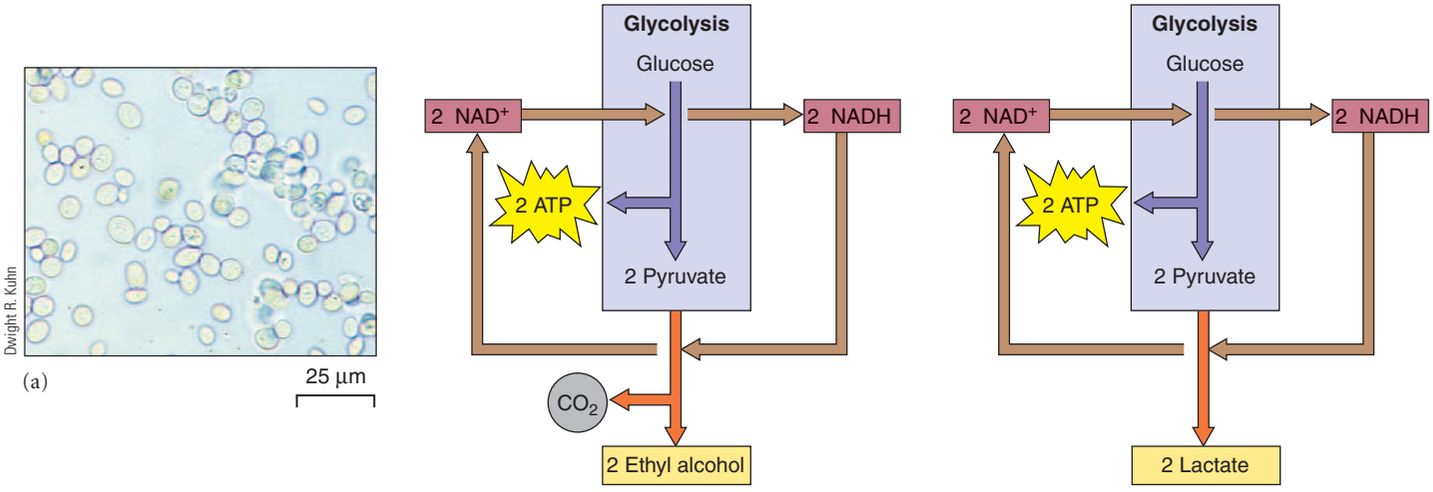

FIGURE **7-13** **Fermentation.**

(a) Light micrograph of live brewer's yeast (*Saccharomyces cerevisiae*). Yeast cells have mitochondria and carry on aerobic respiration when O_2 is present. In the absence of O_2, yeasts carry on alcohol fermentation. **(b, c)** Glycolysis is the first part of fermentation pathways. **(b)** In alcohol fermentation, CO_2 is split off, and the two-carbon compound ethyl alcohol is the end product. **(c)** In lactate fermentation, the final product is the three-carbon compound lactate. In both alcohol and lactate fermentation, there is a net gain of only two ATPs per molecule of glucose. Note that the NAD^+ used during glycolysis is regenerated during both alcohol fermentation and lactate fermentation.

ration. For this reason, your skeletal muscle cells store large quantities of glucose in the form of glycogen, enabling them to metabolize anaerobically for short periods.

Review

- What is the fate of hydrogen atoms removed from glucose during glycolysis when oxygen is present in muscle cells? How does this compare to the fate of hydrogen atoms removed from glucose when the amount of available oxygen is insufficient to support aerobic respiration?
- Why is the ATP yield of fermentation only a tiny fraction of the yield from aerobic respiration?

Biology Now™ Assess your understanding of **anaerobic respiration and fermentation** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Write a summary reaction for aerobic respiration, showing which reactant becomes oxidized and which becomes reduced.

- **Aerobic respiration** is a catabolic process in which a fuel molecule such as glucose is broken down to form carbon dioxide and water. It includes **redox reactions** that result in the transfer of electrons from glucose (which becomes **oxidized**) to oxygen (which becomes **reduced**)
- 
- Energy released during aerobic respiration is used to produce up to 36 to 38 ATPs per molecule of glucose.

2 List and give a brief overview of the four stages of aerobic respiration.

- The chemical reactions of aerobic respiration occur in four stages: glycolysis, formation of acetyl CoA, the citric acid cycle, and the electron transport chain/chemiosmosis.
- During **glycolysis,** a molecule of glucose is degraded to two molecules of **pyruvate.** Two ATP molecules (net) are produced by **substrate-level phosphorylation** during glycolysis. Four hydrogen atoms are removed and used to produce two NADH.
- During the formation of **acetyl CoA,** the two pyruvate molecules each lose a molecule of carbon dioxide, and the remaining acetyl groups each combine with **coenzyme A,** producing two molecules of acetyl CoA; one NADH is produced per pyruvate.
- Each acetyl CoA enters the **citric acid cycle** by combining with a four-carbon compound, **oxaloacetate,** to form **citrate,** a six-carbon compound. Two acetyl CoA molecules enter the cycle for every glucose molecule. For every two carbons that enter the cycle as part of an acetyl CoA molecule, two leave as carbon dioxide. For every acetyl CoA, hydrogen atoms are transferred to three NAD^+ and one FAD; only one ATP is produced by substrate-level phosphorylation.
- Hydrogen atoms (or their electrons) removed from fuel molecules are transferred from one electron acceptor to another down an **electron transport chain** located in the mitochondrial inner membrane; ultimately these electrons reduce molecular oxygen, forming water. In **oxidative phosphorylation,** the redox reac-

SUMMARY WITH KEY TERMS *(continued)*

tions in the electron transport chain are coupled to synthesis of ATP through the mechanism of **chemiosmosis.**

3 Indicate where each stage of aerobic respiration takes place in a eukaryotic cell.

- Glycolysis occurs in the cytosol, and the remaining stages of aerobic respiration take place in the mitochondrion.

4 Add up the energy captured (as ATP, NADH, and $FADH_2$) in each stage of aerobic respiration.

- In glycolysis, each glucose molecule produces 2 NADH and 2 ATP (net). The conversion of 2 pyruvates to acetyl CoA results in the formation of 2 NADH. In the citric acid cycle, the 2 acetyl CoA molecules are metabolized to form 6 NADH, 2 $FADH_2$, and 2 ATP. Adding up, we have 4 ATP, 10 NADH, and 2 $FADH_2$.
- When the 10 NADH and 2 $FADH_2$ pass through the electron transport chain, 32 to 34 ATP are produced by chemiosmosis. Therefore, each glucose molecule produces a total of up to 36 to 38 ATP.

5 Define *chemiosmosis,* and explain how a gradient of protons is established across the inner mitochondrial membrane.

- In chemiosmosis, some of the energy of the electrons in the electron transport chain is used to pump protons across the inner mitochondrial membrane into the intermembrane space. This pumping establishes a proton gradient across the inner mitochondrial membrane. Protons (H^+) accumulate within the intermembrane space, lowering the pH.

6 Describe the process by which the proton gradient drives ATP synthesis in chemiosmosis.

- The diffusion of protons through channels formed by the enzyme **ATP synthase,** through the inner mitochondrial membrane from the intermembrane space to the mitochondrial matrix, provides the energy to synthesize ATP.

7 Summarize how the products of protein and lipid catabolism enter the same metabolic pathway that oxidizes glucose.

- Amino acids are **deaminated,** and their carbon skeletons are converted to metabolic intermediates of aerobic respiration.
- Both the glycerol and fatty acid components of lipids are oxidized as fuel. Fatty acids are converted to acetyl CoA molecules by the process of **β-oxidation.**

8 Compare and contrast anaerobic respiration and fermentation; include the mechanism of ATP formation, the final electron acceptor, and the end products.

- In **anaerobic respiration,** electrons are transferred from fuel molecules to an electron transport chain; the final electron acceptor is an inorganic substance such as nitrate or sulfate, not molecular oxygen.
- **Fermentation** is an anaerobic process that does not use an electron transport chain. There is a net gain of only two ATPs per glucose; these are produced during glycolysis. To maintain the supply of NAD^+ essential for glycolysis, hydrogen atoms are transferred from NADH to an organic compound derived from the initial nutrient.
- Yeast cells carry out **alcohol fermentation,** in which ethyl alcohol and carbon dioxide are the final waste products.
- Certain fungi, prokaryotes, and animal cells carry out **lactate (lactic acid) fermentation,** in which hydrogen atoms are added to pyruvate to form lactate, a waste product.

Summary Reactions for Aerobic Respiration

Summary reaction for the complete oxidation of glucose:

$$C_6H_{12}O_6 + 6\ O_2 + 6\ H_2O \longrightarrow 6\ CO_2 + 12\ H_2O + \text{Energy (36 to 38 ATP)}$$

Summary reaction for glycolysis:

$$C_6H_{12}O_6 + 2\ ATP + 2\ ADP + 2\ P_i + 2\ NAD^+ \longrightarrow 2\ \text{Pyruvate} + 4\ ATP + 2\ NADH + H_2O$$

Summary reaction for the conversion of pyruvate to acetyl CoA:

$$2\ \text{Pyruvate} + 2\ \text{Coenzyme A} + 2\ NAD^+ \longrightarrow 2\ \text{Acetyl CoA} + 2\ CO_2 + 2\ NADH$$

Summary reaction for the citric acid cycle:

$$2\ \text{Acetyl CoA} + 6\ NAD^+ + 2\ FAD + 2\ ADP + 2\ P_i + 2\ H_2O \longrightarrow 4\ CO_2 + 6\ NADH + 2\ FADH_2 + 2\ ATP + 2\ CoA$$

Summary reactions for the processing of the hydrogen atoms of NADH and $FADH_2$ in the electron transport chain:

$$NADH + 3\ ADP + 3\ P_i + \tfrac{1}{2}O_2 \longrightarrow NAD^+ + 3\ ATP + H_2O$$

$$FADH_2 + 2\ ADP + 2\ P_i + \tfrac{1}{2}O_2 \longrightarrow FAD + 2\ ATP + H_2O$$

Summary Reactions for Fermentation

Summary reaction for lactate fermentation:

$$C_6H_{12}O_6 \longrightarrow 2\ \text{Lactate} + \text{Energy (2 ATP)}$$

Summary reactions for alcohol fermentation:

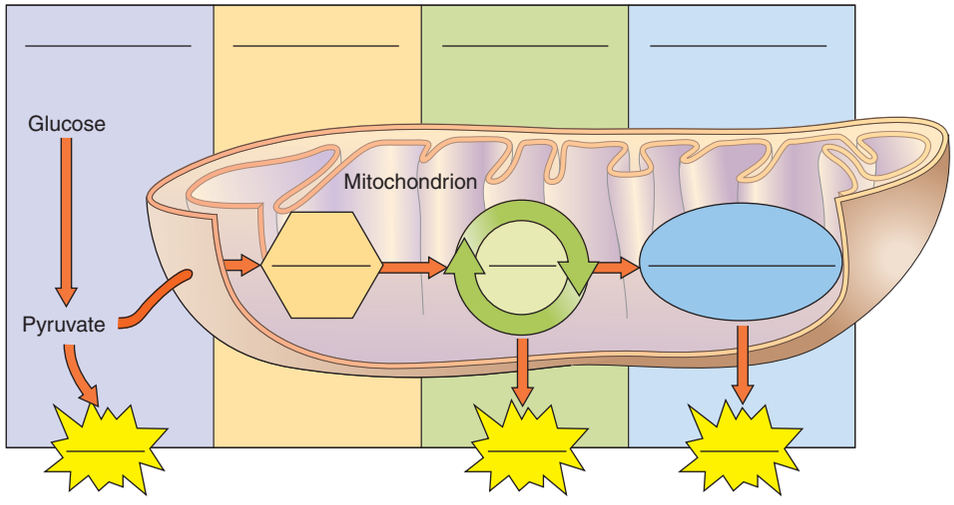
$$C_6H_{12}O_6 \longrightarrow 2\ CO_2 + 2\ \text{Ethyl alcohol} + \text{Energy (2 ATP)}$$

POST-TEST

1. The process of splitting larger molecules into smaller ones is an aspect of metabolism called (a) anabolism (b) fermentation (c) catabolism (d) oxidative phosphorylation (e) chemiosmosis
2. The synthetic aspect of metabolism is called (a) anabolism (b) fermentation (c) catabolism (d) oxidative phosphorylation (e) chemiosmosis
3. A chemical process during which a substance gains electrons is called (a) oxidation (b) oxidative phosphorylation (c) deamination (d) reduction (e) dehydrogenation
4. The pathway through which glucose is degraded to pyruvate is called (a) aerobic respiration (b) the citric acid cycle (c) the oxidation of pyruvate (d) alcohol fermentation (e) glycolysis
5. The reactions of _____ take place within the cytosol of eukaryotic cells. (a) glycolysis (b) oxidation of pyruvate (c) the citric acid cycle (d) chemiosmosis (e) the electron transport chain
6. Before pyruvate enters the citric acid cycle, it is decarboxylated, oxidized, and combined with coenzyme A, forming acetyl CoA, carbon dioxide, and one molecule of (a) NADH (b) $FADH_2$ (c) ATP (d) ADP (e) $C_6H_{12}O_6$

POST-TEST *(continued)*

7. In the first step of the citric acid cycle, acetyl CoA reacts with oxaloacetate to form (a) pyruvate (b) citrate (c) NADH (d) ATP (e) CO_2
8. Dehydrogenase enzymes remove hydrogen atoms from fuel molecules and transfer them to acceptors such as (a) O_2 and H_2O (b) ATP and FAD (c) NAD^+ and FAD (d) CO_2 and H_2O (e) CoA and pyruvate
9. Which of the following is a major source of electrons for the electron transport chain? (a) H_2O (b) ATP (c) NADH (d) ATP synthase (e) coenzyme A
10. In the process of _____, electron transport and ATP synthesis are coupled by a proton gradient across the inner mitochondrial membrane. (a) chemiosmosis (b) deamination (c) anaerobic respiration (d) glycolysis (e) decarboxylation
11. Which of the following is a common energy flow sequence in aerobic respiration, starting with the energy stored in glucose? (a) glucose ⟶ NADH ⟶ pyruvate ⟶ ATP (b) glucose ⟶ ATP ⟶ NADH ⟶ electron transport chain (c) glucose ⟶ NADH ⟶ electron transport chain ⟶ ATP (d) glucose ⟶ oxygen ⟶ NADH ⟶ water (e) glucose ⟶ $FADH_2$ ⟶ NADH ⟶ coenzyme A
12. Which multiprotein complex in the electron transport chain is responsible for reducing molecular oxygen? (a) complex I (NADH-ubiquinone oxidoreductase) (b) complex II (succinate-ubiquinone reductase) (c) complex III (ubiquinone-cytochrome *c* oxidoreductase) (d) complex IV (cytochrome *c* oxidase) (e) complex V (ATP synthase)
13. A net profit of only 2 ATPs can be produced anaerobically from the _____ of one molecule of glucose, compared with a maximum of 38 ATPs produced in _____. (a) fermentation; anaerobic respiration (b) aerobic respiration; fermentation (c) aerobic respiration; anaerobic respiration (d) dehydrogenation; decarboxylation (e) fermentation; aerobic respiration
14. When deprived of oxygen, yeast cells obtain energy by fermentation, producing carbon dioxide, ATP, and (a) acetyl CoA (b) ethyl alcohol (c) lactate (d) pyruvate (e) citrate
15. During strenuous muscle activity, the pyruvate in muscle cells may accept hydrogen from NADH to become _____. (a) acetyl CoA (b) ethyl alcohol (c) lactate (d) pyruvate (e) citrate
16. Label the ten blank lines in the figure. Use Figure 7-2 to check your answers.



CRITICAL THINKING

1. The reactions of glycolysis are identical in *all* organisms—prokaryotes, protists, fungi, plants, and animals—that obtain energy from glucose catabolism. What does this universality suggest about the evolution of glycolysis?
2. How are the endergonic reactions of the first phase of glycolysis coupled to the hydrolysis of ATP, which is exergonic? How are the exergonic reactions of the second phase of glycolysis coupled to the endergonic synthesis of ATP and NADH?
3. In what ways is the inner mitochondrial membrane essential to the coupling of electron transport and ATP synthesis? Could the membrane carry out its function if its lipid bilayer were readily permeable to hydrogen ions (protons)?
4. Based on what you have learned in this chapter, explain why a schoolchild can run 17 miles per hour in a 100-yard dash, but a trained athlete can run only about 11.5 miles per hour in a 26-mile marathon.

Photosynthesis: Capturing Energy

Skip Moody/Dembinsky Photo Associates

Photoautotrophs. These blue lupines (*Lupinus hirsutus*), and the trees behind them, use CO_2 as a carbon source and light as an energy source. This photograph was taken in southern Michigan.

CHAPTER OUTLINE

- Light
- Chloroplasts
- Overview of Photosynthesis
- The Light-Dependent Reactions
- The Carbon Fixation Reactions

Photosynthesis, the process by which light energy is converted into the stored chemical energy of organic molecules, is the first step in the flow of energy through most of the living world. All organisms—from microscopic prokaryotes to dolphins to palm trees—can be classified according to nutritional factors: their carbon and energy requirements. Carbon atoms are required for the carbon skeletons of an organism's organic molecules, and as you learned in Chapters 6 and 7, energy powers all life processes, from growth, to movement, to repair of worn or injured tissues.

Organisms obtain carbon in one of two ways. **Autotrophs** (from the Greek *auto,* "self," and *trophos,* "nourishing") are able to carry out carbon fixation; they convert carbon that is in gaseous form in carbon dioxide (CO_2) into carbon that has a fixed position in a carbon skeleton. **Heterotrophs** (from the Greek *heter,* "other," and *trophos,* "nourishing") cannot fix carbon; they use organic molecules produced by other organisms as the building blocks from which they synthesize the carbon compounds they need.

Organisms obtain energy in one of two ways. **Phototrophs** are photosynthetic organisms that use light as their energy source. In contrast, **chemotrophs** use organic compounds, such as glucose, or inorganic substances, such as iron, nitrate, ammonia, or sulfur, as sources of energy. Chemotrophs typically obtain energy from these materials by redox reactions (Chapters 6 and 7).

All organisms fall into one of four groups based on carbon and energy requirements. Land plants (see photograph), algae, and certain prokaryotes are **photoautotrophs** (that is, both phototrophs and autotrophs). Photoautotrophs use light energy to make ATP and other molecules that temporarily hold chemical energy but are unstable and cannot be stockpiled in the cell. Their energy drives the the anabolic pathway by which a photosynthetic cell synthesizes stable organic molecules from the simple inorganic compounds CO_2 and water. These organic compounds are used not only as starting materials to synthesize all the other organic compounds the photosynthetic organism

needs (such as complex carbohydrates, amino acids, and lipids) but also for energy storage. Glucose and other carbohydrates produced during photosynthesis are relatively reduced compounds that can be subsequently oxidized by aerobic respiration or by some other catabolic pathway (see Chapter 7).

A few bacteria, known as nonsulfur purple bacteria, are **photoheterotrophs** (both phototrophs and heterotrophs). Photoheterotrophs are able to use light energy but unable to carry out carbon fixation. Photoheterotrophs must obtain carbon from organic compounds (as "food").

Some bacteria are **chemoautotrophs**—both chemotrophs and autotrophs. These prokaryotes obtain their energy from the oxidation of reduced inorganic molecules such as hydrogen sulfide (H_2S), nitrite (NO_2^-), or ammonia (NH_3). Some of this energy is then used to carry out carbon fixation.

All animals, fungi, and most bacteria are **chemoheterotrophs;** that is, they are both chemotrophs and heterotrophs. Chemoheterotrophs use preformed organic molecules as a source of both energy and carbon. Plants and other photosynthetic organisms produce almost all the preformed organic molecules used by chemoheterotrophs.

Photosynthesis is the process that captures the vast majority of the energy that living organisms use. Photosynthesis not only sustains plants and other photoautotrophs but also indirectly supports almost all animals and other chemoheterotrophs in the biosphere. Each year plants and other photosynthetic organisms convert CO_2 into billions of tons of organic molecules. The chemical energy stored in these molecules fuels the metabolic reactions that sustain almost all life. ■

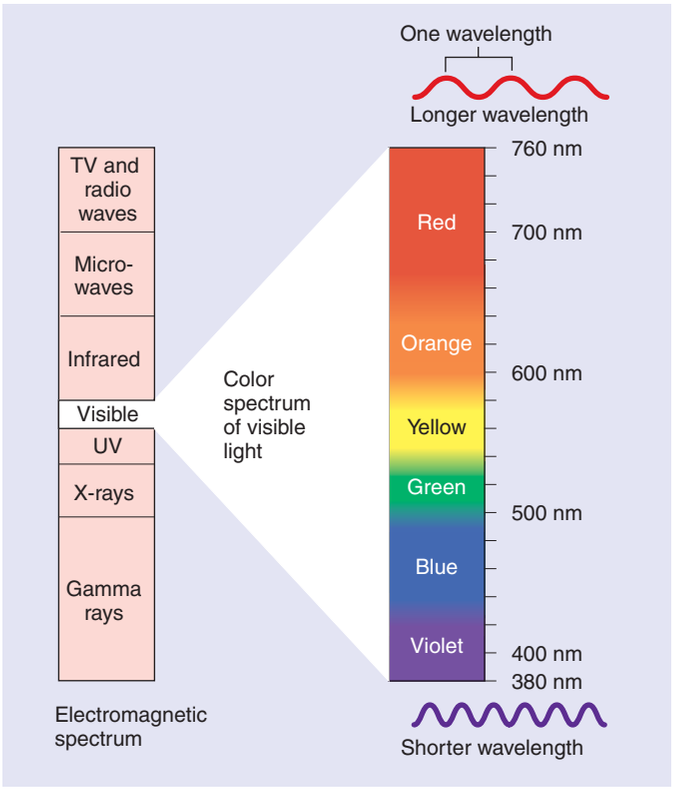

FIGURE **8-1** **The electromagnetic spectrum.**

Waves in the electromagnetic spectrum have similar properties but different wavelengths. Radio waves are the longest (and least energetic) waves, with wavelengths as long as 20 km. Gamma rays are the shortest (and most energetic) waves. Visible light represents a small fraction of the electromagnetic spectrum and consists of a mixture of wavelengths ranging from about 380 to 760 nm. The energy from visible light is used in photosynthesis.

LIGHT

Learning Objective

1 Describe the physical properties of light, and explain the relationship between a wavelength of light and its energy.

Because most life on this planet depends on light, either directly or indirectly, it is important to understand the nature of light and its essential role in photosynthesis. Visible light represents a very small portion of a vast, continuous range of radiation called the *electromagnetic spectrum* (Fig. 8-1). All radiation in this spectrum travels as waves. A **wavelength** is the distance from one wave peak to the next. At one end of the electromagnetic spectrum are gamma rays, which have very short wavelengths measured in fractions of nanometers, or nm (1 nanometer equals 10^{-9} m, one billionth of a meter). At the other end of the spectrum are radio waves, with wavelengths so long they can be measured in kilometers. The portion of the electromagnetic spectrum from 380 to 760 nm is called the *visible spectrum,* because we humans can see it. The visible spectrum includes all the colors of the rainbow (Fig. 8-2); violet has the shortest wavelength, and red has the longest.

Light is composed of small particles, or packets, of energy called **photons.** The energy of a photon is inversely proportional to its wavelength: Shorter-wavelength light has more energy per photon than longer-wavelength light.

Why does photosynthesis depend on light detectable by the human eye (visible light) rather than on some other wavelength of radiation? We can only speculate on the answer. Perhaps it is

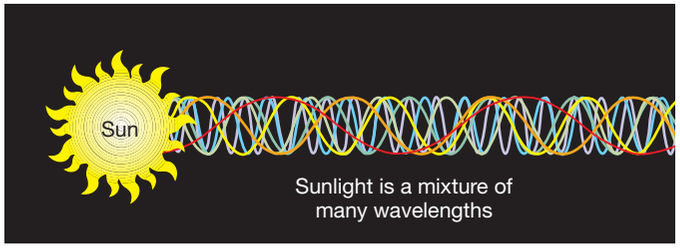

FIGURE **8-2** **Visible radiation emitted from the sun.**

Electromagnetic radiation from the sun includes ultraviolet radiation and visible light of varying colors and wavelengths.

because radiation within the visible light portion of the spectrum excites certain types of biological molecules, moving electrons into higher energy levels. Radiation with wavelengths longer than those of visible light doesn't have enough energy to excite these biological molecules. Radiation with wavelengths shorter than those of visible light is so energetic it disrupts the bonds of many biological molecules. Thus visible light has just the right amount of energy to be useful in photosynthesis.

When a molecule absorbs a photon of light energy, one of its electrons becomes energized, which means that the electron shifts from a lower-energy atomic orbital to a high-energy orbital that is more distant from the atomic nucleus. One of two things then happens, depending on the atom and its surroundings (Fig. 8-3). The atom may return to its **ground state,** which is the condition in which all its electrons are in their normal, lowest-energy levels. When an electron returns to its ground state, its energy dissipates as heat or as an emission of light of a longer wavelength than the absorbed light; this emission of light is called **fluorescence.** Alternatively, the energized electron may leave the atom and be accepted by an electron acceptor molecule, which becomes reduced in the process; this is what occurs in photosynthesis.

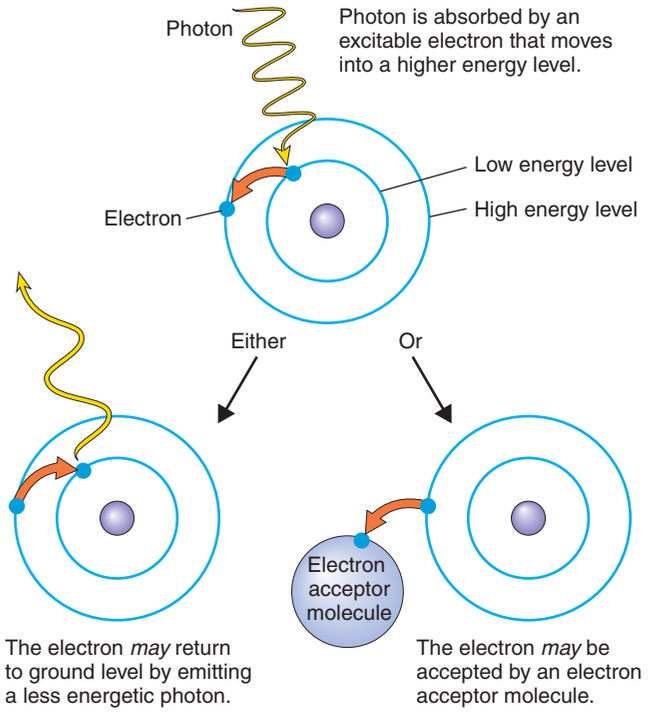

FIGURE **8-3** **Interactions between light and atoms or molecules.**

(Top) When a photon of light energy strikes an atom, or a molecule of which the atom is a part, the energy of the photon may push an electron to an orbital farther from the nucleus (that is, into a higher energy level). *(Lower left)* If the electron returns to the lower, more stable energy level, the energy may be released as a less energetic, longer-wavelength photon, or fluorescence *(shown),* or as heat. *(Lower right)* If the appropriate electron acceptors are available, the electron may leave the atom. During photosynthesis, an electron acceptor captures the energetic electron and passes it to a chain of acceptors.

Now that you understand some of the properties of light, let's consider the organelles that use light for photosynthesis.

CHLOROPLASTS

Learning Objectives

2 Diagram the internal structure of a chloroplast, and explain how its components interact and facilitate the process of photosynthesis.

3 Describe what happens to an electron in a biological molecule such as chlorophyll when a photon of light energy is absorbed.

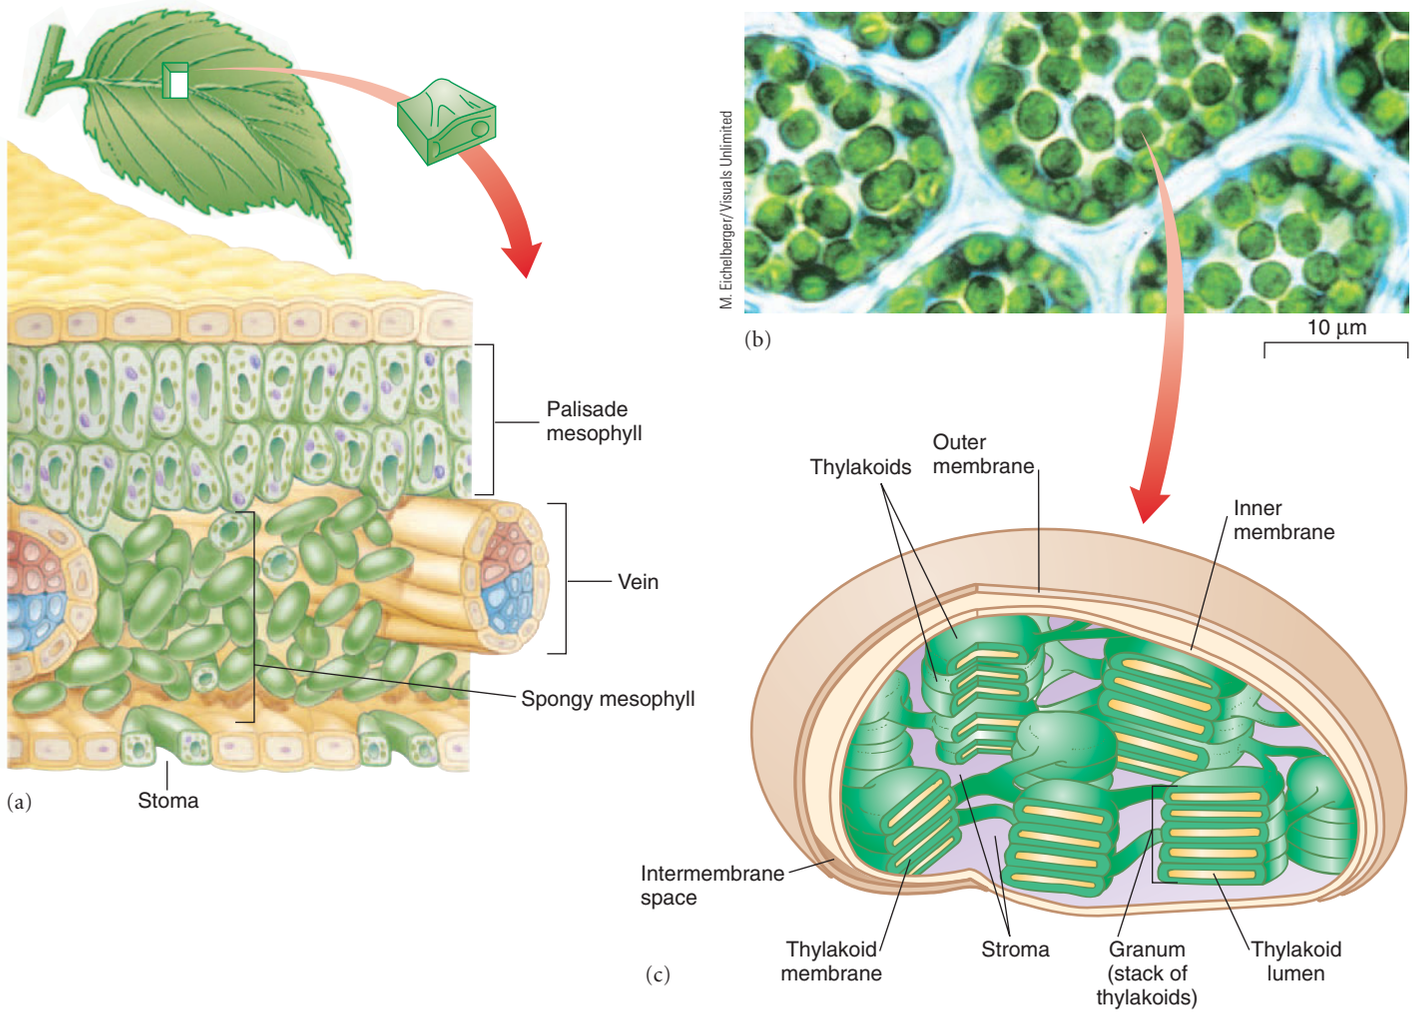
If you examine a section of leaf tissue in a microscope, you see that the green pigment, **chlorophyll,** is not uniformly distributed in the cell but is confined to organelles called **chloroplasts** (Fig. 8-4). In plants, chloroplasts lie mainly inside the leaf, in the cells of the **mesophyll,** a layer with many air spaces and a very high concentration of water vapor (Fig. 8-4a). The interior of the leaf exchanges gases with the outside through microscopic pores, called **stomata** (sing., *stoma*). Each mesophyll cell has 20 to 100 chloroplasts (Fig. 8-4b).

The chloroplast, like the mitochondrion, is enclosed by outer and inner membranes (Fig. 8-4c). The inner membrane encloses a fluid-filled region called the **stroma,** which contains most of the enzymes required to produce carbohydrate molecules. Suspended in the stroma is a third system of membranes that forms an interconnected set of flat, disklike sacs called **thylakoids.** The thylakoid membrane encloses a fluid-filled interior space, the **thylakoid lumen.** In some regions of the chloroplast, thylakoid sacs are arranged in stacks called **grana** (sing., *granum*). Each granum looks something like a stack of coins, with each "coin" being a thylakoid. Some thylakoid membranes extend from one granum to another. These membranes, like the inner mitochondrial membrane (see Chapter 7), are involved in ATP synthesis. (Photosynthetic prokaryotes have no chloroplasts, but thylakoid membranes are often arranged around the periphery of the cell as infoldings of the plasma membrane.)

Chlorophyll is found in the thylakoid membrane

Thylakoid membranes contain several kinds of *pigments,* which are substances that absorb visible light. Different pigments absorb light of different wavelengths. **Chlorophyll,** the main pigment of photosynthesis, absorbs light primarily in the blue and red regions of the visible spectrum. Green light is not appreciably absorbed by chlorophyll. Plants usually appear green because some of the green light that strikes them is scattered or reflected.

A chlorophyll molecule has two main parts, a complex ring and a long side chain (Fig. 8-5). The ring structure, called a *porphyrin ring,* is made up of joined smaller rings composed of



ACTIVE FIGURE **8-4** **The site of photosynthesis.**

(a) This leaf cross section reveals that the mesophyll is the photosynthetic tissue. CO_2 enters the leaf through tiny pores or stomata, and H_2O is carried to the mesophyll in veins. **(b)** Notice the numerous chloroplasts in this LM of plant cells. **(c)** In the chloroplast, pigments necessary for the light-capturing reactions of photosynthesis are part of thylakoid membranes, whereas the enzymes for the synthesis of carbohydrate molecules are in the stroma.

BiologyNow™ Learn more about **photosynthesis in plants** by clicking on this figure on your BiologyNow CD-ROM.

carbon and nitrogen atoms; the porphyrin ring absorbs light energy. The porphyrin ring of chlorophyll is strikingly similar to the heme portion of the red pigment hemoglobin in red blood cells. However, unlike heme, which contains an atom of iron in the center of the ring, chlorophyll contains an atom of magnesium in that position. The chlorophyll molecule also contains a long, hydrocarbon side chain that makes the molecule extremely nonpolar.

All chlorophyll molecules in the thylakoid membrane are associated with specific *chlorophyll-binding proteins;* biologists have identified about 15 different kinds. Each thylakoid membrane is filled with precisely oriented chlorophyll molecules and chlorophyll-binding proteins to facilitate the transfer of energy from one molecule to another.

There are several kinds of chlorophyll. The most important is **chlorophyll *a*,** the pigment that initiates the light-dependent reactions of photosynthesis. **Chlorophyll *b*** is an accessory pigment that also participates in photosynthesis. It differs from chlorophyll *a* only in a functional group on the porphyrin ring: The methyl group (—CH_3) in chlorophyll *a* is replaced in chlorophyll *b* by a terminal carbonyl group (—CHO). This difference shifts the wavelengths of light absorbed and reflected by chlorophyll *b,* making it appear yellow-green, whereas chlorophyll *a* appears bright green.

Chloroplasts have other accessory photosynthetic pigments, such as **carotenoids,** which are yellow and orange (see Fig. 3-14). Carotenoids absorb different wavelengths of light from chlorophyll, thereby expanding the spectrum of light that provides energy for photosynthesis. Chlorophyll may be excited by light directly, by energy passed to it from the light source, or indirectly, by energy passed to it from accessory pigments that have become excited by light. When a carotenoid molecule is excited, its energy can be transferred to chlorophyll *a.* Carotenoids also protect chlorophyll and other parts of the thylakoid membrane

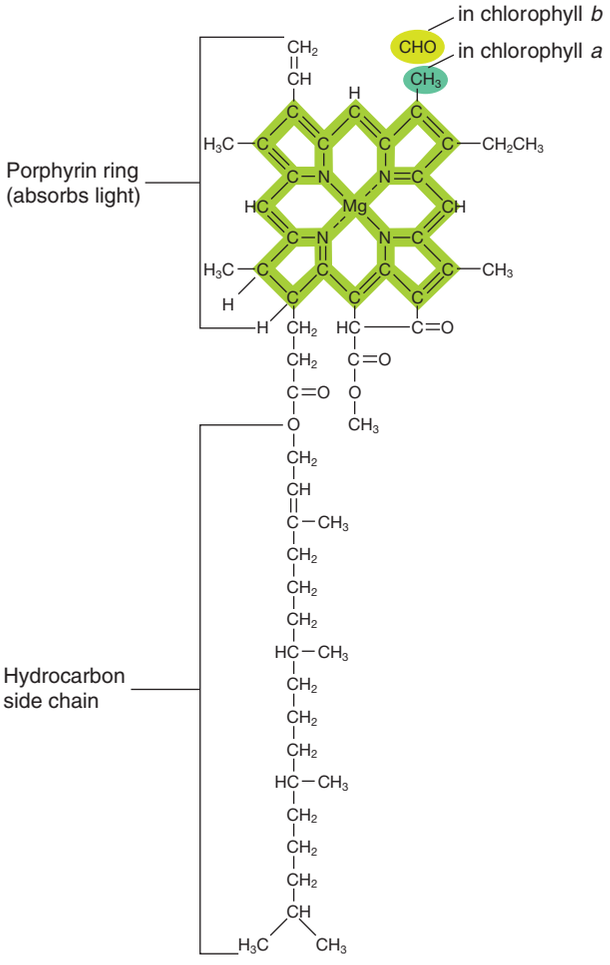


FIGURE **8-5** **The structure of chlorophyll.**

Chlorophyll consists of a porphyrin ring and a hydrocarbon side chain. The porphyrin ring, with a magnesium atom in its center, contains a system of alternating double and single bonds; these are commonly found in molecules that strongly absorb visible light. Notice that at the top right corner of the diagram, the methyl group (—CH_3) distinguishes chlorophyll *a* from chlorophyll *b*, which has a carbonyl group (—CHO) in this position.

(b)

FIGURE **8-6**

The absorption spectra for chlorophylls *a* and *b* and the action spectrum for photosynthesis.

(a) Chlorophylls *a* and *b* absorb light mainly in the blue (422 to 492 nm) and red (647 to 760 nm) regions. **(b)** The action spectrum of photosynthesis indicates the effectiveness of various wavelengths of light in powering photosynthesis. Many plant species have action spectra for photosynthesis that resemble the generalized action spectrum shown here.

from excess light energy that could easily damage the photosynthetic components. (High light intensities often occur in nature.)

Chlorophyll is the main photosynthetic pigment

As you have seen, the thylakoid membrane contains more than one kind of pigment. An instrument called a *spectrophotometer* measures the relative abilities of different pigments to absorb different wavelengths of light. The **absorption spectrum** of a pigment is a plot of its absorption of light of different wavelengths. Figure 8-6a shows the absorption spectra for chlorophylls *a* and *b*.

An **action spectrum** of photosynthesis is a graph of the relative effectiveness of different wavelengths of light. To obtain an action spectrum, scientists measure the rate of photosynthesis at each wavelength for leaf cells or tissues exposed to monochromatic light (light of one wavelength) (Fig. 8-6b).

PROCESS OF SCIENCE

In a classic biology experiment, the German biologist T.W. Engelmann obtained the first action spectrum in 1883. Engelmann's experiment took advantage of the shape of the chloroplast in a species of the green alga *Spirogyra* (Fig. 8-7a). Its long, filamentous strands are found in freshwater habitats, especially slow-moving or still waters. *Spirogyra* cells each contain a long,

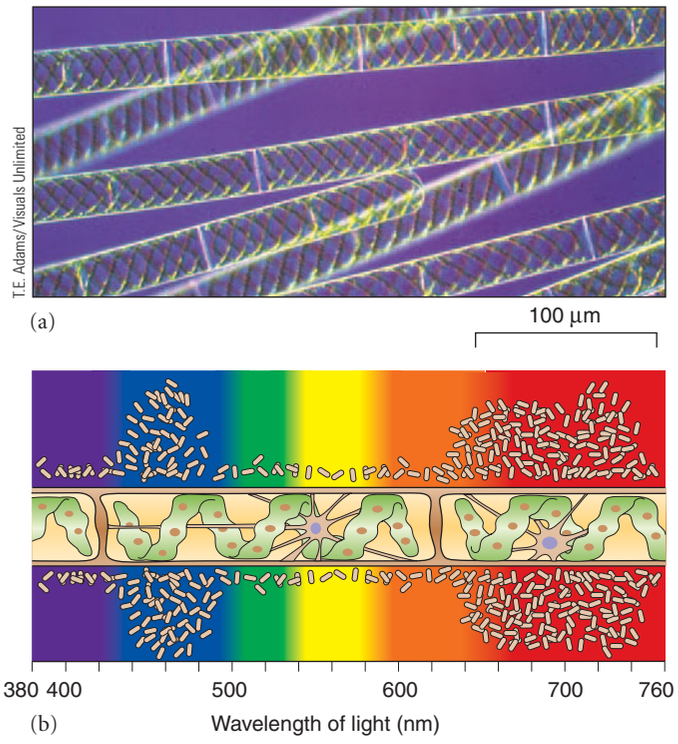

FIGURE **8-7** **The first action spectrum of photosynthesis.**

(a) Light micrograph of filaments of *Spirogyra*, the green alga Engelmann used in his classic experiment. **(b)** The density of bacteria in the blue and red regions of the spectrum indicates the effectiveness of blue and red light for photosynthesis.

spiral-shaped, emerald-green chloroplast embedded in the cytoplasm. Engelmann exposed these cells to a color spectrum produced by passing light through a prism. He hypothesized that if chlorophyll were indeed responsible for photosynthesis, that process would take place most rapidly in the areas where the chloroplast was illuminated by the colors most strongly absorbed by chlorophyll.

Yet how could photosynthesis be measured in those technologically unsophisticated days? Engelmann knew that photosynthesis produces oxygen and that certain motile bacteria are attracted to areas of high oxygen concentration (Fig. 8-7b). He determined the action spectrum of photosynthesis by observing that the bacteria swam toward the parts of the *Spirogyra* filaments in the blue and red regions of the spectrum. How did Engelmann know bacteria were not simply attracted to blue or red light? As a control, Engelmann exposed bacteria to the spectrum of visible light in the absence of *Spirogyra*. The bacteria showed no preference for any particular wavelength of light. Because the action spectrum of photosynthesis closely matched the absorption spectrum of chlorophyll, Engelmann concluded that chlorophyll in the chloroplasts (and not another compound in another organelle) is responsible for photosynthesis. Numerous studies using sophisticated instruments have since confirmed Engelmann's conclusions.

The action spectrum of photosynthesis does not parallel the absorption spectrum of chlorophyll exactly (see Fig. 8-6). This difference occurs because accessory pigments, such as carotenoids, transfer some of the energy of excitation produced by green light to chlorophyll molecules. The presence of these accessory photosynthetic pigments can be demonstrated by chemical analysis of almost any leaf, although it is obvious in temperate climates when leaves change color in the fall. Toward the end of the growing season, chlorophyll breaks down (and its magnesium is stored in the permanent tissues of the tree), leaving orange and yellow accessory pigments in the leaves.

Review

- What chloroplast membrane is most important in photosynthesis? What two spaces does it separate?
- What is the significance of the fact that the combined absorption spectra of chlorophyll *a* and *b* roughly match the action spectrum of photosynthesis? Why do they not coincide exactly?

OVERVIEW OF PHOTOSYNTHESIS

Learning Objectives

4 Describe photosynthesis as a redox process.

5 Distinguish between the light-dependent reactions and carbon fixation reactions of photosynthesis.

During photosynthesis, a cell uses light energy captured by chlorophyll to power the synthesis of carbohydrates. The overall reaction of photosynthesis can be summarized as follows:

$$\underset{\text{Carbon dioxide}}{6\ CO_2} + \underset{\text{Water}}{12\ H_2O} \xrightarrow[\text{Chlorophyll}]{\text{Light energy}} \underset{\text{Glucose}}{C_6H_{12}O_6} + \underset{\text{Oxygen}}{6\ O_2} + \underset{\text{Water}}{6\ H_2O}$$

The equation is typically written in the form just given, with H_2O on both sides, because water is a reactant in some reactions and a product in others. Furthermore, all the oxygen produced comes from water, so 12 molecules of water are required to produce 12 oxygen atoms. However, because there is no net yield of H_2O, we can simplify the summary equation of photosynthesis for purposes of discussion:

$$6\ CO_2 + 6\ H_2O \xrightarrow[\text{Chlorophyll}]{\text{Light}} C_6H_{12}O_6 + 6\ O_2$$

When you analyze this process, it appears that hydrogen atoms are transferred from H_2O to CO_2 to form carbohydrate, so you can recognize it as a redox reaction. Recall from Chapter 6 that in a **redox reaction** one or more electrons, usually as part of one or more hydrogen atoms, are transferred from an electron donor (a reducing agent) to an electron acceptor (an oxidizing agent).

$$6\ CO_2 + 6\ H_2O \xrightarrow[\text{Chlorophyll}]{\text{Light}} C_6H_{12}O_6 + 6\ O_2$$

(Reduction: $CO_2 \rightarrow C_6H_{12}O_6$; Oxidation: $H_2O \rightarrow O_2$)

When the electrons are transferred, some of their energy is transferred as well. However, the summary equation of photo-

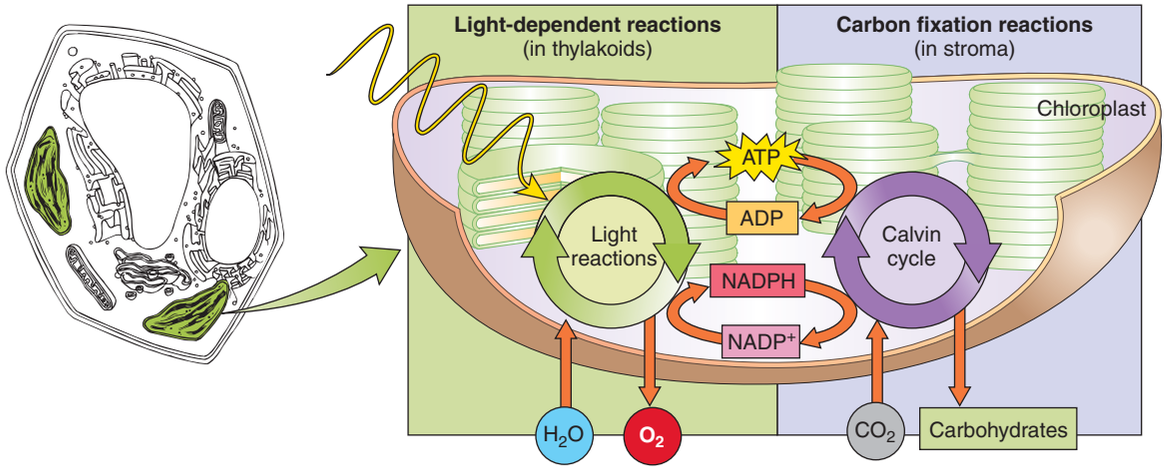

FIGURE **8-8**

An overview of photosynthesis.

Photosynthesis consists of light-dependent reactions, which occur in association with the thylakoids, and carbon fixation reactions, which occur in the stroma.

synthesis is somewhat misleading, because no direct transfer of hydrogen atoms actually occurs. The summary equation describes *what* happens but not *how* it happens. The "how" is more complex and involves multiple steps, many of which are redox reactions.

The reactions of photosynthesis are divided into two phases: the light-dependent reactions (the *photo* part of photosynthesis) and the carbon fixation reactions (the *synthesis* part of photosynthesis). Each set of reactions occurs in a different part of the chloroplast: the light-dependent reactions in association with the thylakoids, and the carbon fixation reactions in the stroma (Fig. 8-8).

ATP and NADPH are the products of the light-dependent reactions: An overview

Light energy is converted to chemical energy in the **light-dependent reactions,** which are associated with the thylakoids. The light-dependent reactions begin as chlorophyll captures light energy, which causes one of its electrons to move to a higher energy state. The energized electron is transferred to an acceptor molecule and is replaced by an electron from H_2O. When this happens, H_2O is split and molecular oxygen is released (Fig. 8-9). Some energy of the energized electrons is used to phosphorylate **adenosine diphosphate (ADP),** forming **adenosine triphosphate (ATP).** In addition, the coenzyme **nicotinamide adenine dinucleotide phosphate (NADP$^+$)** becomes reduced, forming **NADPH.**[1] The products of the light-dependent reactions, ATP and NADPH, are both needed in the endergonic carbon fixation reactions.

Carbohydrates are produced during the carbon fixation reactions: An overview

The ATP and NADPH molecules produced during the light-dependent phase are suited for transferring chemical energy but not for long-term energy storage. For this reason, some of their energy is transferred to chemical bonds in carbohydrates, which can be produced in large quantities and stored for future use. Known as **carbon fixation,** these reactions "fix" carbon atoms from CO_2 to existing skeletons of organic molecules. Because the carbon fixation reactions have no direct requirement for light, they were previously referred to as the "dark" reactions. However, they do not require darkness; in fact, many of the enzymes involved in carbon fixation are much more active in the light than in the dark. Furthermore, carbon fixation reactions depend on the products of the light-dependent reactions. Carbon fixation reactions take place in the stroma of the chloroplast.

Now that we have presented an overview of photosynthesis, let's examine the entire process more closely.

Review

- Which is more oxidized, oxygen that is part of a water molecule, or molecular oxygen?
- In what ways do the carbon fixation reactions depend on the light-dependent reactions?

Bernd Wittich/Visuals Unlimited

FIGURE **8-9** **Oxygen produced by photosynthesis.**

On sunny days, the oxygen released by aquatic plants is sometimes visible as bubbles in the water. This plant (*Elodea*) is actively carrying on photosynthesis.

[1] Although the correct way to write the reduced form of NADP$^+$ is NADPH + H$^+$, for simplicity's sake we present the reduced form as NADPH throughout the book.

THE LIGHT-DEPENDENT REACTIONS

Learning Objectives

6 Describe the flow of electrons through photosystems I and II in the noncyclic electron transport pathway; contrast this with cyclic electron transport.

7 Explain how a proton (H^+) gradient is established across the thylakoid membrane and how this gradient functions in ATP synthesis.

In the light-dependent reactions, the radiant energy from sunlight phosphorylates ADP, producing ATP, and reduces $NADP^+$, forming NADPH. The light energy that chlorophyll captures is temporarily stored in these two compounds. The light-dependent reactions are summarized as follows:

$$12\ H_2O + 12\ NADP^+ + 18\ ADP + 18\ P_i \xrightarrow[\text{Chlorophyll}]{\text{Light}} 6\ O_2 + 12\ NADPH + 18\ ATP$$

Photosystems I and II each consist of a reaction center and multiple antenna complexes

The light-dependent reactions of photosynthesis begin when chlorophyll *a* and/or accessory pigments absorb light. According to the currently accepted model, chlorophylls *a* and *b* and accessory pigment molecules are organized with pigment-binding proteins in the thylakoid membrane into units called **antenna complexes.** The pigments and associated proteins are arranged as highly ordered groups of about 250 chlorophyll molecules associated with specific enzymes and other proteins. Each antenna complex absorbs light energy and transfers it to the **reaction center,** which consists of chlorophyll molecules and proteins, including electron transfer components, that participate directly in photosynthesis (Fig. 8-10). Light energy is converted to chemical energy in the reaction centers by a series of electron transfer reactions.

Two types of photosynthetic units, designated photosystem I and photosystem II, are involved in photosynthesis. Their reaction centers are distinguishable because they are associated with proteins in a way that causes a slight shift in their absorption spectra. Ordinary chlorophyll *a* has a strong absorption peak at about 660 nm. In contrast, the chlorophyll *a* molecule that makes up the reaction center associated with **photosystem I** has an absorption peak at 700 nm and is referred to as **P700.** The reaction center of **photosystem II** is made up of a chlorophyll *a* molecule with an absorption peak of about 680 nm and is referred to as **P680**.

When a pigment molecule absorbs light energy, that energy is passed from one pigment molecule to another until it reaches the reaction center. When the energy reaches a molecule of P700 (in a photosystem I reaction center) or P680 (in a photosystem II reaction center), an electron is then raised to a higher energy level. As we explain in the next section, this energized electron can be donated to an electron acceptor that becomes reduced in the process.

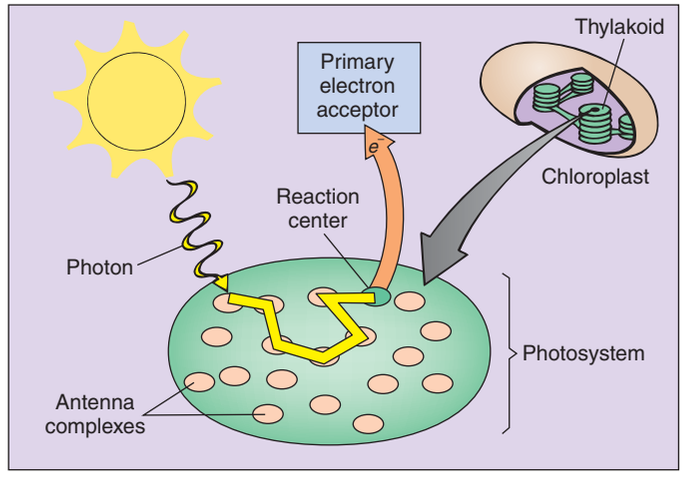

FIGURE **8-10** **A photosystem.**

Chlorophyll molecules and accessory pigments are arranged in light-harvesting arrays, or antenna complexes. When a molecule in an antenna complex absorbs a photon, the photon's energy is funneled into the reaction center. When this energy reaches the P700 (or P680) chlorophyll molecule in the reaction center, an electron becomes energized and is accepted by a primary electron acceptor.

Noncyclic electron transport produces ATP and NADPH

Let's begin our discussion of **noncyclic electron transport** with the events associated with photosystem I (Fig. 8-11). A pigment molecule in an antenna complex associated with photosystem I absorbs a photon of light. The absorbed energy is transferred to the reaction center, where it excites an electron in a molecule of P700. This energized electron is transferred to a primary electron acceptor, which is the first of several electron acceptors in a series. (Uncertainty exists regarding the exact chemical nature of the primary electron acceptor for photosystem I.) The energized electron is passed along an **electron transport chain** from one electron acceptor to another, until it is passed to *ferredoxin,* an iron-containing protein. Ferredoxin transfers the electron to $NADP^+$ in the presence of the enzyme *ferredoxin–NADP$^+$ reductase.* When $NADP^+$ accepts 2 electrons, they unite with a proton (H^+); thus the reduced form of $NADP^+$ is NADPH, which is released into the stroma. P700 becomes positively charged when it gives up an electron to the primary electron acceptor; the missing electron is replaced by one donated by photosystem II.

Like photosystem I, photosystem II is activated when a pigment molecule in an antenna complex absorbs a photon of light energy. The energy is transferred to the reaction center, where it causes an electron in a molecule of P680 to move to a higher energy level. This energized electron is accepted by a primary electron acceptor (a highly modified chlorophyll molecule known as *pheophytin*) and then passes along an electron transport chain until it is donated to P700 in photosystem I.

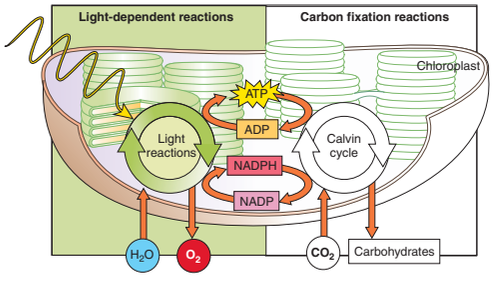
How is the electron that has been donated to the electron transport chain replaced? This occurs through **photolysis** (light

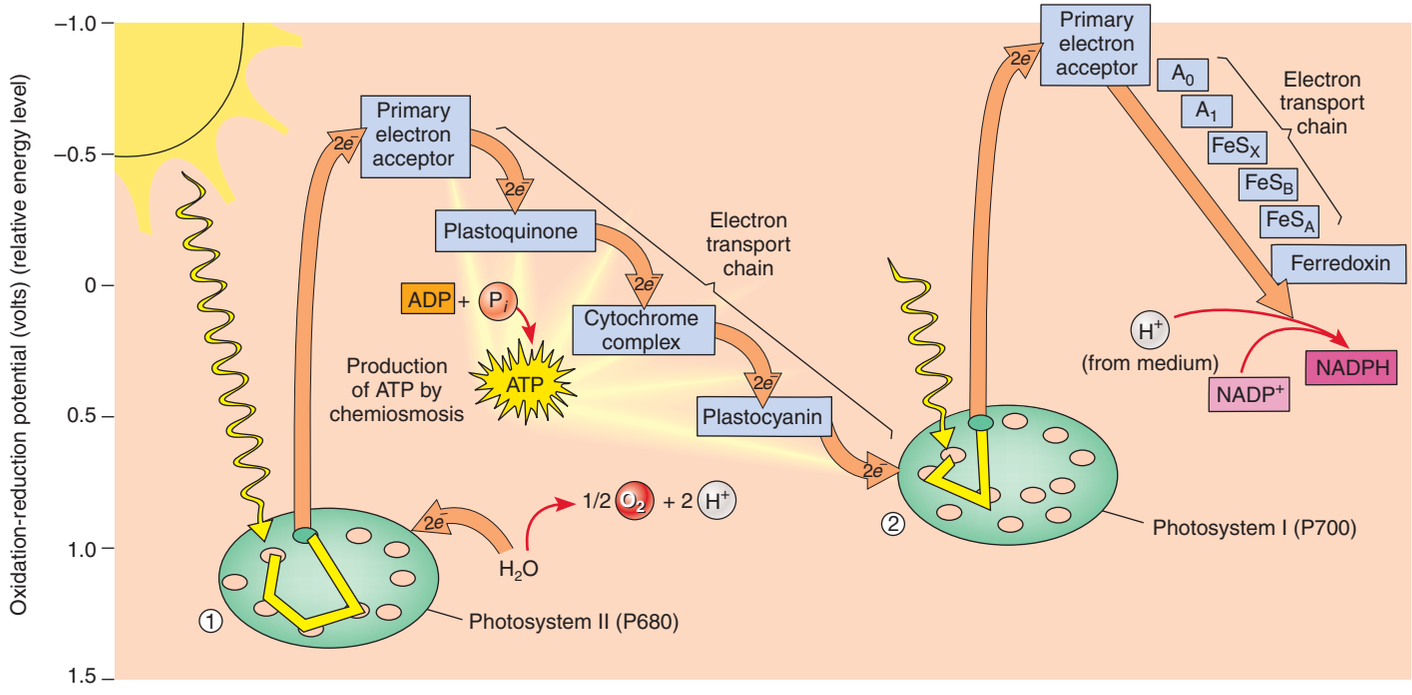
splitting) of water, a process that not only yields electrons, but is also the source of almost all the oxygen in Earth's atmosphere. A molecule of P680 that has given up an energized electron to the primary electron acceptor is positively charged. This P680 molecule is an oxidizing agent so strong that it pulls electrons away from an oxygen atom that is part of a H_2O molecule. In a reaction probably catalyzed by a unique, manganese-containing enzyme, water is broken into its components: 2 electrons, 2 protons, and oxygen. Each electron is donated to a P680 molecule, and the protons are released into the thylakoid lumen. Because oxygen does not exist in atomic form, the oxygen produced by splitting one H_2O molecule is written $\frac{1}{2}\ O_2$. Two water molecules must be split to yield one molecule of oxygen. The photolysis of water is a remarkable reaction, but its name is somewhat misleading because it implies that water is broken by light. Actually, light splits water indirectly, by causing P680 to become oxidized.

Noncyclic electron transport is a continuous linear process

In the presence of light, there is a continuous, one-way flow of electrons from the ultimate electron source, H_2O, to the terminal electron acceptor, $NADP^+$. Water undergoes enzymatically catalyzed photolysis to replace energized electrons donated to the electron transport chain by molecules of P680 in photosystem II. These electrons travel down the electron transport chain that connects photosystem II with photosystem I. Thus they provide a continuous supply of replacements for energized electrons that have been given up by P700.

As electrons are transferred along the electron transport chain that connects photosystem II with photosystem I, they lose energy. Some of the energy released is used to pump protons across the thylakoid membrane, from the stroma to the thylakoid lumen, producing a proton gradient. The energy of this proton gradient is harnessed to produce ATP from ADP by chemiosmosis, which we will discuss shortly. ATP and NADPH, the products of the light-dependent reactions, are released into the stroma, where both are required in the carbon fixation reactions.





ACTIVE FIGURE **8-11** **Noncyclic electron transport.**

In noncyclic electron transport, the formation of ATP is coupled to the one-way flow of energized electrons *(orange arrows)* from H_2O *(lower left)* to $NADP^+$ *(middle right)*. Single electrons actually pass down the electron transport chain; 2 are shown in this figure because 2 electrons are required to form one molecule of NADPH. ① Electrons are supplied to the system from the splitting of H_2O by photosystem II, with the release of O_2 as a byproduct. When photosystem II is activated by absorbing photons, electrons are passed along an electron transport chain and are eventually donated to photosystem I. ② Electrons in photosystem I are "re-energized" by the absorption of additional light energy and are passed to $NADP^+$, forming NADPH.

BiologyNow™ Experience the process of **noncyclic electron transport** by clicking on this figure on your BiologyNow CD-ROM.

Cyclic electron transport produces ATP but no NADPH

Only photosystem I is involved in **cyclic electron transport**, the simplest light-dependent reaction. The pathway is cyclic because energized electrons that originate from P700 at the reaction center eventually return to P700. In the presence of light, electrons flow continuously through an electron transport chain within the thylakoid membrane. As they pass from one acceptor to another, the electrons lose energy, some of which is used to pump protons across the thylakoid membrane. An enzyme (ATP synthase, discussed shortly) in the thylakoid membrane uses the energy of the proton gradient to manufacture ATP. NADPH is not produced, H_2O is not split, and oxygen is not generated. By itself, cyclic electron transport could not serve as the basis of photosynthesis because, as we explain later in the chapter, NADPH is required to reduce CO_2 to carbohydrate.

The significance of cyclic electron transport to photosynthesis in plants is unclear. Cyclic electron transport may occur in plant cells when there is too little $NADP^+$ to accept electrons from ferredoxin. Biologists generally agree that ancient bacteria used this process to produce ATP from light energy. A reaction pathway analogous to cyclic electron transport in plants is present in some modern photosynthetic prokaryotes. Noncyclic and cyclic electron transport are compared in Table 8-1.

ATP synthesis occurs by chemiosmosis

Each member of the electron transport chain that links photosystem II to photosystem I can exist in an oxidized (lower energy) form and a reduced (higher energy) form. The electron accepted from P680 by the primary electron acceptor is highly energized; it is passed from one carrier to the next in a series of exergonic redox reactions, losing some of its energy at each step. Some of the energy given up by the electron is not lost by the system, however; it is used to drive the synthesis of ATP, an endergonic reaction. Because the synthesis of ATP (that is, the phosphorylation of ADP) is coupled to the transport of electrons that have been energized by photons of light, the process is called **photophosphorylation.**

TABLE 8-1 A Comparison of Noncyclic and Cyclic Electron Transport

	Noncyclic Electron Transport	Cyclic Electron Transport
Electron source	H_2O	None—electrons cycle through the system
Oxygen released?	Yes (from H_2O)	No
Terminal electron acceptor	$NADP^+$	None—electrons cycle through the system
Form in which energy is temporarily captured	ATP (by chemiosmosis); NADPH	ATP (by chemiosmosis)
Photosystem(s) required	PS I (P700) and PS II (P680)	PS I (P700) only

The chemiosmotic model explains the coupling of ATP synthesis and electron transport

As discussed earlier, the pigments and electron acceptors of the light-dependent reactions are embedded in the thylakoid membrane. Energy released from electrons traveling through the chain of acceptors is used to pump protons from the stroma, across the thylakoid membrane, and into the thylakoid lumen (Fig. 8-12). Thus the pumping of protons results in the formation of a proton gradient across the thylakoid membrane. Protons also accumulate in the thylakoid lumen as water is split during noncyclic electron transport. Because protons are actually hydrogen ions (H^+), the accumulation of protons causes the pH of the thylakoid interior to fall to a pH of about 5 in the thylakoid lumen, compared to a pH of about 8 in the stroma. This difference of about 3 pH units across the thylakoid membrane means there is an approximately 1000-fold difference in hydrogen ion concentration.

The proton gradient has a great deal of free energy because of its state of low entropy. How does the chloroplast convert that energy to a more useful form? According to the general principles of diffusion, the concentrated protons inside the thylakoid might be expected to diffuse out readily. However, they

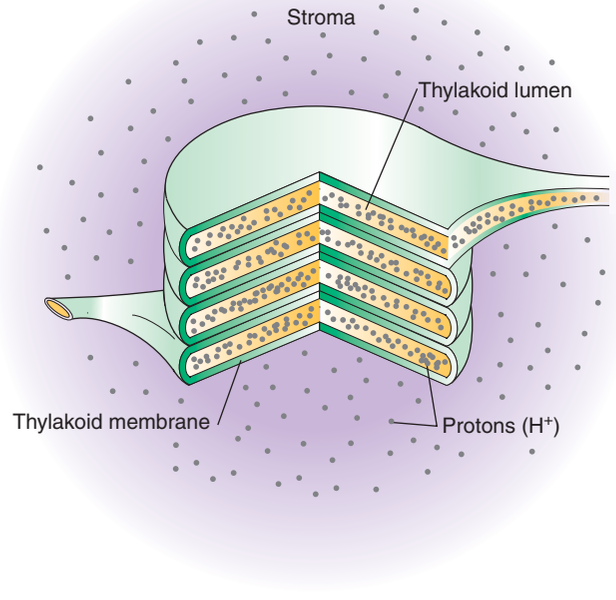


FIGURE 8-12 The accumulation of protons in the thylakoid lumen.

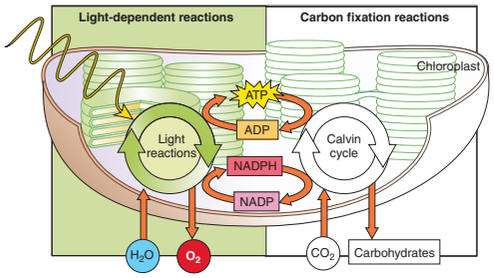
As electrons move down the electron transport chain, protons (H^+) move from the stroma to the thylakoid lumen, creating a proton gradient. The greater concentration of H^+ in the thylakoid lumen lowers the pH.

are prevented from doing so because the thylakoid membrane is impermeable to H^+ except through certain channels formed by the enzyme **ATP synthase.** This enzyme, a transmembrane protein, forms complexes so large they can be seen in electron micrographs; these complexes project into the stroma. As the protons diffuse through an ATP synthase complex, free energy decreases as a consequence of an increase in entropy. Each ATP synthase complex couples this exergonic process of diffusion down a concentration gradient to the endergonic process of phosphorylation of ADP to form ATP, which is released into the stroma (Fig. 8-13). The movement of protons through ATP synthase is thought to induce changes in the conformation of the enzyme that are necessary for the synthesis of ATP. It is estimated that for every 4 protons that move through ATP synthase, one ATP molecule is synthesized.

The mechanism by which the phosphorylation of ADP is coupled to diffusion down a proton gradient is called **chemiosmosis.** As the essential connection between the electron transport chain and the phosphorylation of ADP, chemiosmosis is a basic mechanism of energy coupling in cells. You may recall from Chapter 7 that chemiosmosis also occurs in aerobic respiration (see Table 8-2).



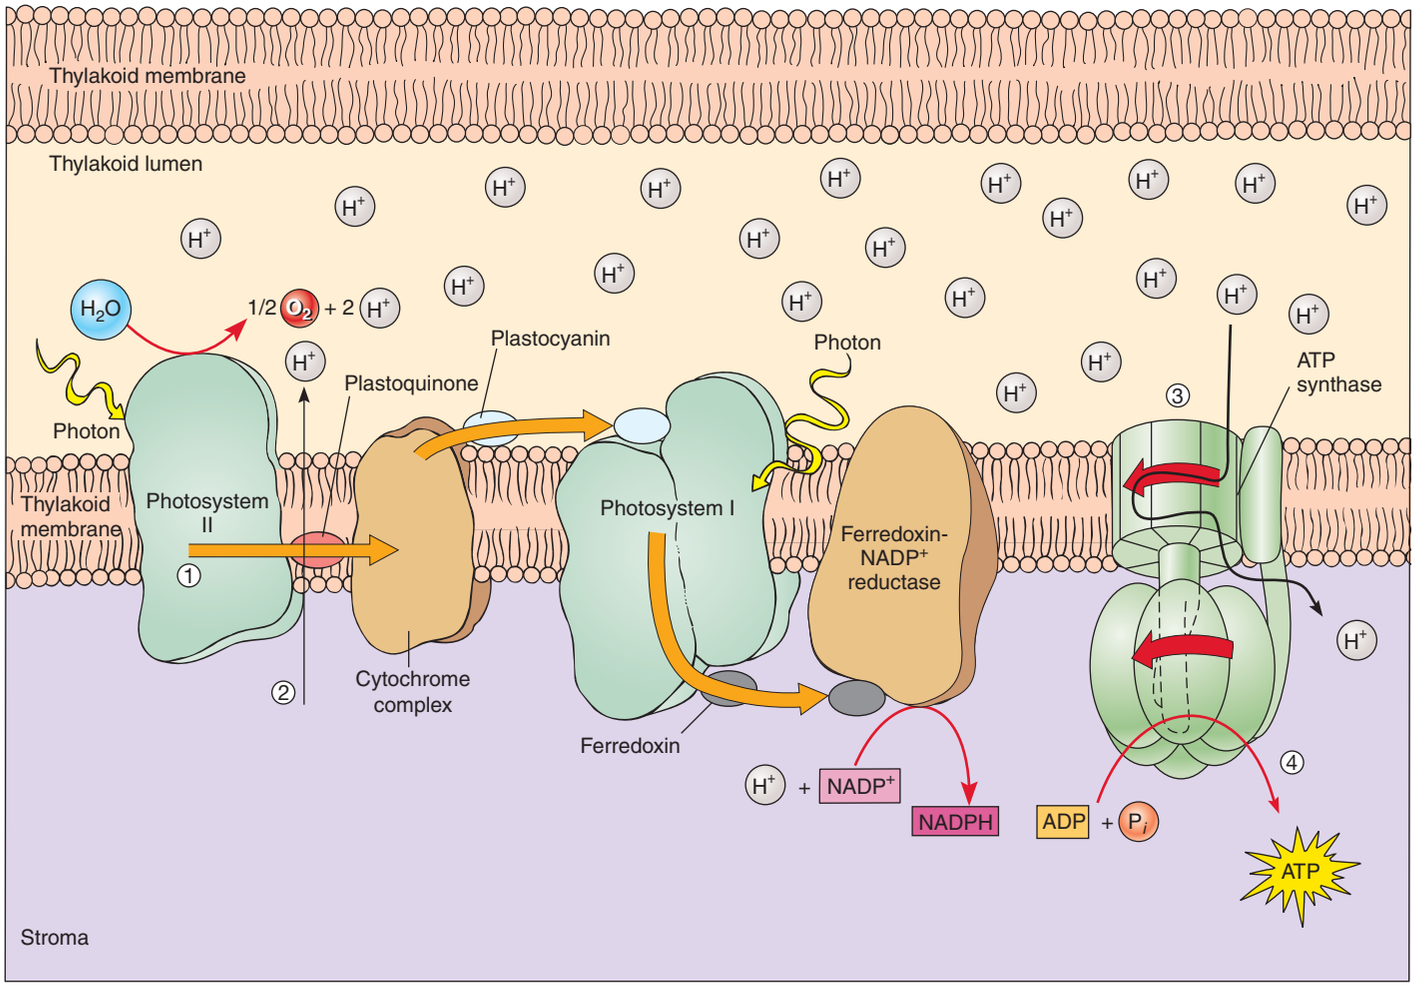


FIGURE **8-13** **A detailed look at electron transport and chemiosmosis.**

① The orange arrows indicate the pathway of electrons along the electron transport chain in the thylakoid membrane. The electron carriers within the membrane become alternately reduced and oxidized as they accept and donate electrons. ② The energy released during electron transport is used to transport H^+ from the stroma to the thylakoid lumen, where a high concentration of H^+ accumulates. ③ The H^+ are prevented from diffusing back into the stroma except through special channels in ATP synthase in the thylakoid membrane. ④ The flow of the H^+ through ATP synthase generates ATP.

TABLE 8-2 A Comparison of Photosynthesis and Aerobic Respiration

	Photosynthesis	Aerobic Respiration
Type of metabolic reaction	Anabolism	Catabolism
Raw materials	CO_2, H_2O	$C_6H_{12}O_6$, O_2
End products	$C_6H_{12}O_6$, O_2	CO_2, H_2O
Which cells have these processes?	Cells that contain chlorophyll (certain cells of plants, algae, and some bacteria)	Every actively metabolizing cell has aerobic respiration or some other energy-releasing pathway
Sites involved (in eukaryotic cells)	Chloroplasts	Cytosol (glycolysis); mitochondria
ATP production	By photophosphorylation (a chemiosmotic process)	By substrate-level phosphorylation and by oxidative phosphorylation (a chemiosmotic process)
Principal electron transfer compound	$NADP^+$ is reduced to form NADPH*	NAD^+ is reduced to form NADH*
Location of electron transport chain	Thylakoid membrane	Mitochondrial inner membrane (cristae)
Source of electrons for electron transport chain	In noncyclic electron transport: H_2O (undergoes photolysis to yield electrons, protons, and oxygen)	Immediate source: NADH, $FADH_2$ Ultimate source: glucose or other carbohydrate
Terminal electron acceptor for electron transport chain	In concyclic electron transport: $NADP^+$ (becomes reduced to form NADPH)	O_2 (becomes reduced to form H_2O)

*NADPH and NADH are very similar hydrogen (i.e., electron) carriers, differing only in a single phosphate group. However, NADPH generally works with enzymes in anabolic pathways, such as photosynthesis. NADH is associated with catabolic pathways, such as cellular respiration.

Review

- Why is molecular oxygen a necessary byproduct of photosynthesis?
- What process is the actual mechanism of photophosphorylation?
- Why are both photosystems I and II required for photosynthesis? Can cyclic phosphorylation alone support photosynthesis?

THE CARBON FIXATION REACTIONS

Learning Objectives

8 Summarize the three phases of the Calvin cycle, and indicate the roles of ATP and NADPH in the process.
9 Discuss how photorespiration reduces photosynthetic efficiency.
10 Compare the C_4 and CAM pathways.

In carbon fixation, the energy of ATP and NADPH is used in the formation of organic molecules from CO_2. The carbon fixation reactions may be summarized as follows:

$$12\ NADPH + 18\ ATP + 6\ CO_2 \longrightarrow C_6H_{12}O_6 + 12\ NADP^+ + 18\ ADP + 18\ P_i + 6\ H_2O$$

Most plants use the Calvin cycle to fix carbon

Carbon fixation occurs in the stroma through a sequence of 13 reactions known as the **Calvin cycle**. During the 1950s, University of California researchers Melvin Calvin, Andrew Benson, and others elucidated the details of this cycle. Calvin was awarded a Nobel Prize for chemistry in 1961.

The 13 reactions of the Calvin cycle are divided into three phases: CO_2 uptake, carbon reduction, and RuBP regeneration (Fig. 8-14). All 13 enzymes that catalyze steps in the Calvin cycle are located in the stroma of the chloroplast. Ten of the enzymes also participate in glycolysis (see Chapter 7). These enzymes catalyze reversible reactions, degrading carbohydrate molecules in cellular respiration and synthesizing carbohydrate molecules in photosynthesis.

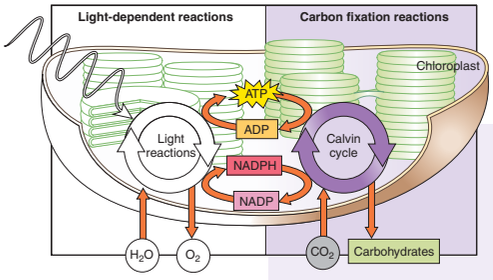
1. *CO_2 uptake.* The first phase of the Calvin cycle consists of a single reaction in which a molecule of CO_2 reacts with a phosphorylated five-carbon compound, *ribulose bisphosphate (RuBP).* This reaction is catalyzed by the enzyme *ribulose bisphosphate carboxylase/oxygenase,* also known as **rubisco.** More rubisco enzyme is present in the chloroplast than any other protein, and it may be one of the most abundant proteins in the biosphere. The product of this reaction is an unstable, six-carbon intermediate, which immediately breaks down into two molecules of **phosphoglycerate (PGA)** with three carbons each. The carbon that was originally part of a CO_2 molecule is now part of a carbon skeleton; the carbon has been "fixed." The Calvin cycle is also known as the **C_3 pathway** because the product of the initial carbon fixation reaction is a three-carbon compound. Plants that initially fix carbon in this way are called **C_3 plants.**

2. *Carbon reduction.* The second phase of the Calvin cycle consists of two steps in which the energy and reducing power from ATP and NADPH (both produced in the light-dependent reactions) are used to convert the PGA molecules to **glyceraldehyde-3-phosphate (G3P).** As shown in Figure 8-14, for every six carbons that enter the cycle as CO_2, six carbons can leave the system as two molecules of G3P, to be used in carbohydrate synthesis. Each of these three carbon molecules of G3P is essentially half a hexose (six-carbon sugar) molecule. (In fact, you may recall that G3P is a key intermediate in the splitting of sugar in glycolysis; see Figs. 7-3 and 7-4.)

The reaction of two molecules of G3P is exergonic and leads to the formation of glucose or fructose. In some plants, glucose and fructose are then joined to produce sucrose (common table sugar). Sucrose is harvested from sugar cane, sugar beets, and maple sap. The plant cell also uses glucose to produce starch or cellulose.

3. *RuBP regeneration.* Notice that although 2 G3P molecules are removed from the cycle, 10 G3P molecules remain; this represents 30 carbon atoms in all. Through a series of 10 reactions that make up the third phase of the Calvin cycle, these 30 carbons and their associated atoms become rearranged into six molecules of ribulose phosphate, each of which becomes phosphorylated to produce RuBP, the 5-carbon compound with which the cycle started. These RuBP molecules begin the process of CO_2 fixation and eventual G3P production once again.

In summary, the inputs required for the carbon fixation reactions are six molecules of CO_2, phosphates transferred from ATP, and electrons (as hydrogen) from NADPH. In the end, the six carbons from the CO_2 are accounted for by the harvest of a hexose molecule. The remaining G3P molecules are used to



ACTIVE FIGURE 8-14 **A detailed look at the Calvin cycle.**

① This diagram, in which carbon atoms are black balls, shows that six molecules of CO_2 must be "fixed" (incorporated into pre-existing carbon skeletons) in the CO_2 uptake phase to produce one molecule of a six-carbon sugar such as glucose. ② Glyceraldehyde-3-phosphate (G3P) is formed in the carbon reduction phase. Two G3P molecules "leave" the cycle for every glucose formed. ③ Ribulose bisphosphate (RuBP) is regenerated and a new cycle can begin. Although these reactions do not require light directly, the energy that drives the Calvin cycle comes from ATP and NADPH, which are the products of the light-dependent reactions.

BiologyNow™ See the **Calvin cycle in action** by clicking on this figure on your BiologyNow CD-ROM.

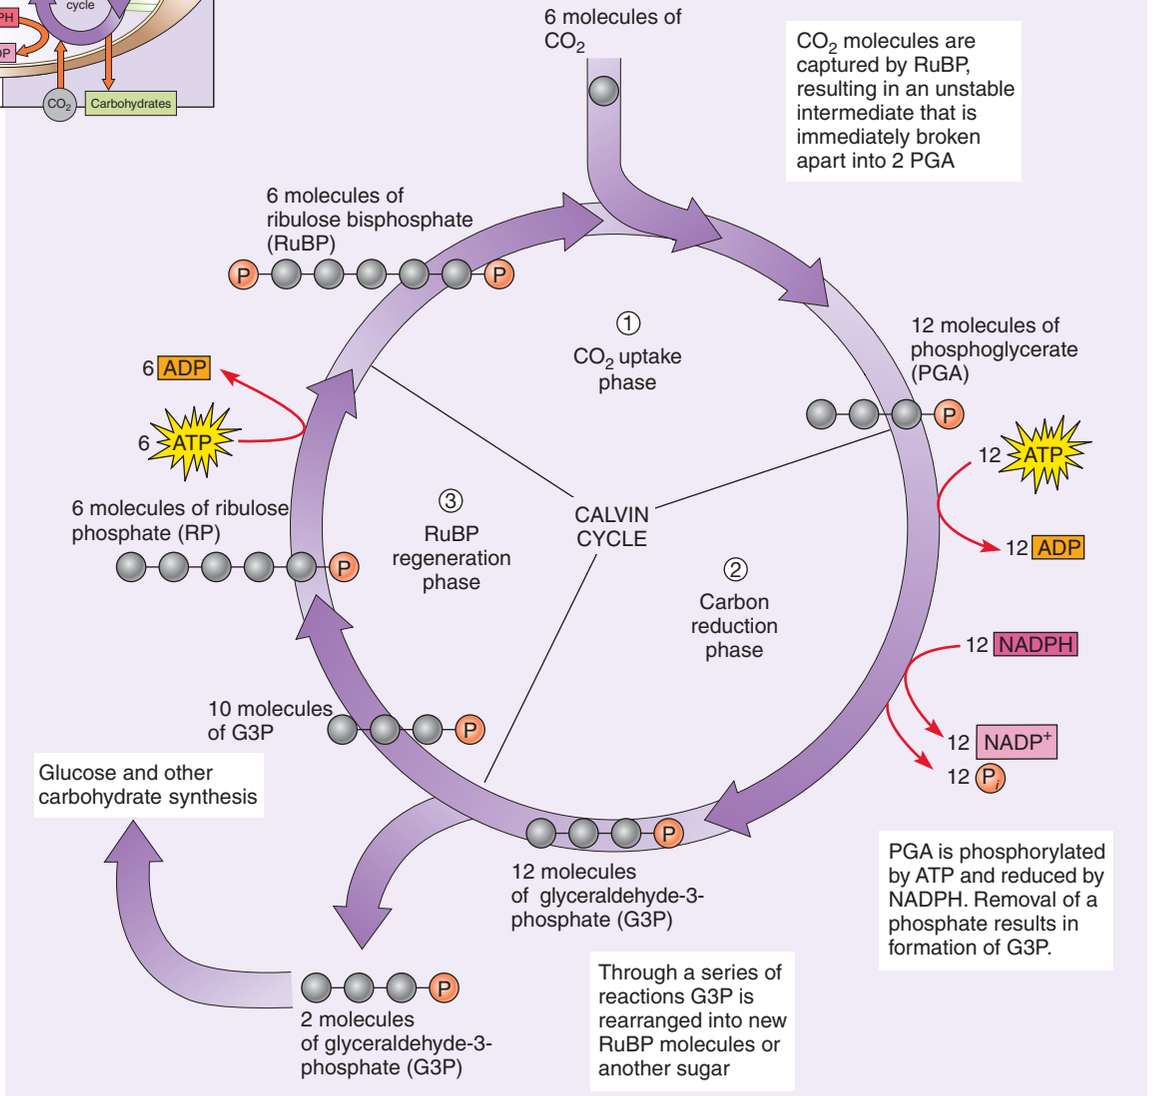


TABLE **8-3** **Summary of Photosynthesis**

Reaction Series	Summary of Process	Needed Materials	End Products
Light-dependent reactions (take place in thylakoid membranes)	Energy from sunlight used to split water, manufacture ATP, and reduce $NADP^+$		
Photochemical reactions	Chlorophyll-activated; reaction center gives up photoexcited electron to electron acceptor	Light energy; pigments (chlorophyll)	Electrons
Electron transport	Electrons transported along chain of electron acceptors in thylakoid membranes; electrons reduce $NADP^+$; splitting of water provides some H^+ that accumulates inside thylakoid space	Electrons, $NADP^+$, H_2O, electron acceptors	NADPH, O_2
Chemiosmosis	H^+ permitted to diffuse across the thylakoid membrane down their gradient; they cross the membrane through special channels in ATP synthase complex; energy released is used to produce ATP	Proton gradient, ADP + P_i	ATP
Carbon fixation reactions (take place in stroma)	Carbon fixation: Carbon dioxide used to make carbohydrate	Ribulose bisphosphate, CO_2, ATP, NADPH, necessary enzymes	Carbohydrates, ADP + P_i, $NADP^+$

synthesize the RuBP molecules with which more CO_2 molecules may combine. Table 8-3 provides a summary of photosynthesis.

Photorespiration reduces photosynthetic efficiency

Many C_3 plants, including certain agriculturally important crops such as soybeans, wheat, and potatoes, do not yield as much carbohydrate from photosynthesis as might be expected, especially during very hot spells in summer. This phenomenon is a consequence of tradeoffs between the plant's need for CO_2 and its need to prevent water loss. Recall that most photosynthesis occurs in mesophyll cells inside the leaf and that the entry and exit of gases from the interior of the leaf is regulated by stomata, tiny pores concentrated on the underside of the leaf (see Fig. 8-4a). On hot, dry days, plants close their stomata to conserve water. Once the stomata close, photosynthesis rapidly uses up the CO_2 remaining in the leaf and produces O_2, which accumulates in the chloroplasts.

Recall that the enzyme RuBP carboxylase/oxygenase (rubisco) catalyzes CO_2 fixation in the Calvin cycle by attaching CO_2 to RuBP. As its full name implies, rubisco acts not only as a carboxylase, but also as an oxygenase because high levels of O_2 compete with CO_2 for the active site of rubisco. Some of the intermediates involved in the Calvin cycle are degraded to CO_2 and H_2O in a process that is called **photorespiration,** because (1) it occurs in the presence of light; (2) it requires oxygen, like aerobic respiration; and (3) it produces CO_2 and H_2O, like aerobic respiration. However, photorespiration does not produce ATP, and it reduces photosynthetic efficiency because it removes some of the intermediates used in the Calvin cycle.

The reasons for photorespiration are incompletely understood, although scientists hypothesize that it reflects the origin of rubisco at an ancient time when CO_2 levels were high and molecular oxygen levels were low. Genetic engineering to produce plants with Rubisco that has a much lower affinity for oxygen is a promising area of research to improve yields of certain valuable crop plants.

The initial carbon fixation step differs in C_4 plants and in CAM plants

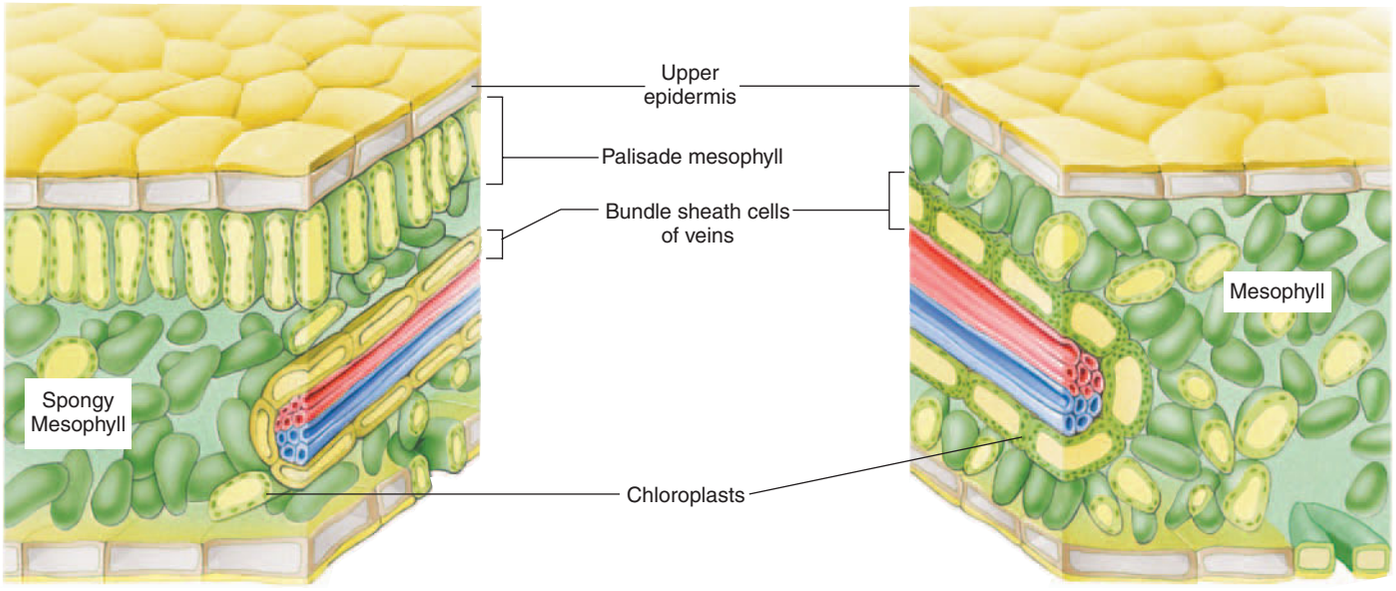
Photorespiration is not the only problem faced by plants engaged in photosynthesis. Because CO_2 is not a very abundant gas (composing only about 0.03% of the atmosphere), it is not easy for plants to obtain the CO_2 they need. As you have learned, when conditions are hot and dry, the stomata close to reduce the loss of water vapor, greatly diminishing the supply of CO_2. Ironically, CO_2 is potentially less available at the very times when maximum sunlight is available to power the light-dependent reactions.

Many plant species living in hot, dry environments have adaptations that facilitate carbon fixation. **C_4 plants** first fix CO_2 into a four-carbon compound, oxaloacetate. **CAM plants** initially fix carbon at night through the formation of oxaloacetate. These special pathways found in C_4 and CAM plants precede the Calvin cycle (C_3 pathway); they do not replace it.

The C_4 pathway efficiently fixes CO_2 at low concentrations

The **C_4 pathway,** in which CO_2 is fixed through the formation of oxaloacetate, occurs not only before the C_3 pathway but also in different cells. Leaf anatomy is usually distinctive in C_4 plants. The photosynthetic mesophyll cells are closely associated with prominent, chloroplast-containing **bundle sheath cells,** which tightly encircle the veins of the leaf (Fig. 8-15). The C_4 pathway occurs in the mesophyll cells, whereas the Calvin cycle takes place within the bundle sheath cells.

The key component of the C_4 pathway is a remarkable enzyme that has an extremely high affinity for CO_2, binding it effectively even at unusually low concentrations. This enzyme, **PEP carboxylase,** catalyzes the reaction by which CO_2 reacts



(a) Arrangement of cells in a C_3 leaf

(b) Arrangement of cells in a C_4 leaf

FIGURE **8-15** **C_3 and C_4 plant structure compared.**

(a) In C_3 plants, the Calvin cycle takes place in the mesophyll cells, and the bundle sheath cells are nonphotosynthetic. **(b)** In C_4 plants, reactions that fix CO_2 into four-carbon compounds take place in the mesophyll cells. The four-carbon compounds are transferred from the mesophyll cells to the photosynthetic bundle sheath cells, where the Calvin cycle takes place.

with the three-carbon compound **phosphoenolpyruvate (PEP),** forming **oxaloacetate** (Fig. 8-16).

In a step that requires NADPH, oxaloacetate is converted to some other four-carbon compound, usually malate. The malate then passes to chloroplasts within bundle sheath cells, where a different enzyme catalyzes the decarboxylation of malate to yield pyruvate (which has three carbons) and CO_2. NADPH is formed, replacing the one used earlier.

$$\text{Malate} + \text{NADP}^+ \longrightarrow \text{pyruvate} + CO_2 + \text{NADPH}$$

The CO_2 released in the bundle sheath cell combines with ribulose bisphosphate in a reaction catalyzed by rubisco, and goes through the Calvin cycle in the usual manner. The pyruvate formed in the decarboxylation reaction returns to the mesophyll cell, where it reacts with ATP to regenerate phosphoenolpyruvate.

Because the C_4 pathway captures CO_2 and provides it to the bundle sheath cells so efficiently, CO_2 concentration within the bundle sheath cells is about 10 to 60 times greater than its concentration in the mesophyll cells of plants having only the C_3 pathway. Photorespiration is negligible in C_4 plants, because the concentration of CO_2 in bundle sheath cells (where rubisco is present) is always high.

The combined C_3–C_4 pathway involves the expenditure of 30 ATPs per hexose, rather than the 18 ATPs used by the C_3

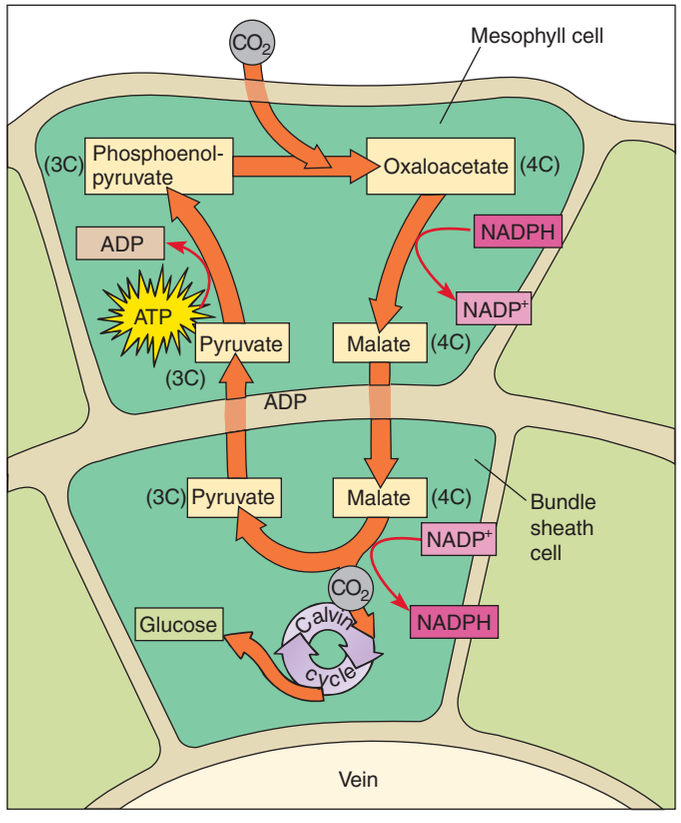


FIGURE **8-16** **Summary of the C_4 pathway.**

CO_2 combines with phosphoenolpyruvate (PEP) in the chloroplasts of mesophyll cells, forming a four-carbon compound that is converted to malate. Malate goes to the chloroplasts of bundle sheath cells, where it is decarboxylated. The CO_2 released in the bundle sheath cell is used to make carbohydrate by way of the Calvin cycle.

pathway alone. The extra energy expense required to regenerate PEP from pyruvate is worthwhile at high light intensities because it ensures a high concentration of CO_2 in the bundle sheath cells and permits them to carry on photosynthesis at a rapid rate. At lower light intensities and temperatures, C_3 plants are favored. For example, winter rye, a C_3 plant, grows lavishly in cool weather, when crabgrass cannot because it requires more energy to fix CO_2.

CAM plants fix CO_2 at night

Plants living in very dry, or *xeric,* conditions have a number of structural adaptations that enable them to survive. Many xeric plants have physiological adaptations as well, including a special carbon fixation pathway, the **CAM pathway,** or **crassulacean acid metabolism.** The name comes from the stonecrop plant family (the Crassulaceae), which possesses the CAM pathway, although it has evolved independently in some members of more than 25 other plant families, including the cactus family (Cactaceae), the lily family (Liliaceae), and the orchid family (Orchidaceae) (Fig. 8-17).

Unlike most plants, CAM plants open their stomata at night, admitting CO_2 while minimizing water loss. They use the enzyme PEP carboxylase to fix CO_2, forming oxaloacetate, which is converted to malate and stored in cell vacuoles. During the day, when stomata are closed and gas exchange cannot occur between the plant and the atmosphere, CO_2 is removed from malate by a decarboxylation reaction. Now the CO_2 is available within the leaf tissue to be fixed into sugar by the Calvin cycle (C_3 pathway).

The CAM pathway is very similar to the C_4 pathway but with important differences. C_4 plants initially fix CO_2 into four-carbon organic acids in mesophyll cells. The acids are later decarboxylated to produce CO_2, which is fixed by the C_3 pathway in the bundle sheath cells. In other words, the C_4 and C_3 pathways occur in *different locations* within the leaf of a C_4 plant. In CAM plants, the initial fixation of CO_2 occurs at night. Decarboxylation of malate and subsequent production of sugar from CO_2 by the normal C_3 photosynthetic pathway occur during the day. In other words, the CAM and C_3 pathways occur at *different times* within the same cell of a CAM plant.

Robert W. Domm/Visuals Unlimited

FIGURE **8-17** **A typical CAM plant.**

Prickly pear cactus (*Opuntia*) is a CAM plant. The more than 200 species of *Opuntia* living today originated in various xeric habitats in North and South America.

Although it does not promote rapid growth the way that the C_4 pathway does, the CAM pathway is a very successful adaptation to xeric conditions. CAM plants can exchange gases for photosynthesis and to reduce water loss significantly. Plants with CAM photosynthesis survive in deserts where neither C_3 nor C_4 plants can.

Review

- Which phase of the Calvin cycle requires both ATP and NADPH?
- In what ways does photorespiration differ from aerobic respiration?
- Do C_3, C_4, and CAM plants all have rubisco? PEP carboxylase?

BiologyNow™ Assess your understanding of the **carbon fixation reactions** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Describe the physical properties of light and explain the relationship between a wavelength of light and its energy.

- Light consists of particles called **photons** that move as waves. Photons with shorter **wavelengths** have more energy than those with longer wavelengths.

2 Diagram the internal structure of a chloroplast, and explain how its components interact and facilitate the process of photosynthesis.

- In plants, **photosynthesis** occurs in chloroplasts, which are located mainly within **mesophyll** cells inside the leaf.
- **Chloroplasts** are organelles enclosed by a double membrane; the inner membrane encloses the **stroma** in which membranous, saclike **thylakoids** are suspended. Each thylakoid encloses a **thylakoid lumen.** Thylakoids arranged in stacks are called **grana.**
- **Chlorophyll *a*, chlorophyll *b*, carotenoids,** and other photosynthetic pigments are components of the thylakoid membranes of chloroplasts.

3 Describe what happens to an electron in a biological molecule such as chlorophyll when a photon of light energy is absorbed.

- Photons excite biological molecules such as chlorophyll and other photosynthetic pigments, causing one or more electrons to become energized. These energized electrons may be accepted by electron acceptor compounds.
- The combined **absorption spectra** of chlorophylls *a* and *b* are similar to the **action spectrum** for photosynthesis.

SUMMARY WITH KEY TERMS *(continued)*

4 Describe photosynthesis as a redox process.

- During photosynthesis, light energy is captured and converted to the chemical energy of carbohydrates; hydrogens from water are used to reduce carbon, and oxygen derived from water becomes oxidized, forming molecular oxygen.

5 Distinguish between the light-dependent reactions and carbon fixation reactions of photosynthesis

- In the **light-dependent reactions,** electrons energized by light are used to generate **ATP** and **NADPH;** these compounds provide energy for the formation of carbohydrate during the **carbon fixation reactions.**

6 Describe the flow of electrons through photosystems I and II in the noncyclic electron transport pathway; contrast this with cyclic electron transport.

- **Photosystems I** and **II** are the two types of photosynthetic units involved in photosynthesis. Each photosystem includes chlorophyll molecules and accessory pigments organized with pigment-binding proteins into **antenna complexes.**
- Only a special chlorophyll *a* in the **reaction center** of an antenna complex gives up its energized electrons to a nearby electron acceptor. **P700** is the reaction center for photosystem I; **P680** is the photosystem II reaction center.
- During the noncyclic light-dependent reactions, known as **noncyclic electron transport, ATP** and **NADPH** are formed. Electrons in photosystem I are energized by the absorption of light and passed through an **electron transport chain** to $NADP^+$, forming NADPH. Electrons given up by P700 in photosystem I are replaced by electrons from P680 in photosystem II. A series of redox reactions takes place as energized electrons are passed along the electron transport chain from photosystem II to photosystem I. Electrons given up by P680 in photosystem II are replaced by electrons made available by the **photolysis** of H_2O; oxygen is released in the process.
- During **cyclic electron transport,** electrons from photosystem I are eventually returned to photosystem I. ATP is produced by chemiosmosis, but no NADPH or oxygen is generated.

7 Explain how a proton (H^+) gradient is established across the thylakoid membrane and how this gradient functions in ATP synthesis.

- **Photophosphorylation** is the synthesis of ATP coupled to the transport of electrons energized by photons of light. Some of the energy of the electrons is used to pump protons across the thylakoid membrane, providing the energy to generate ATP by **chemiosmosis.**
- As protons diffuse through **ATP synthase,** an enzyme complex in the thylakoid membrane, ADP is phosphorylated to form ATP.

8 Summarize the three phases of the Calvin cycle, and indicate the roles of ATP and NADPH in the process.

- The **carbon fixation reactions** proceed by way of the **Calvin cycle,** also known as the **C_3 pathway.**
- In the CO_2 uptake phase of the Calvin cycle, CO_2 is combined with ribulose bisphosphate (RuBP), a five-carbon sugar, by the enzyme ribulose bisphosphate carboxylase/oxygenase, commonly known as **rubisco,** forming the three-carbon molecule **phosphoglycerate (PGA).**
- In the carbon reduction phase of the Calvin cycle, the energy and reducing power of ATP and NADPH are used to convert PGA molecules to **glyceraldehyde-3-phosphate (G3P).** For every 6 CO_2 molecules fixed, 12 molecules of G3P are produced, and 2 molecules of G3P leave the cycle to produce the equivalent of 1 molecule of glucose.
- In the RuBP regeneration phase of the Calvin cycle, the remaining G3P molecules are modified to regenerate RuBP.

9 Discuss how photorespiration reduces photosynthetic efficiency.

- In **photorespiration,** C_3 plants consume oxygen and generate CO_2 by degrading Calvin cycle intermediates but do not produce ATP. Photorespiration is significant on bright, hot, dry days when plants close their stomata, conserving water but preventing the passage of CO_2 into the leaf.

10 Compare the C_4 and CAM pathways.

- In the **C_4 pathway,** the enzyme **PEP carboxylase** binds CO_2 effectively, even when CO_2 is at a low concentration. C_4 reactions take place within mesophyll cells. The CO_2 is fixed in **oxaloacetate,** which is then converted to malate. The malate moves into a **bundle sheath cell,** and CO_2 is removed from it. The released CO_2 then enters the Calvin cycle.
- The **crassulacean acid metabolism (CAM)** pathway is similar to the C_4 pathway. PEP carboxylase fixes carbon at night in the mesophyll cells, and the Calvin cycle occurs during the day in the same cells.

Summary Reactions for Photosynthesis

The light-dependent reactions (noncyclic electron transport):

$$12\ H_2O + 12\ NADP^+ + 18\ ADP + 18\ P_i \xrightarrow[\text{Chlorophyll}]{\text{Light}} 6\ O_2 + 12\ NADPH + 18\ ATP$$

The carbon fixation reactions (Calvin cycle):

$$12\ NADPH + 18\ ATP + 6\ CO_2 \longrightarrow C_6H_{12}O_6 + 12\ NADP^+ + 18\ ADP + 18\ P_i + 6\ H_2O$$

By canceling out the common items on opposite sides of the arrows in these two coupled equations, we obtain the simplified overall equation for photosynthesis:

$$\underset{\text{Carbon dioxide}}{6\ CO_2} + \underset{\text{Water}}{12\ H_2O} \xrightarrow[\text{Chlorophyll}]{\text{Light energy}} \underset{\text{Glucose}}{C_6H_{12}O_6} + \underset{\text{Oxygen}}{6\ O_2} + \underset{\text{Water}}{6\ H_2O}$$

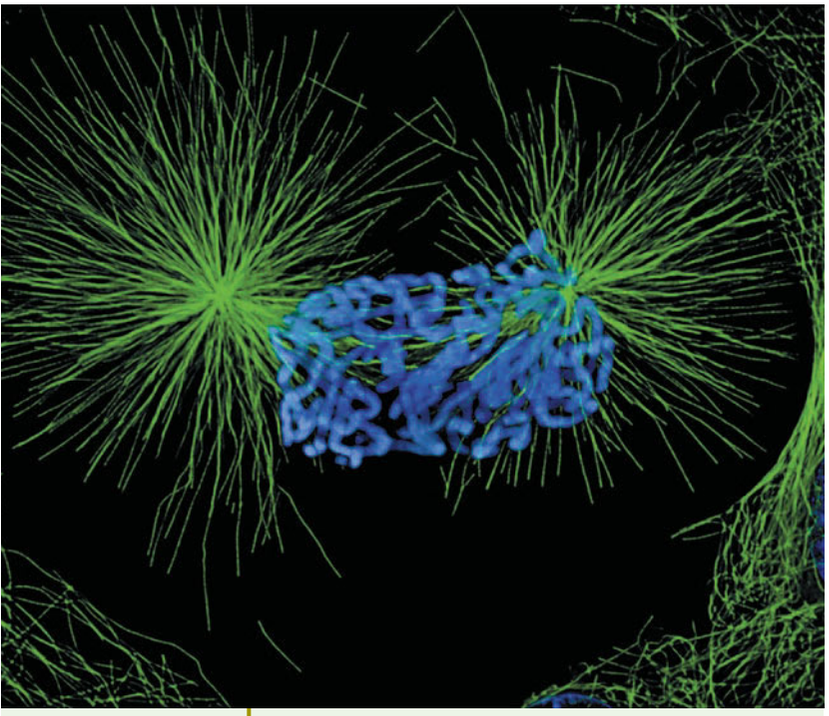
Chromosomes, Mitosis, and Meiosis



Alexey Khodjakov, Wadsworth Center, Albany, NY

Fluorescence LM of a cultured newt lung cell in early mitosis. The nuclear envelope has broken down, and the microtubules of the mitotic spindle *(green)* now interact with the chromosomes *(blue)*.

CHAPTER OUTLINE

- **Eukaryotic Chromosomes**
- **The Cell Cycle and Mitosis**
- **Sexual Reproduction and Meiosis**

Pre-existing cells divide to form new cells. This remarkable process enables an organism to grow, repair damaged parts, and reproduce. Cells serve as the basic units of life and the essential link between generations. Even the simplest cell contains a massive amount of precisely coded genetic information in the form of deoxyribonucleic acid (DNA), collectively called the organism's **genome.** Genomes are organized into informational units called *genes,* which control the activities of the cell and are passed on to its descendants.

When a cell divides, the information contained in the DNA must be faithfully duplicated and the copies then transmitted to each daughter cell through a precisely choreographed series of steps (see photograph). DNA is a very long, thin molecule that could easily become tangled and broken, and a eukaryotic cell's nucleus contains a huge amount of DNA. In this chapter, we consider how eukaryotes accommodate the genetic material by packaging each DNA molecule with proteins to form a structure called a *chromosome,* each of which contains hundreds or thousands of genes.

We then consider *mitosis,* the process that ensures a parent cell transmits one copy of every chromosome to each of its two daughter cells. In this way, the chromosome number is preserved through successive mitotic divisions. Most body cells of eukaryotes divide by mitosis.

Finally we discuss *meiosis,* a process that reduces the chromosome number by half. Sexual life cycles in eukaryotes require meiosis. Sexual reproduction involves the fusion of two sex cells, or *gametes,* to form a single cell called a *zygote.* Meiosis makes it possible for each gamete to contain only half the number of parent chromosomes, preventing the zygotes from having twice as many chromosomes as the parents.

Bacterial reproduction is described in Chapter 23. Prokaryotic cells contain much less DNA than do most eukaryotic cells. Their DNA is usually circular and is packaged with associated proteins. Although the distribution of genetic material in dividing prokaryotic cells is a simpler process than mitosis, it never-

theless is very precise, to ensure that the daughter cells are genetically identical to the parent cell. ■

EUKARYOTIC CHROMOSOMES

Learning Objectives

1. Discuss the significance of chromosomes in terms of their information content.
2. Compare the organization of DNA in prokaryotic and eukaryotic cells.

The major carriers of genetic information in eukaryotes are the **chromosomes,** which lie within the cell nucleus. Although *chromosome* means "colored body," chromosomes are virtually colorless; the term refers to their ability to be stained by certain dyes. In the 1880s, light microscopes had been improved to the point that biologists such as the German biologist Walther Fleming began to observe chromosomes during cell division. In 1903, American biologist Walter Sutton and German biologist Theodor Boveri noted independently that chromosomes were the physical carriers of genes, the genetic factors Gregor Mendel discovered in the 19th century (see Chapter 10).

Chromosomes are made of **chromatin,** a material consisting of DNA and associated proteins. When a cell is not dividing, the chromosomes are present but in an extended, partially unraveled form. Chromatin consists of long, thin threads that are somewhat aggregated, giving them a granular appearance when viewed with the electron microscope (see Fig. 4-11). During cell division, the chromatin fibers condense and the chromosomes become visible as distinct structures (Fig. 9-1).

DNA is organized into informational units called genes

An organism's genome may contain hundreds or even thousands of genes. For example, the **Human Genome Project** estimates that humans have less than 30,000 genes that code for proteins (see Chapter 15). As you will see in later chapters, the concept of the gene has changed considerably since the science of genetics began, but our definitions have always centered on the gene as an informational unit. By providing information needed to carry out one or more specific cell functions, a **gene** ultimately affects some characteristic of the organism. For example, genes govern eye color in humans, wing length in flies, and seed color in peas.

DNA is packaged in a highly organized way in chromosomes

Prokaryotic and eukaryotic cells differ markedly in their DNA content as well as in the organization of DNA molecules. The bacterium *E. coli* normally contains about 4×10^6 base pairs (almost 1.35 mm) of DNA in its single circular DNA molecule. In fact, the total length of its DNA is about 1000 times longer than the length of the cell itself. Therefore, the DNA molecule is, with the help of proteins, twisted and folded compactly to fit inside the bacterial cell.

A typical eukaryotic cell contains much more DNA than a bacterium does, and it is organized in the nucleus as multiple chromosomes; these vary widely in size and number among different species. Although a human cell nucleus is about the size of a large bacterial cell, it contains more than 1000 times the amount of DNA found in *E. coli*. The DNA content of a human sperm cell is about 3×10^9 base pairs; stretched end to end, it would measure almost 1 m long.

How does a eukaryotic cell pack its DNA into the chromosomes? Chromosome packaging is facilitated by certain proteins known as **histones.**[1] Histones have a positive charge because they have a high proportion of amino acids with basic side chains (see Chapter 3). The positively charged histones associate with DNA, which has a negative charge because of its phosphate groups, to form structures called **nucleosomes.** The fundamental unit of each nucleosome consists of a beadlike structure with 146 base pairs of DNA wrapped around a disc-shaped core of eight histone molecules (two each of four different histone types) (Fig. 9-2). Although the nucleosome was originally defined as a bead plus a DNA segment that links it to an adjacent bead, today the term more commonly refers only to the bead itself (that is, the eight histones and the DNA wrapped around them).

Nucleosomes function like tiny spools, preventing DNA strands from becoming tangled. You can see the importance of this role in Figure 9-3, which illustrates the enormous number of DNA fibers that unravel from a mouse chromosome after researchers have removed the histones. **Scaffolding proteins** are nonhistone proteins that help maintain chromosome structure. But the role of histones is more than structural, because their arrangement also affects the activity of the DNA with which they are associated.

[1] A few types of eukaryotic cells lack histones. Conversely, histones occur in one group of prokaryotes, the archaea (see Chapter 23).

2 µm

FIGURE **9-3** **TEM of a mouse chromosome depleted of histones.**

Notice how densely packed the DNA strands are, even though they have been released from the histone proteins that organize them into tightly coiled structures.

Nucleosomes are part of the chromatin. Figure 9-4 shows the higher-order structures of chromatin leading to the formation of a condensed chromosome. The nucleosomes themselves are 11 nm in diameter. The packed nucleosome state occurs when a fifth type of histone, known as *histone H1*, associates with the linker DNA, packing adjacent nucleosomes together to form a 30-nm-diameter fiber. In extended chromatin, these fibers form large, coiled loops held together by scaffolding proteins. The loops then interact to form the condensed chromatin found in a metaphase chromosome.

Chromosome number and informational content differ among species

Every individual of a given species has a characteristic number of chromosomes in most nuclei of its body cells. However, it is not the number of chromosomes that makes each species unique, but the information the genes specify.

Most human body cells have exactly 46 chromosomes, but humans are not humans merely because they have 46 chromosomes. In fact, some individuals have an abnormal chromosome constitution, or **karyotype,** with more or fewer than 46 (see Fig. 15-5). Humans are not unique in having 46 chromosomes; some other species—the olive tree, for example—also have 46.

Other species have different chromosome numbers. A certain species of roundworm has only 2 chromosomes in each cell, whereas some crabs have as many as 200, and some ferns have more than 1000. Most animal and plant species have between 8 and 50 chromosomes per body cell. Numbers above and below these are uncommon.

Review

- What are the informational units on chromosomes called? Of what do these informational units consist?
- How are bacterial DNA molecules and eukaryotic chromosomes similar? How do they differ?

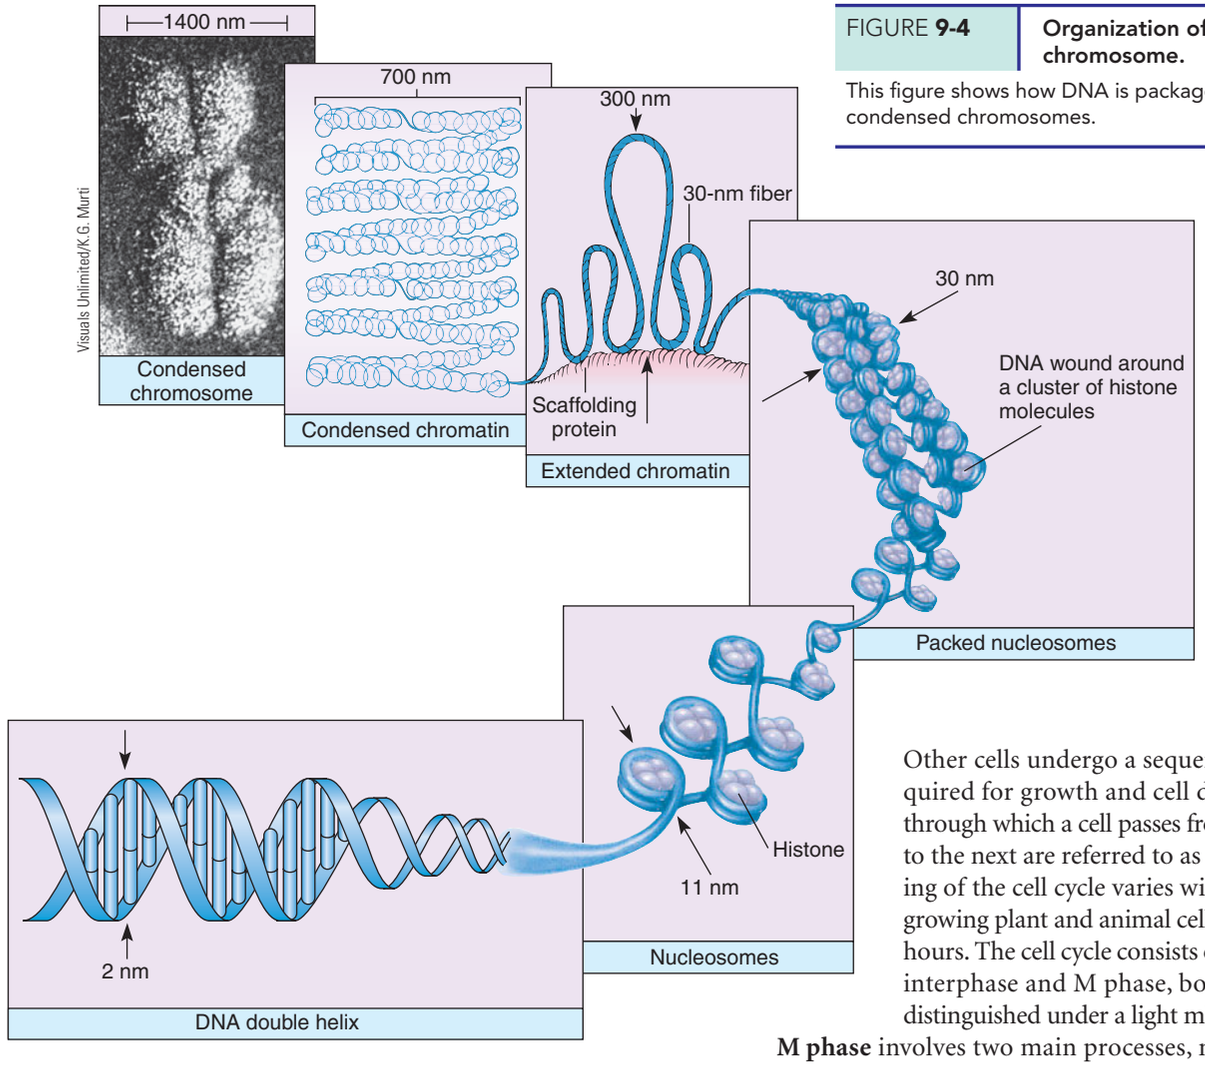

FIGURE **9-4** **Organization of a eukaryotic chromosome.**

This figure shows how DNA is packaged into highly condensed chromosomes.

- How is the large discrepancy between DNA length and nucleus size addressed in eukaryotic cells?
- How can two species have the same chromosome number, yet have very different attributes?

THE CELL CYCLE AND MITOSIS

Learning Objectives

3 Identify the stages in the eukaryotic cell cycle, describe their principal events, and point out some ways in which the cycle is controlled.

4 Describe the structure of a duplicated chromosome, including the sister chromatids, centromeres, and kinetochores.

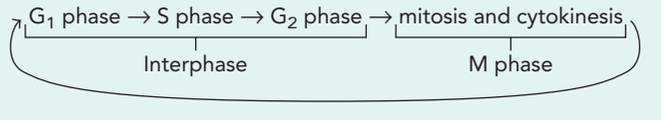
5 Explain the significance of mitosis, and describe the process.

When cells reach a certain size, they usually either stop growing or divide. Not all cells divide; some, such as nerve, skeletal muscle, and red blood cells, do not normally divide once they are mature. Other cells undergo a sequence of activities required for growth and cell division. The stages through which a cell passes from one cell division to the next are referred to as the **cell cycle.** Timing of the cell cycle varies widely, but in actively growing plant and animal cells, it is about 8 to 20 hours. The cell cycle consists of two main phases, interphase and M phase, both of which can be distinguished under a light microscope (Fig. 9-5).

M phase involves two main processes, mitosis and cytokinesis. *Mitosis,* a process involving the nucleus, ensures that each new nucleus receives the same number and types of chromosomes as were present in the original nucleus. *Cytokinesis,* which generally begins before mitosis is complete, is the division of the cell cytoplasm to form two cells. Multinucleated cells form if mitosis is not followed by cytokinesis; this is a normal condition for certain cell types.

Chromosomes duplicate during interphase

Most of a cell's life is spent in **interphase,** the time when no cell division is occurring. Although the appearance of the nucleus is generally unremarkable (see Fig. 4-11), a cell that is capable of dividing is typically very active during this time, synthesizing needed materials and growing. The cell synthesizes most proteins, lipids, and other biologically important materials throughout interphase. Here is the sequence of interphase and M phase in the eukaryotic cell cycle:



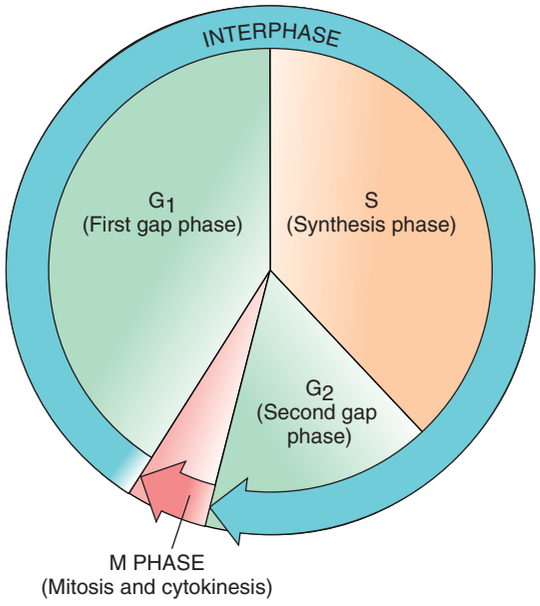


FIGURE **9-5** **The eukaryotic cell cycle.**

The cell cycle includes interphase (G_1, S, and G_2) and M phase (mitosis and cytokinesis). Proportionate amounts of time spent at each stage vary among species, cell types, and growth conditions. If the cell cycle were a period of 12 hours, G_1 would be about 5 hours, S would be 4.5 hours, G_2 would be 2 hours, and M phase would be 30 minutes.

The time between the end of mitosis and the beginning of the S phase is termed the **G_1 phase** (*G* stands for *gap,* an interval during which no DNA synthesis occurs). Growth and normal metabolism take place during the G_1 phase, which is typically the longest phase. Cells that are not dividing usually become arrested in this part of the cell cycle and are said to be in a state called G_0. Toward the end of G_1, the enzymes required for DNA synthesis become more active. Synthesis of these enzymes, along with proteins needed to initiate cell division (discussed later in the chapter), enable the cell to enter the S phase.

PROCESS OF SCIENCE

During the **synthesis phase,** or **S phase,** DNA replicates and histone is synthesized, as the cell makes duplicate copies of its chromosomes. How did researchers identify the S phase of the cell cycle? In the early 1950s, researchers demonstrated that cells preparing to divide duplicate their chromosomes at a relatively restricted interval during interphase and not during early mitosis, as previously hypothesized. These investigators used isotopes, such as ^3H, to synthesize radioactive thymidine, a nucleotide that is incorporated specifically into DNA as it is synthesized. After radioactive thymidine was supplied for a brief period (such as 30 minutes) to actively growing cells, autoradiography (see Chapter 2) on exposed film showed that a fraction of the cells had silver grains over their chromosomes. The nuclei of these cells were radioactive, because during the experiment they had replicated DNA. DNA replication was not occurring in the cells that did not have radioactively labeled chromosomes. Researchers therefore inferred that the proportion of labeled cells out of the total number of cells provides a rough estimate of the length of the S phase relative to the rest of the cell cycle.

After it completes the S phase, the cell enters a second gap phase, the **G_2 phase.** At this time, increased protein synthesis occurs, as the final steps in the cell's preparation for division take place. For many cells, the G_2 phase is short relative to the G_1 and S phases.

Mitosis, the nuclear division that produces two nuclei identical to the parental nucleus, begins at the end of the G_2 phase. Mitosis is a continuous process, but for descriptive purposes, it is divided into four stages:

Prophase ⟶ metaphase ⟶ anaphase ⟶ telophase

Look at Figure 9-6 while you read the following descriptions of these stages as they occur in a typical plant or animal cell.

During prophase, duplicated chromosomes become visible with the microscope

The first stage of mitosis, **prophase,** begins with **chromosome compaction,** when the long chromatin fibers begin a coiling process that makes them shorter and thicker (see Fig. 9-4). The chromatin can then be distributed to the daughter cells without tangling. Cell biologists have identified a group of proteins, collectively called **condensin,** required for chromosome compaction. Using the energy of ATP hydrolysis, condensin binds to DNA and wraps it into coiled loops that are compacted into a mitotic chromosome.

When stained with certain dyes and viewed through the light microscope, chromosomes become visible as darkly staining bodies as prophase progresses. Each chromosome was duplicated during the preceding S phase and consists of a pair of **sister chromatids,** which contain identical, double-stranded DNA sequences. Each chromatid includes a constricted region called the **centromere.** Sister chromatids are tightly associated in the vicinity of their centromeres (Fig. 9-7). Precise DNA sequences and proteins that bind to those DNA sequences are the chemical basis for this close association at the centromeres. Attached to each centromere is a **kinetochore,** a structure formed from proteins to which **microtubules** can bind. These microtubules function in chromosome distribution during mitosis.

A dividing cell is usually described as a globe, with an equator that determines the midplane (equatorial plane) and two opposite poles. This terminology is used for all cells regardless of

▶ ACTIVE FIGURE **9-6** **Interphase and the stages of mitosis.**

The drawings depict generalized animal cells with a diploid chromosome number of 4; the sizes of the nuclei and chromosomes are exaggerated to show the structures more clearly. The left column of LMs shows cells of the whitefish (*Coregonus*). The right column of LMs shows sectioned cells of the onion (*Allium cepa*).

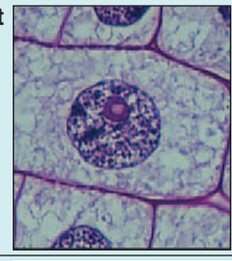
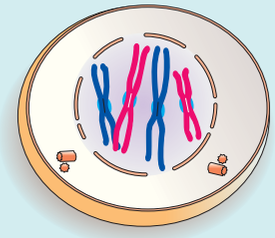
INTERPHASE

Cell is carrying out its normal life activities. Chromosomes become duplicated.

Animal

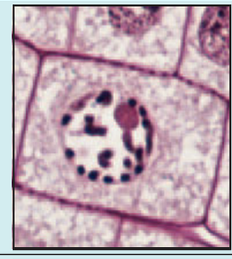
Plant

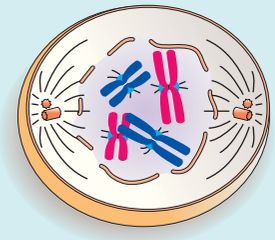




EARLY PROPHASE

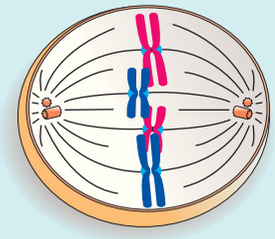
Nuclear envelope begins to disappear. Nucleolus disappears. Long fibers of chromatin become evident and begin to condense as visible chromosomes.





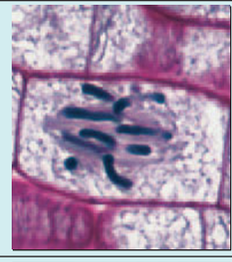
LATE PROPHASE

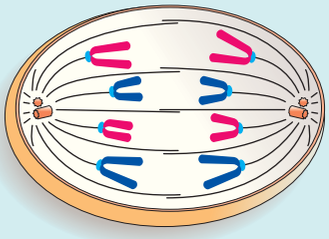
Chromosomes continue to shorten and thicken. Spindle forms between centrioles, which have moved to the poles of the cell. Kinetochores begin attaching to microtubules.



METAPHASE

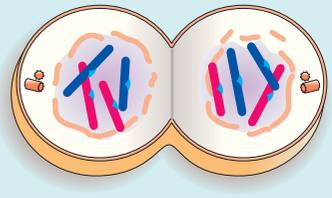
Spindle fibers attach to the kinetochores of the chromosomes, which line up along the cell's midplane.





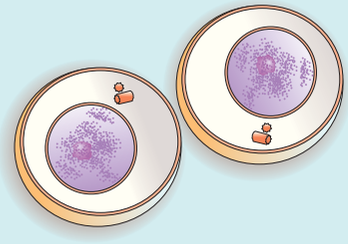
ANAPHASE

Chromatids separate at centromeres, and one group of chromosomes moves toward each pole.



TELOPHASE

Chromosomes have arrived at the poles, and the nuclear envelopes begin to form. Cytokinesis produces two daughter cells.



INTERPHASE

Daughter cells formed are genetically identical to the parent cell.

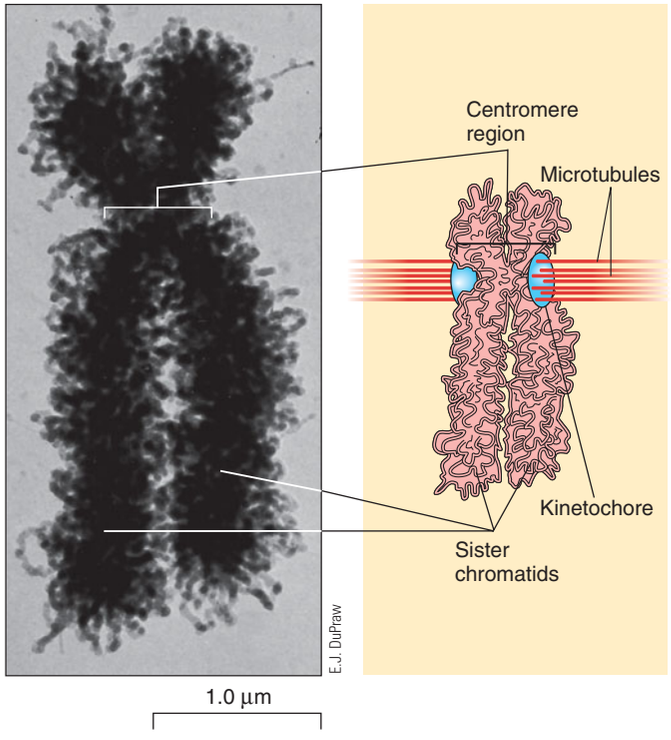

FIGURE 9-7 Sister chromatids and centromeres.

The sister chromatids, each consisting of tightly coiled chromatin fibers, are tightly associated at their centromere regions, indicated by the brackets. Associated with each centromere is a kinetochore, which serves as a microtubule attachment site. Kinetochores and microtubules are not visible in this SEM of a metaphase chromosome.

their actual shape. Microtubules radiate from each pole, and some of these protein fibers elongate toward the chromosomes, forming the **mitotic spindle,** which separates the chromosomes during anaphase (Fig. 9-8).

Animal cells differ from plant cells in the details of mitotic spindle formation. In both types of dividing cells, each pole contains a region, the **microtubule-organizing center,** from which extend the microtubules that form the mitotic spindle. The electron microscope shows that microtubule-organizing centers in plant cells consist of fibrils with little or no discernible structure.

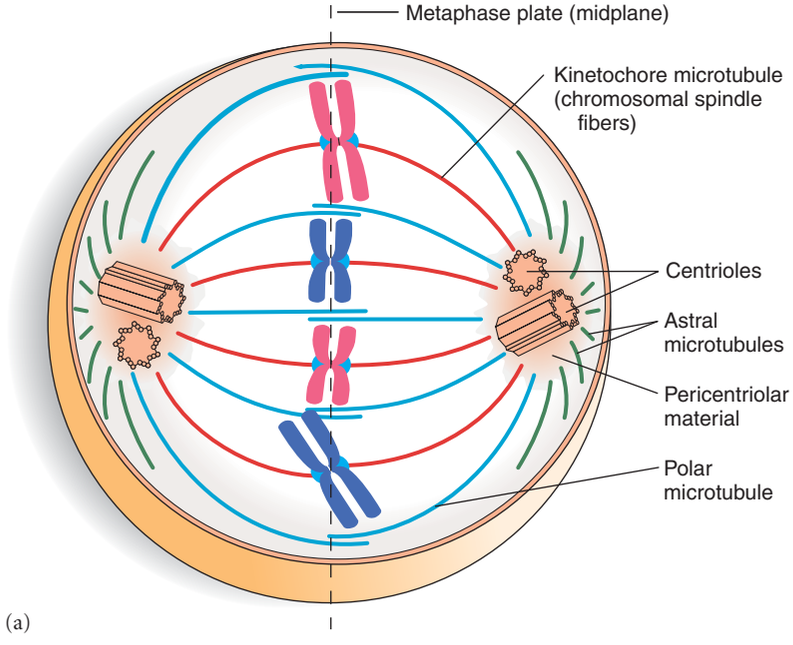
In contrast, animal cells have a pair of **centrioles** in the middle of each microtubule-organizing center (see Fig. 4-22). The centrioles are surrounded by fibrils that make up the **pericentriolar material.** The spindle microtubules terminate in the pericentriolar material, but they do not actually touch the centrioles. Although cell biologists once thought spindle formation in animal cells required centrioles, their involvement is probably coincidental. Current evidence suggests centrioles organize the pericentriolar material and ensure its duplication when the centrioles duplicate.

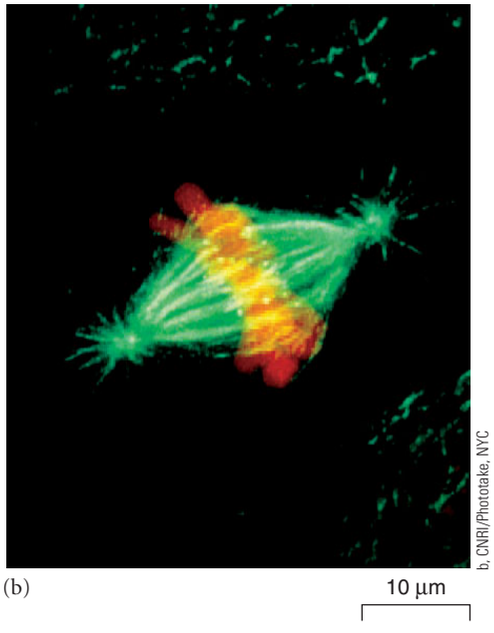
Each of the two centrioles is duplicated during interphase, yielding two centriole pairs. Late in prophase, microtubules radiate from the pericentriolar material surrounding the centrioles; these clusters of microtubules are called **asters.** The two asters move to opposite sides of the nucleus, establishing the two poles of the mitotic spindle.

During prophase, the nucleolus shrinks and usually disappears. Toward the end of prophase, the nuclear envelope breaks

FIGURE 9-8 The mitotic spindle.

(a) One end of each microtubule of this animal cell is associated with one of the poles. Astral microtubules *(green)* radiate in all directions, forming the aster. Kinetochore microtubules *(red)* connect the kinetochores to the poles, and polar microtubules *(blue)* overlap at the midplane. **(b)** This fluorescence LM of an animal cell at metaphase shows a well-defined spindle and asters (chromosomes, *orange;* microtubules, *green*).





down, and each sister chromatid attaches to some of the spindle microtubules at its kinetochore. Each chromosome consists of a pair of sister chromatids associated along their entire length and joined tightly at their centromeres.

Duplicated chromosomes line up on the midplane during metaphase

During **metaphase,** all the cell's chromosomes align at the cell's midplane, or **metaphase plate.** One chromatid of each chromosome attaches by its kinetochore to microtubules from one pole, and its sister chromatid attaches by its kinetochore to microtubules from the opposite pole. The mitotic spindle has two types of microtubules: polar microtubules and kinetochore microtubules (see Fig. 9-8). **Polar microtubules** extend from each pole to the equatorial region, where they generally overlap. **Kinetochore microtubules,** also called *chromosomal spindle fibers,* extend from each pole and attach to the kinetochores.

During metaphase each chromatid is completely condensed and appears quite thick and distinct. Because individual chromosomes can be seen more distinctly at metaphase than at any other time, they are usually photographed for a karyotype at this stage when chromosomal abnormalities are suspected, (see Chapter 15).

During anaphase, chromosomes move toward the poles

Anaphase begins as the sister chromatids separate. Once the chromatids are no longer attached to their duplicates, each chromatid is called a *chromosome.* The now separate chromosomes move to opposite poles, using the spindle microtubules as tracks. The kinetochores, still attached to kinetochore microtubules, lead the way, with the chromosome arms trailing behind. Anaphase ends when all the chromosomes have reached the poles.

PROCESS OF SCIENCE

The overall mechanism of chromosome movement in anaphase is still poorly understood, although researchers are making significant progress in this area. Microtubules lack elastic or contractile properties. Then how do the chromosomes move apart? Are they pushed or pulled, or do other forces operate?

Chromosome movements are studied in several ways. Researchers determine the number of microtubules at a particular stage or after certain treatments, by carefully analyzing electron micrographs. Researchers also physically perturb living cells that are dividing, using laser beams or mechanical devices known as *micromanipulators.* Skilled researchers can move chromosomes, break their connections to microtubules, and even remove them from the cell entirely.

Microtubules are dynamic structures, with *tubulin* subunits being constantly removed from their ends and others being added. Evidence indicates that kinetochore microtubules shorten during anaphase. Therefore, current hypotheses to explain anaphase movement include the idea that chromosomes move poleward because they remain anchored to the kinetochore microtubules even as tubulin subunits are being removed at the kinetochore. Multiple types of motor proteins, including forms of *kinesin* and *dynein,* probably play a role in this movement.

A second phenomenon also plays a role in chromosome separation. During anaphase the spindle as a whole elongates, at least partly because polar microtubules originating at opposite poles are associated with motors that let them slide past one another at the midplane. The sliding decreases the degree of overlap, thereby "pushing" the poles apart. This mechanism indirectly causes the chromosomes to move apart because they are attached to the poles by kinetochore microtubules.

During telophase, two separate nuclei form

The final stage of mitosis, **telophase,** is characterized by the arrival of the chromosomes at the poles and, in its final stage, by a return to interphase-like conditions. The chromosomes decondense by partially uncoiling. A new nuclear envelope forms around each set of chromosomes, made at least in part from small vesicles and other components derived from the old nuclear envelope. The spindle microtubules disappear, and the nucleoli reorganize.

Cytokinesis forms two separate daughter cells

Cytokinesis, the division of the cytoplasm to yield two daughter cells, usually overlaps mitosis, generally beginning during telophase. Cytokinesis of an animal cell begins as a ring of actin microfilaments associated with the plasma membrane encircles the cell in the equatorial region, at right angles to the spindle (Fig. 9-9a). The ring contracts, producing a **cleavage furrow** that gradually deepens and separates the cytoplasm into two daughter cells, each with a complete nucleus.

In plant cells, cytokinesis occurs by forming a **cell plate** (Fig. 9-9b), a partition constructed in the equatorial region of the spindle and growing laterally toward the cell wall. The cell plate forms as a line of vesicles originating in the *Golgi complex.* The vesicles contain materials to construct both a primary cell wall for each daughter cell and a middle lamella that cements the primary cell walls together. The vesicle membranes fuse to become the plasma membrane of each daughter cell.

Mitosis produces two cells genetically identical to the parent cell

The remarkable regularity of the process of cell division ensures that each daughter nucleus receives exactly the same number and kinds of chromosomes that the parent cell had. Thus, with a few exceptions, every cell of a multicellular organism has the same genetic makeup. If a cell receives more or fewer than the characteristic number of chromosomes through some malfunction of the cell division process, the resulting cell may show marked abnormalities and often cannot survive.

Mitosis provides for the orderly distribution of chromosomes (and of centrioles, if present), but what about the various cytoplasmic organelles? For example, all eukaryotic cells,

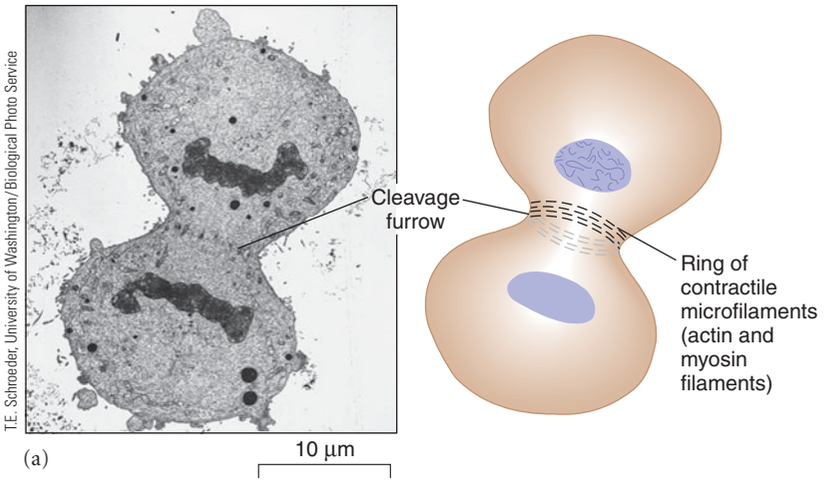


FIGURE **9-9** **Cytokinesis in plant and animal cells.**

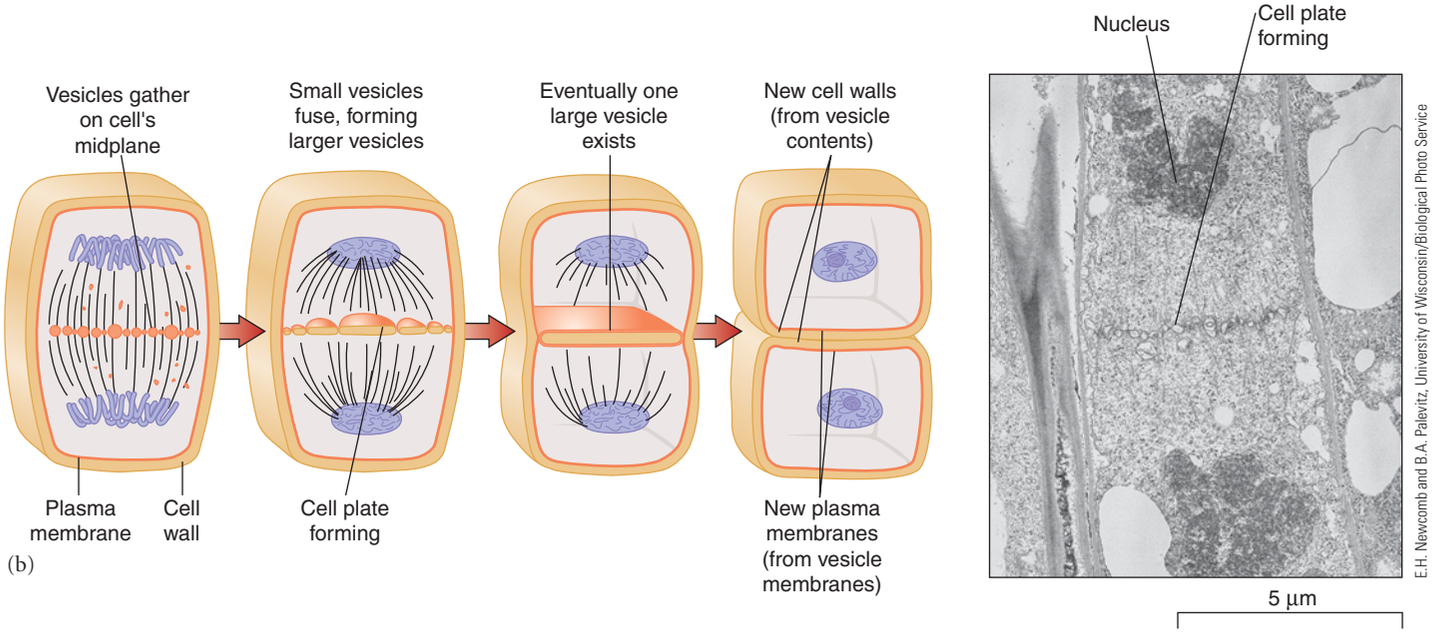
The nuclei in both TEMs are in telophase. The drawings show 3-D relationships. **(a)** TEM of the equatorial region of a cultured animal cell undergoing cytokinesis shows a cleavage furrow. **(b)** TEM of a maple leaf cell (*Acer saccharinum*) undergoing cytokinesis shows cell plate formation.



including plant cells, require mitochondria. Likewise, photosynthetic plant cells cannot carry out photosynthesis without chloroplasts. These organelles contain their own DNA and appear to form by the division of previously existing mitochondria or plastids or their precursors. This nonmitotic division process is similar to prokaryotic cell division (see Chapter 23) and generally occurs during interphase, not when the cell divides. Because many copies of each organelle are present in each cell, organelles are apportioned with the cytoplasm that each daughter cell receives during cytokinesis.

An internal genetic program interacting with external signals regulates the cell cycle

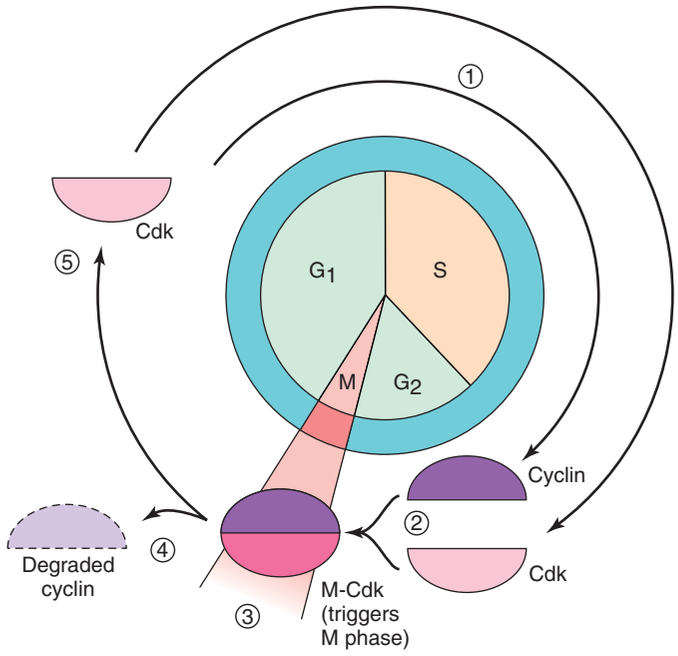
When conditions are optimal, some prokaryotic cells can divide every 20 minutes. The generation times of eukaryotic cells are generally much longer, although the frequency of cell division varies widely among different species and among different tissues of the same species. Some cells in the central nervous system usually stop dividing after the first few months of life, whereas blood-forming cells, digestive tract cells, and skin cells divide frequently throughout the life of the organism. Under optimal conditions of nutrition, temperature, and pH, the length of the eukaryotic cell cycle is constant for any given cell type. Under less favorable conditions, however, the generation time may be longer.

Certain regulatory molecules that control the cell cycle are common to all eukaryotes. Genetically programmed in the cell's nucleus, these regulatory molecules are found in organisms as diverse as yeast (a unicellular fungus), clams, frogs, humans, and plants. Molecular regulators trigger a specific sequence of events during the cell cycle. Because a failure to carefully control cell division can have disastrous consequences, signals in the genetic program, called **cell cycle checkpoints,** ensure that all the events of a particular stage have been completed before the next stage begins. For example, if a cell produces damaged or unreplicated DNA, the cell cycle halts and the cell will not undergo mitosis.

Figure 9-10 shows the key molecules involved in regulating the cell cycle. Among them are **protein kinases,** enzymes that

FIGURE **9-10** **Molecular control of the cell cycle.**

Different cyclins associate with Cdks (cyclin-dependent kinases), triggering the onset of the different stages of the cell cycle. This diagram is a simplified view of the control system that triggers the cell to move from G_2 to M phase. ① Cyclin is synthesized and accumulates. ② Cdk associates with cyclin, forming a cyclin-Cdk complex, M-Cdk. ③ M-Cdk phosphorylates proteins, activating those that facilitate mitosis and inactivating those that inhibit mitosis. ④ An activated enzyme complex recognizes a specific amino acid sequence in cyclin and targets it for destruction. When cyclin is degraded, M-Cdk activity is terminated, and the cells formed by mitosis enter G_1. ⑤ Cdk is not degraded but is recycled and reused.



activate or inactivate other proteins by *phosphorylating* (adding phosphate groups to) them. The protein kinases involved in controlling the cell cycle are **cyclin-dependent kinases (Cdks).** The activity of various Cdks increases and then decreases as the cell moves through the cell cycle. Cdks are active only when they bind tightly to regulatory proteins called **cyclins.** The cyclins are so named because their levels fluctuate predictably during the cell cycle (that is, they "cycle," or are alternately synthesized and degraded as part of the cell cycle).

Three scientists who began their research in the 1980s on the roles of protein kinases and cyclins in the cell cycle (American Leland Hartwell, Briton Paul Nurse, and Briton Tim Hunt) won the Nobel Prize in Physiology or medicine in 2001. Their discoveries were cited as important not only in working out the details of the fundamental cell process of mitosis but also in understanding why cancer cells divide when they should not. For example, cyclin levels are often higher than normal in human cancer cells.

When a specific Cdk associates with a specific cyclin, it forms a **cyclin-Cdk complex.** Cyclin-Cdk complexes phosphorylate enzymes and other proteins. Some of these proteins become activated when they are phosphorylated, and others become inactivated. For example, phosphorylation of the protein **p27,** known to be a major inhibitor of cell division, is thought to initiate degradation of the protein. As various enzymes are activated or inactivated by phosphorylation, the activities of the cell change. Thus, a decrease in a cell's level of p27 causes a nondividing cell to resume division.

Eukaryotic cells form four major cyclin-Cdk complexes (G_1-Cdk, G_1/S-Cdk, S-Cdk, and M-Cdk), and each cyclin-Cdk complex phosphorylates a different group of proteins. G_1-Cdk prepares the cell to pass from the G_1 phase to the S phase, and then G_1/S-Cdk commits the cell to undergo DNA replication. S-Cdk initiates DNA replication. M-Cdk promotes the events of mitosis, including chromosome condensation, nuclear envelope breakdown, and mitotic spindle formation.

M-Cdk also activates another enzyme complex, the **anaphase-promoting complex (APC),** toward the end of metaphase. APC initiates anaphase by allowing degradation of the proteins that hold the sister chromatids together during metaphase. As a result, the sister chromatids separate into two daughter chromosomes. At this point, cyclin is degraded to negligible levels and M-Cdk activity drops, allowing the mitotic spindle to disassemble and the cell to exit mitosis.

Certain drugs can stop the cell cycle at a specific checkpoint. Some of these prevent DNA synthesis, whereas others inhibit the synthesis of proteins that control the cycle or inhibit the synthesis of structural proteins that contribute to the mitotic spindle. Because one of the distinguishing features of most cancer cells is their high rate of cell division relative to most normal body cells, they can be most affected by these drugs. Many side effects of certain anticancer drugs (such as nausea and hair loss) are due to the drugs' effects on rapidly dividing normal cells in the digestive system and hair follicles.

In plant cells, certain hormones stimulate mitosis. These include the **cytokinins,** a group of plant hormones that promote mitosis both in normal growth and in wound healing (see Chapter 36).

Similarly, animal hormones, such as certain steroids, stimulate growth (see Chapter 47). Protein **growth factors,** which are active at extremely low concentrations, stimulate mitosis in some animal cells by forming G_1-Cdk. Of the approximately 50 protein growth factors known, some act only on specific types of cells, whereas others act on a broad range of cell types. For example, the effects of the growth factor erythropoietin are limited to cells that will develop into red blood cells, but epidermal growth factor stimulates many cell types to divide. Many types of cancer cells divide in the absence of growth factors.

Review

- What are the stages of the cell cycle? During which stage does DNA replicate?
- What are sister chromatids?
- How does the DNA content of the cell change from the beginning of interphase to the end of interphase? Does the number of chromatids change? Does the number of chromosomes change?
- Assume an animal has a chromosome number of 10. (a) How many chromosomes would it have in a typical body cell, such as a skin cell during G_1? (b) How many chromosomes would

be present in each daughter cell produced by mitosis? Assuming the daughter cells are in G_1, are these duplicated chromosomes?

BiologyNow™ Assess your understanding of the **cell cycle and mitosis** by taking the pretest on your BiologyNow CD-ROM.

SEXUAL REPRODUCTION AND MEIOSIS

Learning Objectives

6 Differentiate between asexual and sexual reproduction.
7 Distinguish between haploid and diploid cells, and define *homologous chromosomes.*
8 Explain the significance of meiosis, and diagram the process.
9 Contrast mitosis and meiosis, emphasizing the different outcomes.
10 Compare the roles of mitosis and meiosis in various generalized life cycles.

Although the details of the reproductive process vary greatly among different kinds of eukaryotes, biologists distinguish two basic types of reproduction: asexual and sexual. In **asexual reproduction** a single parent splits, buds, or fragments to produce two or more individuals. In most forms of eukaryotic asexual reproduction, all the cells are the result of mitotic divisions, so their genes and inherited traits are like those of the parent. Such a group of genetically identical organisms is termed a **clone.** In asexual reproduction, organisms well adapted to their environment produce new generations of similarly adapted organisms. Asexual reproduction occurs rapidly and efficiently, partly because the organism does not need to expend time and energy finding a mate.

In contrast, **sexual reproduction** involves the union of two sex cells, or **gametes,** to form a single cell called a **zygote.** Usually two different parents contribute the gametes, but in some cases a single parent furnishes both gametes. In the case of animals and plants, the egg and sperm cells are the gametes, and the fertilized egg is the zygote.

Sexual reproduction results in genetic variation among the offspring. (How this genetic variation arises is discussed later in this chapter and in Chapter 10.) Because the offspring produced by sexual reproduction are not genetically identical to their parents or to each other, some offspring may be able to survive environmental changes better than either parent does. However, one disadvantage of sexual reproduction is that some offspring with a different combination of traits may be less likely to survive than their parents.

There is a potential problem in eukaryotic sexual reproduction: If each gamete had the same number of chromosomes as the parent cell that produced it, then the zygote would have twice as many chromosomes. This doubling would occur generation after generation. How do organisms avoid producing zygotes with ever-increasing chromosome numbers? To answer this question, we need more information about the types of chromosomes found in cells.

Each chromosome in a somatic (body) cell of a plant or animal normally has a partner chromosome. The two partners, known as **homologous chromosomes,** are similar in size, shape, and the position of their centromeres. Futhermore, special chromosome-staining procedures make a characteristic pattern of bands evident in the members of each chromosome pair. In most species, chromosomes vary enough in their structure that cytologists can distinguish the different chromosomes and match up the homologous pairs. The 46 chromosomes in human cells constitute 23 homologous pairs. The most important feature of homologous chromosomes is that they carry very similar, but not necessarily identical, genetic information. For example, each member of a homologous pair may carry a gene that specifies hemoglobin structure. But one member may have the information for the normal hemoglobin β chain (see Fig. 3-22a), whereas the other may specify the abnormal form of hemoglobin associated with sickle cell anemia (see Chapter 15). Homologous chromosomes can therefore be contrasted with the two members of a pair of sister chromatids, which are precisely identical to each other.

A *set* of chromosomes has one of each kind of chromosome; in other words, it contains one member of each homologous pair. If a cell or nucleus contains two sets of chromosomes, it is said to have a **diploid** chromosome number. If it has only a single set of chromosomes, it has the **haploid** number. In humans, the diploid chromosome number is 46 and the haploid number is 23. When a sperm and egg fuse at fertilization, each gamete is haploid, contributing one set of chromosomes; the diploid number is thereby restored in the fertilized egg (zygote). When the zygote divides by mitosis to form the first two cells of the embryo, each daughter cell receives the diploid number of chromosomes, and subsequent mitotic divisions repeat this. Thus, most human body cells are diploid.

If an individual's cells have three or more sets of chromosomes, we say that it is **polyploid.** Polyploidy is relatively rare among animals but quite common among plants (see Chapter 19). In fact, polyploidy has been important in plant evolution. As many as 80% of all flowering plants are polyploid. Polyploid plants are often larger and hardier than diploid members of the same group. Many commercially important plants, such as wheat and cotton, are polyploid.

The chromosome number found in the gametes of a particular species is represented as n, and the zygotic chromosome number is represented as $2n$. If the organism is not polyploid, the haploid chromosome number is equal to n, and the diploid number is equal to $2n$; thus in humans, $n = 23$ and $2n = 46$. For simplicity, in the rest of this chapter we assume the organisms used as examples are not polyploid. We use diploid and $2n$ interchangeably, and haploid and n interchangeably, although the terms are not strictly synonymous.

Meiosis produces haploid cells with unique gene combinations

We have examined the process of mitosis, which ensures that each daughter cell receives exactly the same number and kinds of chromosomes as the parent cell. A diploid cell that under-

goes mitosis produces two diploid cells. Similarly, a haploid cell that undergoes mitosis produces two haploid cells. (Some eukaryotic organisms—certain yeasts, for example—are haploid.)

A division that reduces chromosome number is called **meiosis.** The term means "to make smaller," and the chromosome number is reduced by one half. In meiosis a diploid cell undergoes two cell divisions, potentially yielding four haploid cells.

The events of meiosis are similar to the events of mitosis, with four important differences:

1. Meiosis involves two successive nuclear and cytoplasmic divisions, producing up to four cells.
2. Despite two successive nuclear divisions, the DNA and other chromosomal components duplicate only once—during the interphase preceding the first meiotic division.
3. Each of the four cells produced by meiosis contains the haploid chromosome number, that is, only one chromosome set containing only one representative of each homologous pair.
4. During meiosis, the genetic information from both parents is shuffled, so each resulting haploid cell has a virtually unique combination of genes.

Meiosis typically consists of two nuclear and cytoplasmic divisions, designated the *first* and *second meiotic divisions,* or simply **meiosis I** and **meiosis II.** Each includes prophase, metaphase, anaphase, and telophase stages. During meiosis I, the members of each homologous chromosome pair first join together and then separate and move into different nuclei. In meiosis II, the sister chromatids that make up each chromosome separate and are distributed to two different nuclei. The following discussion describes meiosis in an organism with a diploid chromosome number of 4. Refer to Figures 9-11 and 9-12 as you read.

Prophase I includes synapsis and crossing-over

As in mitosis, the chromosomes duplicate during the S phase of interphase, before meiosis actually begins. Each duplicated chromosome consists of two chromatids. During **prophase I,** while the chromatids are still elongated and thin, the homologous chromosomes come to lie lengthwise side by side. This process is called **synapsis,** which means "fastening together." In our example, because the diploid number is 4, synapsis results in two homologous pairs.

One member of each homologous pair is called the **maternal homologue,** because it was originally inherited from the female parent during the formation of the zygote; the other member of a homologous pair is the **paternal homologue,** because it was inherited from the male parent. Because each chromosome duplicated during interphase and now consists of two chromatids, synapsis results in the association of four chromatids. The resulting association is a **tetrad.** The number of tetrads per prophase I cell is equal to the haploid chromosome number. In our example of an animal cell with a diploid number of 4, there are 2 tetrads (and a total of 8 chromatids); in a human cell at prophase I, there are 23 tetrads (and a total of 92 chromatids).

Homologous chromosomes become closely associated during synapsis. Electron microscopic observations reveal that a characteristic structure, the **synaptonemal complex,** forms be-

FIGURE **9-11** **Meiosis in the trumpet lily (*Lilium longiflorum*).**

The chromosomes shown in these LMs have been stained and the cells flattened on microscope slides. **(a)** Mid-prophase I. **(b)** Late prophase I. **(c)** Metaphase I. **(d)** Anaphase I. **(e)** Prophase II. **(f)** Metaphase II. **(g)** Anaphase II. **(h)** Four daughter cells.

MEIOSIS I
Homologous chromosomes
Sister chromatids
MEIOSIS II
INTERPHASE
Interphase preceding meiosis; DNA replicates.
PROPHASE I
Homologous chromosomes synapse, forming tetrads; nuclear envelope breaks down.
METAPHASE I
Tetrads line up on cell's midplane.Tetrads held together at chiasmata (sites of prior crossing-over).
ANAPHASE I
Homologous chromosomes separate and move to opposite poles. Note that sister chromatids remain attached at their centromeres.
TELOPHASE I
One of each pair of homologous chromosomes is at each pole. Cytokinesis occurs.
PROPHASE II
Chromosomes condense again following a brief period of interkinesis. DNA does *not* replicate again.
METAPHASE II
Chromosomes line up along cell's midplane.
ANAPHASE II
Sister chromatids separate, and chromosomes move to opposite poles.
TELOPHASE II
Nuclei formed at opposite poles of each cell. Cytokinesis occurs.
HAPLOID CELLS
Four gametes (animal) or four spores (plant) are produced.

◀ FIGURE **9-12** **Meiosis.**

Meiosis consists of two nuclear divisions, meiosis I and meiosis II. Shown here is an animal cell with a diploid chromosome number of 4. The maternal chromosomes are shown in red; the paternal chromosomes are blue. Meiosis ends with the formation of four haploid cells with two chromosomes each.

tween the synapsed homologues (Fig. 9-13). This structure holds the synapsed homologues together and is thought to play a role in chromosomal **crossing-over,** a process in which paired homologous chromosomes exchange genetic material (DNA). Crossing-over produces new combinations of genes. The **genetic recombination** from crossing-over greatly enhances the genetic variation—that is, new combinations of traits—among sexually produced offspring.

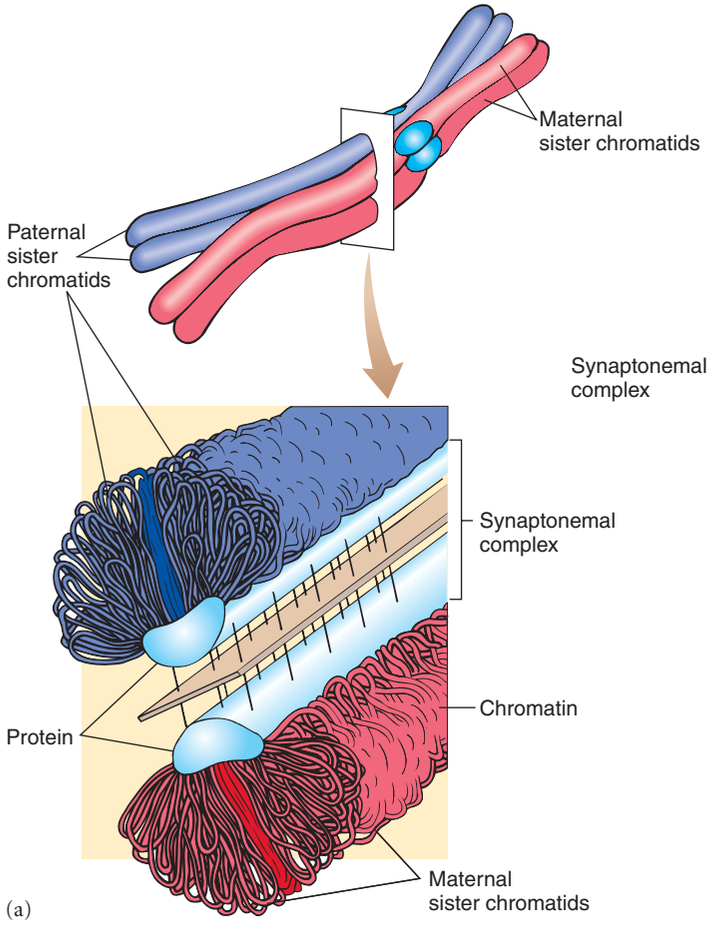
In addition to the unique processes of synapsis and crossing-over, events similar to those in mitotic prophase also occur during prophase I. A spindle forms consisting of microtubules and other components. In animal cells, one pair of centrioles moves to each pole, and astral microtubules form. The nuclear envelope disappears in late prophase I, and in cells with large and distinct chromosomes, the structure of the tetrads can be seen clearly with the microscope. The sister chromatids remain closely aligned along their lengths. However, the centromeres (and kinetochores) of the homologous chromosomes become separated from one another. In late prophase I, the homologous chromosomes are held together only at specific regions, termed **chiasmata.** Each chiasma originates at a crossing-over site, that is, a site at which homologous chromatids exchanged genetic material, and rejoined, producing an X-shaped configuration (Fig. 9-14). The consequences of crossing-over and genetic recombination are discussed in Chapter 10.

During meiosis I, homologous chromosomes separate

Prophase I ends when the tetrads align on the midplane. The cell is now said to be at **metaphase I.** Both sister kinetochores of one duplicated chromosome are attached by spindle fibers to the same pole, and both sister kinetochores of the duplicated homologous chromosome are attached to the opposite pole. (By contrast, in mitosis sister kinetochores are attached to opposite poles.)

During **anaphase I,** the paired homologous chromosomes separate, or disjoin, and move toward opposite poles. Each pole receives a random mixture of maternal and paternal chromosomes, but only one member of each homologous pair is present at each pole. The sister chromatids are united at their centromere regions. Again, this differs from mitotic anaphase, in which the sister chromatids separate and move to opposite poles.

During **telophase I,** the chromatids generally decondense somewhat, the nuclear envelope may reorganize, and cytokinesis may take place. Each telophase I nucleus contains the haploid number of chromosomes, but each chromosome is a duplicated chromosome (it consists of a pair of chromatids). In our example, two duplicated chromosomes lie at each pole, for a total of four chromatids; humans have 23 duplicated chromosomes (46 chromatids) at each pole.



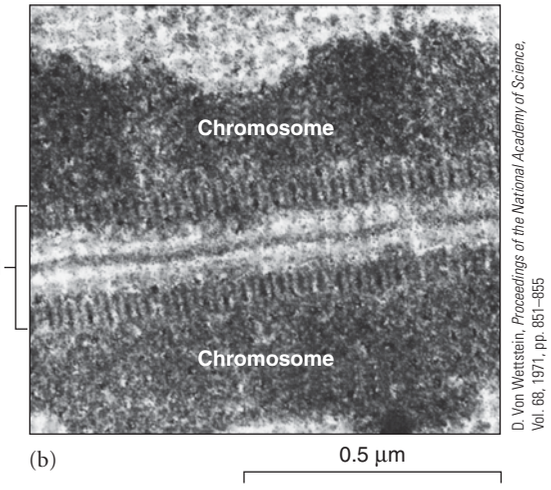


FIGURE **9-13** **A synaptonemal complex.**

Synapsing homologous chromosomes in meiotic prophase I are held together by a synaptonemal complex, composed mainly of protein. **(a)** A 3-D model of a tetrad with a complete synaptonemal complex. **(b)** TEM of a synaptonemal complex.

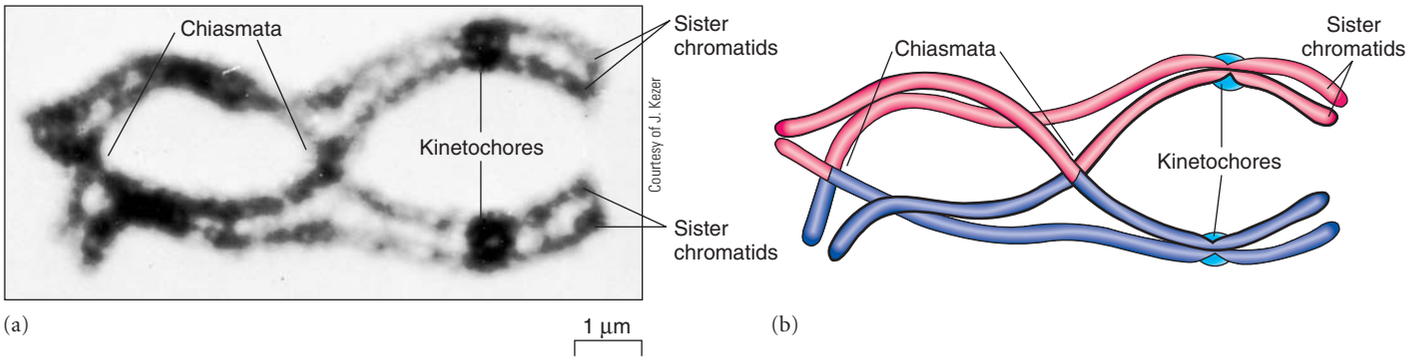

FIGURE **9-14** **A meiotic tetrad with two chiasmata.**

The two chiasmata are the result of separate crossing-over events. **(a)** This LM is of a tetrad during late prophase I of a male meiotic cell (spermatocyte) from a salamander. **(b)** This drawing shows the structure of the tetrad. The paternal chromatids are purple, and the maternal chromatids are pink.

An interphase-like stage usually follows. Because it is not a true interphase—there is no S phase and therefore no intervening DNA replication—it is called **interkinesis.** Interkinesis is very brief in most organisms and absent in some.

Chromatids separate in meiosis II

Because the chromosomes usually remain partially condensed between divisions, the prophase of the second meiotic division is brief. **Prophase II** is similar to mitotic prophase in many respects. There is no pairing of homologous chromosomes (indeed, only one member of each pair is present in each nucleus) and no crossing-over.

During **metaphase II,** the chromosomes line up on the midplanes of their cells. You can easily distinguish the first and second metaphases in diagrams; at metaphase I the chromatids are arranged in bundles of four (tetrads), and at metaphase II they are in groups of two (as in mitotic metaphase). This is not always so obvious in living cells.

During **anaphase II** the chromatids, attached to spindle fibers at their kinetochores, separate and move to opposite poles, just as they would at mitotic anaphase. As in mitosis, each former chromatid is now referred to as a *chromosome.* Thus, at **telophase II** there is one representative for each homologous pair at each pole. Each is an unduplicated (single) chromosome. Nuclear envelopes then re-form, the chromosomes gradually elongate to form chromatin fibers, and cytokinesis occurs.

The two successive divisions of meiosis yield four haploid nuclei, each containing *one* of each kind of chromosome. Each resulting haploid cell has a different combination of genes. This genetic variation has two sources: (1) During meiosis, the maternal and paternal chromosomes of homologous pairs separate independently. The chromosomes are "shuffled" so that each member of a pair becomes randomly distributed to one of the poles at anaphase I. (2) DNA segments are exchanged between maternal and paternal homologues during crossing-over.

Mitosis and meiosis lead to contrasting outcomes

Although mitosis and meiosis share many similar features, specific distinctions between these processes result in the formation of different types of cells (Fig. 9-15). Mitosis is a single nuclear division in which sister chromatids separate from each other. If cytokinesis occurs, they are distributed to the two daughter cells, which are genetically identical to each other and to the original cell. Homologous chromosomes do not associate physically at any time in mitosis.

In meiosis, a diploid cell undergoes two successive nuclear divisions, meiosis I and meiosis II. In prophase I of meiosis, the homologous chromosomes undergo synapsis to form tetrads. Homologous chromosomes separate during meiosis I, and sister chromatids separate during meiosis II. Meiosis ends with the formation of four genetically different, haploid daughter cells. The fates of these cells depend on the type of life cycle; in animals they differentiate as gametes, whereas in plants they become spores.

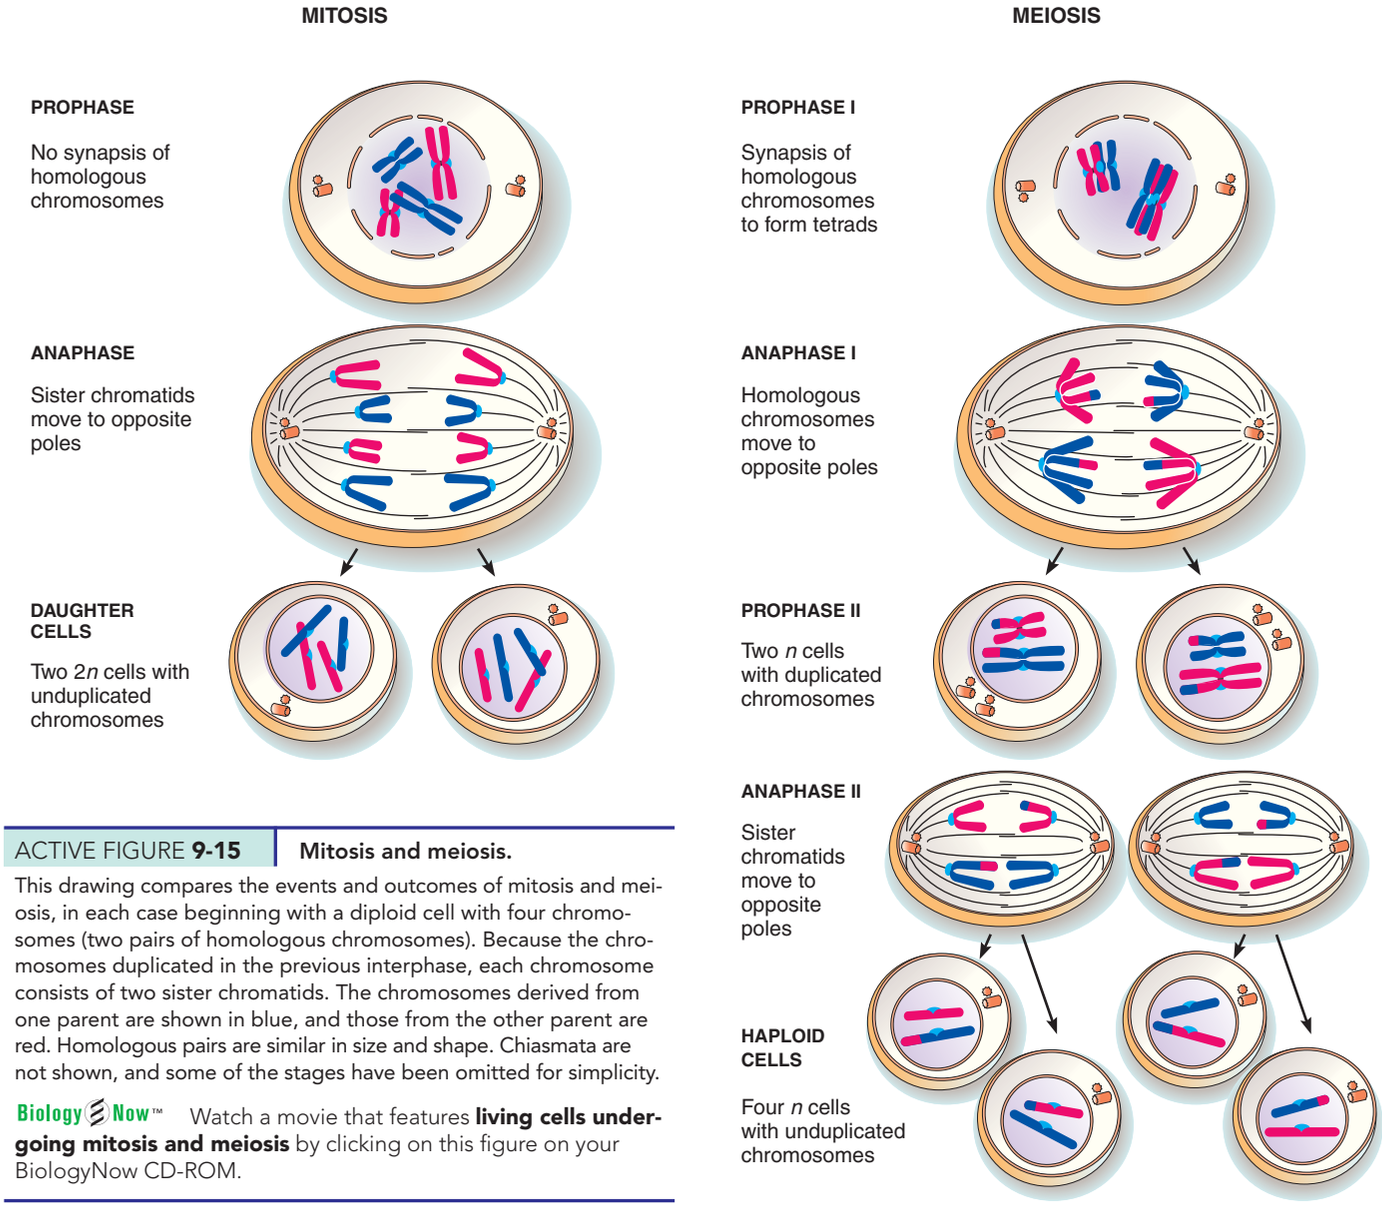
The timing of meiosis in the life cycle varies among species

Because sexual reproduction is characterized by the fusion of two haploid sex cells to form a diploid zygote, it follows that in a sexual life cycle, meiosis must occur before gametes can form.

In animals and a few other organisms, meiosis leads directly to gamete production (Fig. 9-16a). An organism's **somatic cells** (body cells) multiply by mitosis and are diploid; the only haploid cells produced are the gametes. Gametes develop when **germ line cells,** which give rise to the next generation, undergo meiosis.

The formation of gametes is known as **gametogenesis.** Male gametogenesis, termed **spermatogenesis,** forms four haploid sperm cells for each cell that enters meiosis. (See Chapter 48 and Fig. 48-5 for a detailed description of spermatogenesis.)

In contrast, female gametogenesis, termed **oogenesis,** forms a single egg cell, or *ovum,* for every cell that enters meiosis. In



ACTIVE FIGURE **9-15** **Mitosis and meiosis.**

This drawing compares the events and outcomes of mitosis and meiosis, in each case beginning with a diploid cell with four chromosomes (two pairs of homologous chromosomes). Because the chromosomes duplicated in the previous interphase, each chromosome consists of two sister chromatids. The chromosomes derived from one parent are shown in blue, and those from the other parent are red. Homologous pairs are similar in size and shape. Chiasmata are not shown, and some of the stages have been omitted for simplicity.

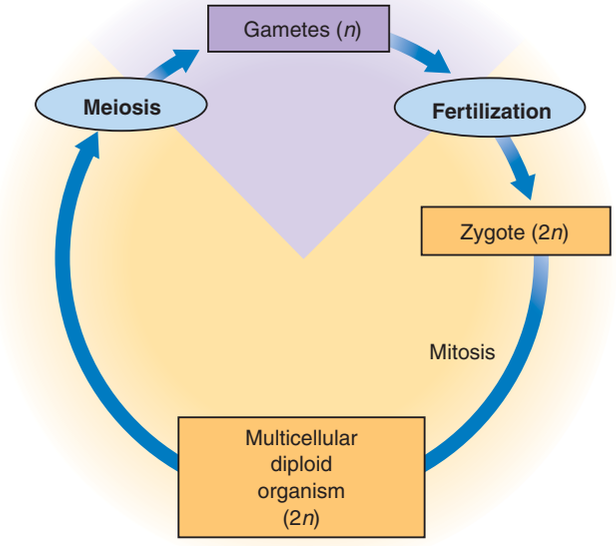
BiologyNow™ Watch a movie that features **living cells undergoing mitosis and meiosis** by clicking on this figure on your BiologyNow CD-ROM.

this process, all the cytoplasm goes to only one of the two cells produced during each meiotic division. At the end of the first meiotic division, one nucleus is retained and the other, called the first *polar body,* degenerates. Similarly, at the end of the second division one nucleus becomes the second polar body and the other nucleus survives. In this way, one haploid nucleus receives most of the accumulated cytoplasm and nutrients from the original meiotic cell. (See Chapter 48 and Fig. 48-11 for a detailed description of oogenesis.)

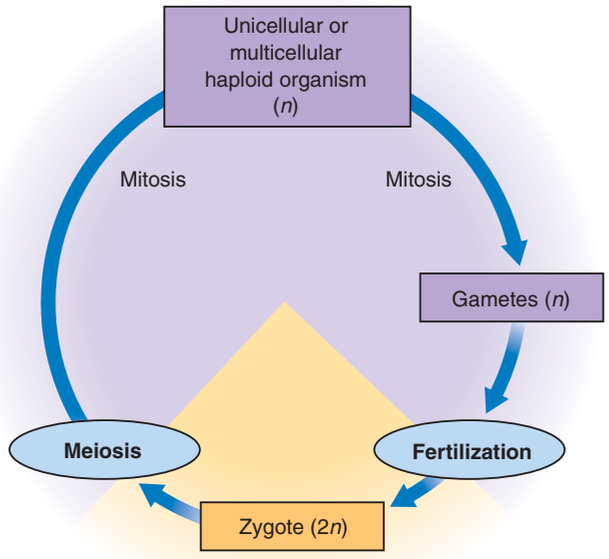
Although meiosis occurs at some point in a sexual life cycle, it does not always *immediately* precede gamete formation. Many simple eukaryotes, including some fungi and algae, remain haploid (their cells dividing mitotically) throughout most of their life cycles, with individuals being unicellular or multicellular. Two haploid gametes (produced by mitosis) fuse to form a diploid zygote that undergoes meiosis to restore the haploid state (Fig. 9-16b). Examples of these types of life cycles are found in Figures 24-19 and 25-7.

Plants, some algae, and some fungi have some of the most complicated life cycles (Fig. 9-16c). These life cycles, characterized by an **alternation of generations,** consist of a multicellular diploid stage, the **sporophyte generation,** and a multicellular haploid stage, the **gametophyte generation.** Diploid sporophyte cells undergo meiosis to form haploid spores, each of which then divides mitotically to produce a multicellular haploid gametophyte. Gametophytes produce gametes by mitosis. The female and male gametes (egg and sperm cells) then fuse to form a diploid zygote that divides mitotically to form a multicellular, diploid sporophyte.

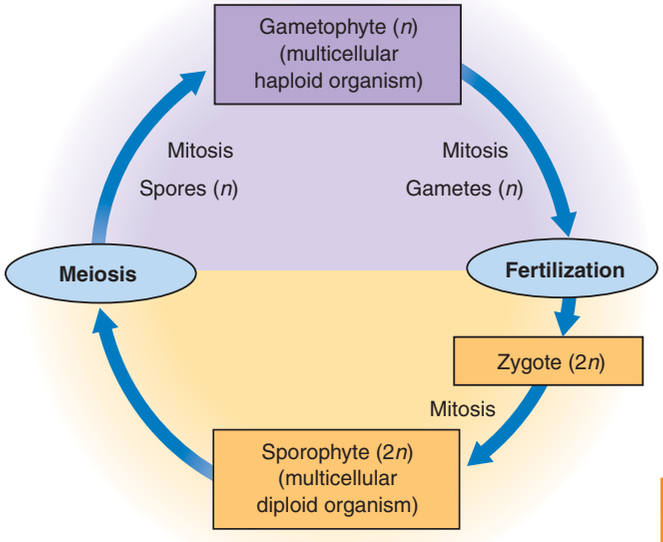
In ferns, conifers, and flowering plants, the diploid sporophyte—which includes the roots, stems, and leaves of the plant body—is the dominant form. The gametophytes are small and in-



(a) Animals



(b) Simple eukaryotes



(c) Plants, some algae, and some fungi

KEY CONCEPT: Each species has a characteristic number of chromosomes that does not change. In each life cycle, the doubling of chromosomes that occurs during fertilization is compensated for by the reduction in chromosome number that occurs during meiosis.

FIGURE **9-16** **Representative life cycles.**

The color code and design here is used throughout the rest of the book. For example, in all life cycles the haploid (*n*) generation is shown in purple, and the diploid (2*n*) generation is gold. The processes of meiosis and fertilization always link the haploid and diploid generations.

conspicuous. For example, in flowering plants, a microscopic pollen grain contains a haploid male gametophyte that forms haploid sperm cells by mitosis. You can find more detailed descriptions of alternation of generations in plants in Chapters 26 and 27.

Review

- Are homologous chromosomes present in a diploid cell? Are they present in a haploid cell?
- Assume an animal cell has a diploid chromosome number of 10. (a) How many tetrads would form in prophase I of meiosis? (b) How many chromosomes would be present in each gamete? Are these duplicated chromosomes?
- How does the outcome of meiosis differ from the outcome of mitosis?
- Can haploid cells divide by mitosis? By meiosis?

BiologyNow™ Assess your understanding of the **sexual reproduction and mitosis** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Discuss the significance of chromosomes in terms of their information content.

- **Genes,** the cell's informational units, are made of DNA. In eukaryotes, DNA associates with protein to form the **chromatin** fibers that make up **chromosomes.** The organization of eukaryotic DNA into chromosomes allows the DNA, which is much longer than a cell's nucleus, to be accurately replicated and sorted into daughter cells without tangling.

2 Compare the organization of DNA in prokaryotic and eukaryotic cells.

- Prokaryotic cells usually have circular DNA molecules.
- Eukaryotic chromosomes have several levels of organization. The DNA is associated with **histones** (basic proteins) to form **nucleosomes,** each of which consists of a histone bead with DNA wrapped around it. The nucleosomes are organized into large, coiled loops held together by nonhistone **scaffolding proteins.**

3 Identify the stages in the eukaryotic cell cycle, describe their principal events, and point out some ways in which the cycle is controlled.

- The eukaryotic **cell cycle** is the period from the beginning of one division to the beginning of the next. The cell cycle consists of interphase and M phase.
- **Interphase** consists of the first gap phase (G_1), the synthesis phase (S), and the second gap phase (G_2). During the **G_1 phase,** the cell grows and prepares for the S phase. During the **S phase,** DNA and the chromosomal proteins are synthesized, and chromosome duplication occurs. During the **G_2 phase,** protein synthesis increases in preparation for cell division.
- **Cyclin-dependent kinases** (**Cdks**) are **protein kinases** involved in controlling the cell cycle. Cdks are active only when they bind tightly to regulatory proteins called **cyclins.** Cyclin levels fluctuate predictably during the cell cycle.
- **M phase** consists of **mitosis,** the nuclear division that produces two nuclei identical to the parental nucleus, and **cytokinesis,** the division of the cytoplasm to yield two daughter cells.

4 Describe the structure of a duplicated chromosome, including the sister chromatids, centromeres, and kinetochores.

- A duplicated chromosome consists of a pair of **sister chromatids,** which contain identical DNA sequences. Each chromatid includes a constricted region called the **centromere.** Sister chromatids are tightly associated in the region of their centromeres. Attached to each centromere is a **kinetochore,** a structure formed from proteins to which microtubules can bind.

5 Explain the significance of mitosis, and describe the process.

- In mitosis, identical chromosomes are distributed to each pole of the cell, and a nuclear envelope forms around each set.
- During **prophase,** duplicated chromosomes, each composed of a pair of sister chromatids, become visible with the microscope. The nucleolus disappears, the nuclear envelope breaks down, and the **mitotic spindle** begins to form.
- During **metaphase,** the chromosomes are aligned on the **metaphase plate** of the cell; the mitotic spindle is complete and the kinetochores of the sister chromatids are attached by microtubules to opposite poles of the cell.
- During **anaphase,** the sister chromatids separate and move to opposite poles. Each former chromatid is now a chromosome.
- During **telophase,** a nuclear envelope re-forms around each set of chromosomes, nucleoli become apparent, the chromosomes uncoil, and the spindle disappears. Cytokinesis generally begins in telophase.

6 Differentiate between asexual and sexual reproduction.

- Offspring produced by **asexual reproduction** usually have hereditary traits identical to those of the single parent. Mitosis is the basis for asexual reproduction in eukaryotic organisms.
- In **sexual reproduction,** two haploid sex cells, or **gametes,** fuse to form a single diploid **zygote.** In a sexual life cycle, **meiosis** must occur before gametes can be produced.

7 Distinguish between haploid and diploid cells, and define *homologous chromosomes.*

- A **diploid** cell has a characteristic number of chromosome pairs per cell. The members of each pair, called **homologous chromosomes,** are similar in length, shape, and other features and carry genes affecting the same kinds of attributes of the organism.
- A **haploid** cell contains only one member of each homologous chromosome pair.

8 Explain the significance of meiosis, and diagram the process.

- A diploid cell undergoing **meiosis** completes two successive cell divisions, yielding four haploid cells.
- **Meiosis I** begins with **prophase I,** in which the members of a homologous pair of chromosomes physically join by the process of **synapsis. Crossing-over** is a process of **genetic recombination** during which homologous (nonsister) chromatids exchange segments of DNA strands.
- At **metaphase I, tetrads**—each consisting of a pair of homologous chromosomes held together by one or more **chiasmata**—line up on the **metaphase plate.** The members of each pair of homologous chromosomes separate during meiotic **anaphase I** and are distributed to different nuclei. Each nucleus contains the haploid number of chromosomes; each chromosome consists of two chromatids.
- During **meiosis II,** the two chromatids of each chromosome separate, and one is distributed to each daughter cell. Each former chromatid is now a chromosome.

9 Contrast mitosis and meiosis, emphasizing the different outcomes.

- Mitosis involves a single nuclear division in which the two daughter cells formed are genetically identical to each other and to the original cell. Synapsis of homologous chromosomes does not occur during mitosis.
- Meiosis involves two successive nuclear divisions and forms four haploid cells. Synapsis of homologous chromosomes occurs during prophase I of meiosis.

10 Compare the roles of mitosis and meiosis in various generalized life cycles.

- The **somatic cells** of animals are diploid and are produced by mitosis. The only haploid cells are the gametes, produced by **gametogenesis,** which in animals occurs by meiosis.

SUMMARY WITH KEY TERMS *(continued)*

- Simple eukaryotes may be haploid. The only diploid stage is the zygote, which undergoes meiosis to restore the haploid state.
- The life cycle of plants and some algae includes an **alternation of generations.** The multicellular diploid **sporophyte generation** forms haploid spores by meiosis. Each spore divides mitotically to form a multicellular haploid **gametophyte generation** which produces gametes by mitosis. Two haploid gametes then fuse to form a diploid zygote, which divides mitotically to produce a new diploid sporophyte generation.

POST-TEST

1. Chromatin fibers include (a) DNA and structural polysaccharides (b) RNA and phospholipids (c) protein and carbohydrate (d) DNA and protein (e) triacylglycerol and steroids
2. A nucleosome consists of (a) DNA and scaffolding proteins (b) scaffolding proteins and histones (c) DNA and histones (d) DNA, histones, and scaffolding proteins (e) histones only
3. The term *S phase* refers to (a) DNA synthesis during interphase (b) synthesis of chromosomal proteins during prophase (c) gametogenesis in animal cells (d) synapsis of homologous chromosomes (e) fusion of gametes in sexual reproduction
4. At which of the following stages do human skin cell nuclei have the same DNA content? (a) early mitotic prophase; late mitotic telophase (b) G_1; G_2 (c) G_1; early mitotic prophase (d) G_1; late mitotic telophase (e) G_2; late mitotic telophase
5. In a cell at _____, each chromosome consists of a pair of attached chromatids. (a) mitotic prophase (b) meiotic prophase II (c) meiotic prophase I (d) meiotic anaphase I (e) all of the preceding
6. In an animal cell at mitotic metaphase, you would expect to find (a) two pairs of centrioles located on the metaphase plate (b) a pair of centrioles inside the nucleus (c) a pair of centrioles within each microtubule-organizing center (d) a centriole within each centromere (e) no centrioles
7. Cell plate formation usually begins during (a) telophase in a plant cell (b) telophase in an animal cell (c) G_2 in a plant cell (d) G_2 in an animal cell (e) a and b are correct
8. A particular plant species has a diploid chromosome number of 20. A haploid cell of that species at mitotic prophase contains a total of _____ chromosomes and _____ chromatids. (a) 20; 20 (b) 20; 40 (c) 10; 10 (d) 10; 20 (e) none of the preceding, because haploid cells cannot undergo mitosis
9. A diploid nucleus at early mitotic prophase has _____ set(s) of chromosomes; a diploid nucleus at mitotic telophase has _____ set(s) of chromosomes. (a) 1; 1 (b) 1; 2 (c) 2; 2 (d) 2; 1 (e) not enough information has been given
10. The life cycle of a sexually reproducing organism includes (a) mitosis (b) meiosis (c) fusion of sex cells (d) b and c (e) a, b, and c
11. Which of the following are genetically identical? (a) two cells resulting from meiosis I (b) two cells resulting from meiosis II (c) four cells resulting from meiosis I followed by meiosis II (d) two cells resulting from a mitotic division (e) all of the preceding
12. You would expect to find a synaptonemal complex in a cell at (a) mitotic prophase (b) meiotic prophase I (c) meiotic prophase II (d) meiotic anaphase I (e) meiotic anaphase II
13. A chiasma links a pair of (a) homologous chromosomes at prophase II (b) homologous chromosomes at late prophase I (c) sister chromatids at metaphase II (d) sister chromatids at mitotic metaphase (e) sister chromatids at metaphase I

CRITICAL THINKING

Decide whether each of the following is an example of sexual or asexual reproduction, and state why.

1. A diploid queen honeybee produces haploid eggs by meiosis. Some of these eggs are never fertilized and develop into haploid male honeybees (drones).
2. Seeds develop after a flower has been pollinated with pollen from the same plant.
3. After it has been placed in water, a cutting from a plant develops roots. After it is transplanted to soil, the plant survives and grows.

The Basic Principles of Heredity

Corbis/Bettmann

Gregor Mendel. This painting shows Mendel with his pea plants in the monastery garden at Brünn, Austria (now Brüno, Czech Republic).

CHAPTER OUTLINES

- **Mendel's Principles of Inheritance**
- **Mendelian Inheritance and Chromosomes**
- **Extensions of Mendelian Genetics**

Do you have your father's height and your mother's eye color and freckles? You have inherited these and a multitude of other characteristics, passed on from one generation to another. **Heredity,** the transmission of genetic information from parent to offspring, generally follows predictable patterns in organisms as diverse as humans, penguins, baker's yeast, and sunflowers. **Genetics,** the science of heredity, studies both genetic similarities and **genetic variation,** the differences, between parents and offspring or among individuals of a population.

The study of inheritance as a modern branch of science began in the mid-19th century with the work of Gregor Mendel (1822–1884), a monk who bred pea plants. Mendel was the first scientist to effectively apply quantitative methods to the study of inheritance. He didn't merely describe his observations; he planned his experiments carefully, recorded the data, and analyzed the results mathematically. Although unappreciated during his lifetime, his work was rediscovered in 1900. The science of genetics is based on his major findings, including those now known as *Mendel's principles of segregation and independent assortment.*

During the decades following the rediscovery of Mendel's findings, geneticists initially extended Mendel's principles by correlating the transmission of genetic information from generation to generation with the behavior of chromosomes during meiosis. They also refined his methods and, by studying a variety of organisms, both verified Mendel's findings and added to a growing list of so-called exceptions to his principles. These exceptions include such phenomena as linkage, X linkage, and pleiotropy.

Some geneticists were very active in developing the science of statistical analysis, which was emerging during Mendel's time. Using statistics, scientists could analyze and interpret experimental data in increasingly sophisticated ways. Statistical analysis was also essential for studying the genetic makeup of natural populations of organisms. Scientists eventually combined the genetics of populations with Charles Darwin's theory of evolution by natural selection, to develop a unified modern theory of evolution, firmly based on genetic principles (see Chapters 17 and 18).

Geneticists study not only the transmission of genes but also the expression of genetic information. As you will see in this chapter and those that follow, understanding of the relationship between an organism's genes and its characteristics has become increasingly sophisticated as people have learned more about the flow of information in cells. ■

MENDEL'S PRINCIPLES OF INHERITANCE

Learning Objectives

1. Define the terms *phenotype, genotype, locus, allele, dominant allele, recessive allele, homozygous, and heterozygous.*
2. Describe Mendel's principles of segregation and independent assortment.
3. Solve genetics problems involving monohybrid, dihybrid, and test crosses.
4. Apply the product rule and sum rule appropriately when predicting the outcomes of genetic crosses.

PROCESS OF SCIENCE

Gregor Mendel was not the first plant breeder. At the time he began his work, breeders had long recognized the existence of **hybrid** plants and animals, the offspring of two genetically dissimilar parents. When Mendel began his breeding experiments in 1856, two main concepts about inheritance were widely accepted: (1) All hybrid plants that are the offspring of genetically pure, or **true-breeding,** parents are similar in appearance. (2) When these hybrids mate with each other, they do not breed true; their offspring show a mixture of traits. Some look like their parents, and some have features like their grandparents.

Mendel's genius lay in his ability to recognize a pattern in the way the parental traits reappear in the offspring of hybrids. Before Mendel, no one had categorized and counted the offspring and analyzed these regular patterns over several generations to the extent he did. Just as do geneticists today, Mendel chose the organism for his experiments very carefully. The garden pea, *Pisum sativum,* had several advantages. Pea plants are easy to grow, and many varieties were commercially available. Another advantage of pea plants is that controlled pollinations are relatively easy to conduct. Pea flowers have both male and female parts and naturally self-pollinate (Fig. 10-1). However, the anthers (the male parts of the flower that produce pollen) can be removed to prevent self-fertilization. Pollen from a different source can then be applied to the stigma (the receptive surface of the female part). Pea flowers are easily protected from other sources of pollen because the petals completely enclose the reproductive structures.

Mendel obtained his original pea seeds from commercial sources and did some important preliminary work before starting his actual experiments. For two years he verified that the varieties were true-breeding lines for various inherited features. Today scientists use the term **phenotype** to refer to the physical appearance of an organism. A true-breeding line produces only offspring expressing the same phenotype (for example, round seeds or tall plants), generation after generation. During this time Mendel apparently chose those traits of his pea strains that he could study most easily. He probably made the initial observations that later formed the basis of his theories.

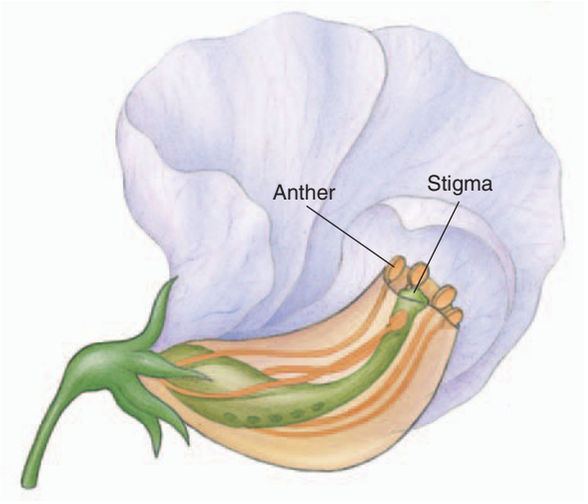

FIGURE **10-1** **Reproductive structures of a pea flower.**
This cutaway view shows the pollen-producing anthers and the stigma, the portion of the female part of the flower that receives the pollen.

Mendel eventually chose strains representing seven **characters,** the attributes (such as seed color) for which heritable differences, or **traits,** are known (such as yellow seeds and green seeds). The characters Mendel selected had clearly contrasting phenotypes (Fig. 10-2). Mendel's results were easy to analyze because he chose easily distinguishable phenotypes and limited the genetic variation studied in each experiment.

Mendel began his experiments by crossing plants from two different true-breeding lines with contrasting phenotypes; these genetically pure individuals constituted the **parental generation,** or **P generation.** In every case, the members of the first generation of offspring all looked alike and resembled one of the two parents. For example, when he crossed tall plants with short plants, all the offspring were tall (Fig. 10-3). These offspring were the first filial generation, or the **F_1 generation** (*filial* is from the Latin for "sons and daughters"). The second filial generation, or **F_2 generation,** resulted from a cross between F_1 individuals, or by self-pollination of F_1 individuals. Mendel's F_2 generation in this experiment included 787 tall plants and 277 short plants.

Most breeders in Mendel's time thought fluids "blended" together to control inheritance in hybrids. One implication of this idea is that a hybrid should be intermediate between the two parents, and in fact plant breeders had obtained such hybrids. Although Mendel observed some intermediate types of hybrids, he chose for further study those F_1 hybrids in which "hereditary factors" (as he called them) from one of the parents apparently masked the expression of those factors from the other parent. Other breeders had also observed these types of hybrids, but they had not explained them. Using modern terms, the factor expressed in the F_1 generation (tallness, in our example) is

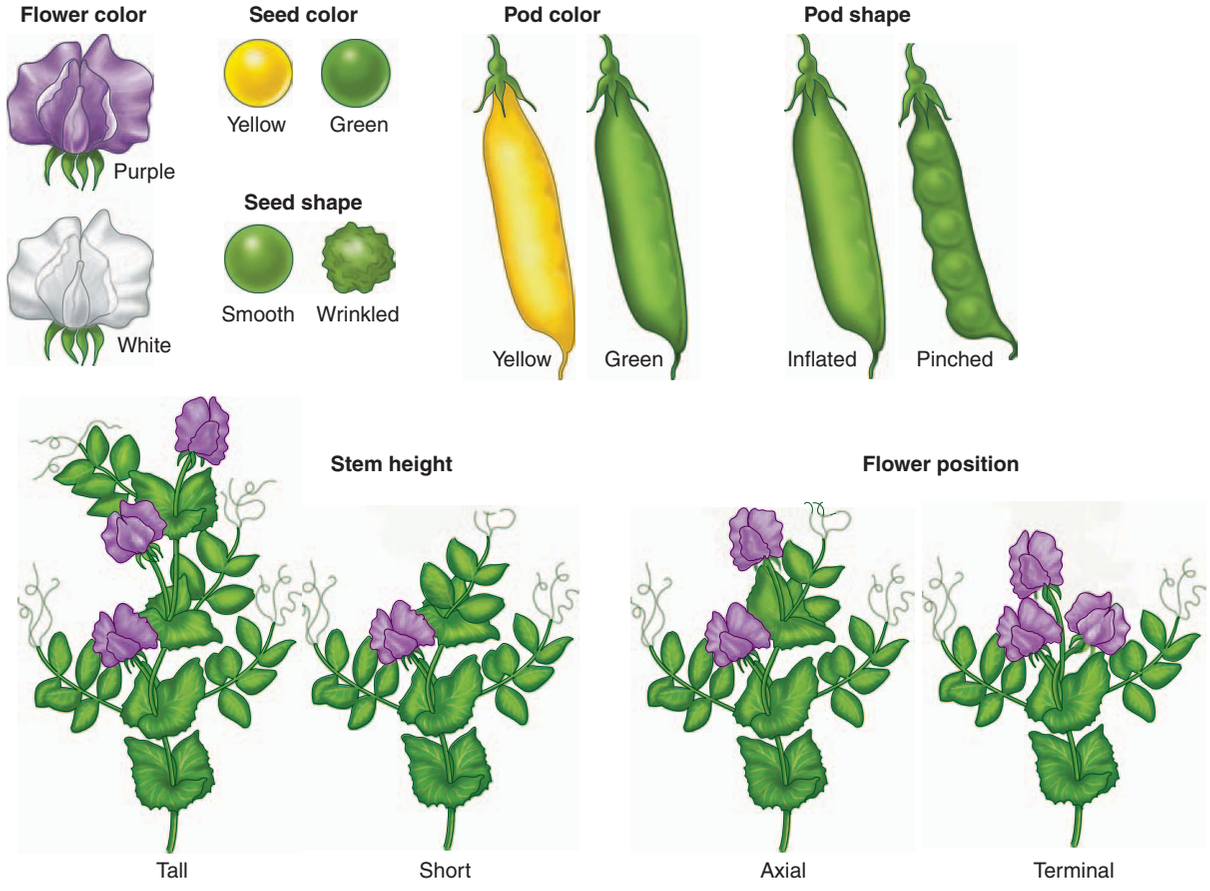

FIGURE **10-2** **Seven characters in Mendel's study of pea plants.**

Each character had two clearly distinguishable phenotypes.

said to be **dominant;** the one hidden in the F_1 (shortness) is **recessive.** Dominant traits mask recessive ones when both are present in the same individual. Although scientists know today that dominance is not always observed (we'll explore exceptions later in this chapter), the fact that dominance can occur was not entirely consistent with the notion of blending inheritance.

Mendel's results also argued against blending inheritance in a more compelling way. Once two fluids have blended, it is very difficult to imagine how they can separate. However, in the preceding example, in the F_1 generation the hereditary factor(s) that controlled shortness clearly were not lost or blended inseparably with the hereditary factor(s) that controlled tallness, because shortness reappeared in the F_2 generation. Mendel was very comfortable with the theoretical side of biology, because he was also a student of physics and mathematics. He therefore proposed that each kind of inherited feature of an organism is controlled by two factors that behave like discrete particles and are present in every individual. To Mendel these hereditary factors were abstractions—he knew nothing about chromosomes and DNA. These factors are essentially what scientists today call **genes.**

Mendel's experiments led to his discovery and explanation of the major principles of heredity, which we now know as the principles of segregation and independent assortment. We discuss the first principle next and the second later in the chapter.

Alleles separate before gametes are formed

The term **alleles** refers to the alternative forms of a gene. In the example in Figure 10-3, each F_1 generation tall plant had two different alleles that control plant height: a **dominant allele** for tallness (which we designate *T*) and a **recessive allele** for shortness (designated *t*), but because the tall allele was dominant these plants were tall. To explain his experimental results, Mendel proposed an idea now known as the principle of segregation. Using modern terminology, the **principle of segregation** states that before sexual reproduction occurs, the two alleles carried by an individual parent must become separated (segregated). As a result, each sex cell (egg or sperm) formed contains only one allele of each pair. An essential feature of the process is that the alleles remain intact (one does not mix with or eliminate the other); thus recessive alleles are not lost and can reappear in the F_2 generation.

In our example, before the F_1 plants formed gametes, the allele for tallness separated (segregated) from the allele for shortness, so that half the gametes contained a *T* allele and the other half a *t* allele. The random process of fertilization led to three possible combinations of alleles in the F_2 offspring: one fourth with two tallness alleles *(TT)*, one fourth with two shortness alleles *(tt)*, and one half with one allele for tallness and one for

shortness *(Tt)*. Because both *TT* and *Tt* plants are tall, on average Mendel expected approximately three fourths (787 of the 1064 plants he obtained) to express the phenotype of the dominant allele (tall) and about one fourth (277/1064) the phenotype of the recessive allele (short). (We will explain the mathematical reasoning behind these predictions shortly.)

KEY CONCEPT: Mendel inferred the existence of genes by observing the offspring of crosses between individuals with different phenotypes.

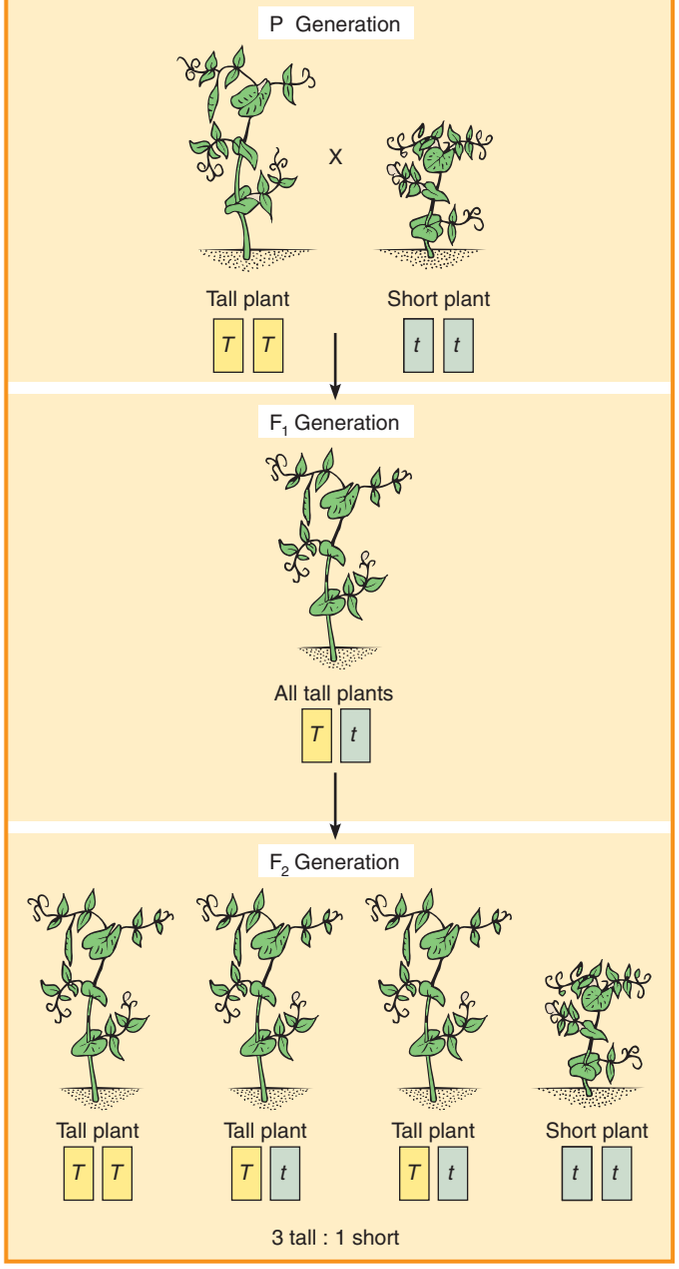

FIGURE **10-3** **One of Mendel's pea crosses.**

Crossing a true-breeding tall pea plant with a true-breeding short pea plant yielded only tall offspring in the F_1 generation. But when these F_1 individuals self-pollinated, or when two F_1 individuals were crossed, the resulting F_2 generation included tall and short plants in a ratio of about 3:1.

Mendel reported these and other findings at a meeting of the Brünn Society for the Study of Natural Science; he published his results in the society's report in 1866. At that time biology was largely a descriptive science, and biologists had little interest in applying quantitative and experimental methods such as Mendel had used. Other biologists of the time did not appreciate the importance of his results and his interpretations of those results. For 34 years his findings were largely neglected.

In 1900, Hugo DeVries in Holland, Carl Correns in Germany, and Erich von Tschermak in Austria recognized Mendel's principles in their own experiments; they later discovered Mendel's paper and found it explained their own research observations. Correns gave credit to Mendel by naming the basic laws of inheritance after him. By this time biologists had a much greater appreciation of the value of quantitative experimental methods. The details of mitosis, meiosis, and fertilization had been described, and in 1902, German biologist Theodor Boveri and American biologist Walter Sutton independently pointed out the connection between Mendel's segregation of alleles and the separation of homologous chromosomes during meiosis. The time was right for wider acceptance and extension of these ideas and their implications.

Alleles occupy corresponding loci on homologous chromosomes

Today scientists know that each unduplicated chromosome consists of one long linear DNA molecule and that each gene is actually a segment of that DNA molecule. We also know homologous chromosomes are similar not only in size and shape, but they also usually have the same genes (often with different alleles) located in corresponding positions. The term **locus** (pl., *loci*) originally designated the location of a particular gene on the chromosome (Fig. 10-4). We are actually referring to a segment of the DNA that has the information for controlling some aspect of the structure or function of the organism. One locus may govern seed color, another seed shape, still another the shape of the pods, and so on. Traditional genetic methods can infer the existence of a particular locus only if at least two allelic variants of that locus, producing contrasting phenotypes (for example, yellow peas versus green peas), are available for study. In the simplest cases an individual can express one (yellow) or the other (green) but not both.

Alleles are, therefore, genes that govern variations of the same character (yellow versus green seed color) and occupy corresponding loci on homologous chromosomes. Geneticists assign each allele of a locus a single letter or group of letters as its symbol. Although they often use more complicated forms of notation, it is customary when working simple genetics problems to indicate a dominant allele with a capital letter and a recessive allele with the same letter in lowercase.

Remember that the term *locus* designates not only a position on a chromosome but also a type of gene controlling a particular character; thus, *Y* (yellow) and *y* (green) represent a specific pair of alleles of a locus involved in determining seed color in

peas. Although you may initially be uncomfortable with the fact that geneticists sometimes use the term *gene* to specify a locus and at other times to specify one of the alleles of that locus, the meaning is usually clear from the context.

A monohybrid cross involves individuals with different alleles of a given locus

The basic principles of genetics and the use of genetics terms are best illustrated by examples. In the simplest case, a **monohybrid cross,** the inheritance of two different alleles of a single locus is studied. Figure 10-5 illustrates a monohybrid cross featuring a locus that governs coat color in guinea pigs. The female comes from a true-breeding line of black guinea pigs. We say she is **homozygous** for black because the two alleles she carries for this locus are identical. The brown male is also from a true-breeding line and is homozygous for brown. What color would you expect the F_1 offspring to be? Dark brown? Spotted? It is impossible to make such a prediction without more information.

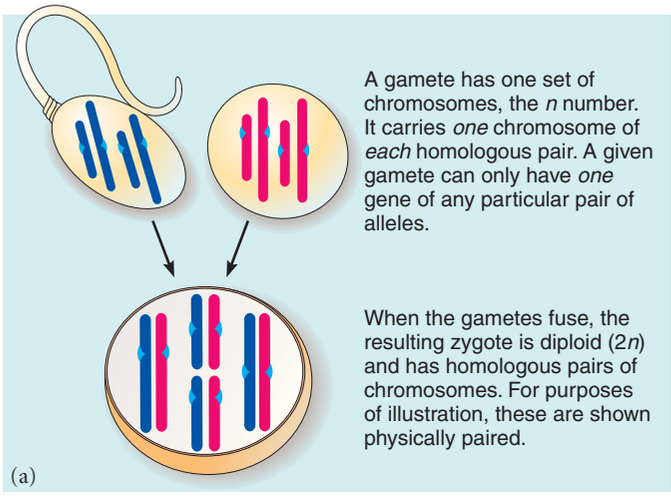
In this particular case, the F_1 offspring are black, but they are **heterozygous,** meaning they carry two different alleles for this locus. The brown allele influences coat color only in a homozygous brown individual; it is a recessive allele. The black allele influences coat color in both homozygous black and heterozygous individuals; it is a dominant allele. On the basis of this information, we can use standard notation to designate the dominant black allele *B* and the recessive brown allele *b*.

During meiosis in the female parent *(BB),* the two *B* alleles separate, according to Mendel's principle of segregation, so each egg has only one *B* allele. In the male *(bb)* the two *b* alleles separate, so each sperm has only one *b* allele. The fertilization of each *B* egg by a *b* sperm results in heterozygous F_1 offspring, each with the alleles *Bb;* that is, each individual has one allele for brown coat and one for black coat. Because this is the only possible combination of alleles present in the eggs and sperm, all the F_1 offspring are *Bb.*

A Punnett square predicts the ratios of the various offspring of a cross

During meiosis in heterozygous black guinea pigs *(Bb),* the chromosome containing the *B* allele becomes separated from its homologue (the chromosome containing the *b* allele), so each normal sperm or egg contains *B* or *b* but never both. Heterozygous *Bb* individuals form gametes containing *B* alleles and gametes containing *b* alleles in equal numbers. Because no special attraction or repulsion occurs between an egg and a sperm containing the same allele, fertilization is a random process.

As you can see in Figure 10-5, the possible combinations of eggs and sperm at fertilization can be represented in the form of a grid known as a **Punnett square,** devised by the early English geneticist Sir Reginald Punnett. The types of gametes (and their expected frequencies) from one parent are listed across the top, and those from the other parent are listed along the left side. The squares are then filled in with the resulting F_2 zygote



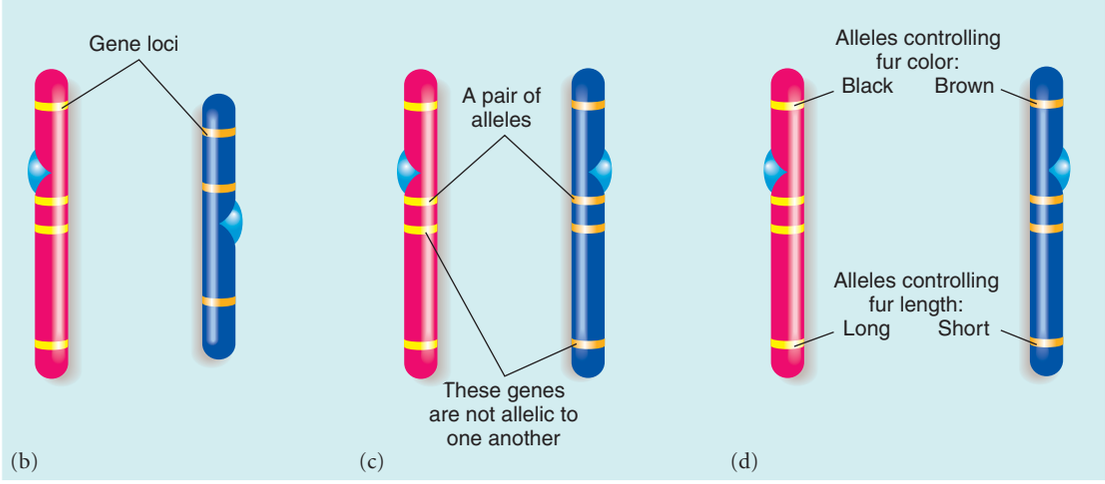


FIGURE **10-4** **Gene loci and their alleles.**

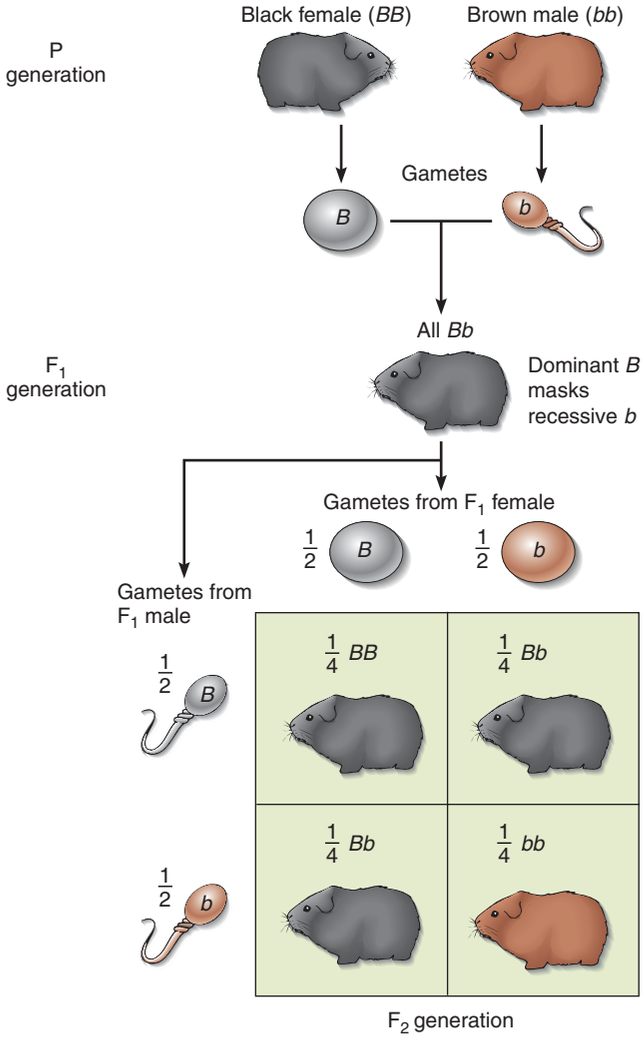
(a) One member of each pair of homologous chromosomes is of maternal origin (red), and the other is paternal (blue). **(b)** These chromosomes are nonhomologous. Each chromosome is made up of thousands of genes. A locus is the specific place on a chromosome where a gene is located. **(c)** These chromosomes are homologous. Alleles are members of a gene pair that occupy corresponding loci on homologous chromosomes. **(d)** Alleles govern the same character but do not necessarily contain the same information.



ACTIVE FIGURE **10-5** **A monohybrid cross in guinea pigs.**

In this example, a homozygous black guinea pig is mated with a homozygous brown guinea pig. The F_1 generation includes only black individuals. However, the mating of two of these F_1 offspring yields F_2 generation offspring in the expected ratio of 3 black to 1 brown, indicating that the F_1 individuals are heterozygous.

BiologyNow™ Learn more from an interactive tutorial on **monohybrid crosses** by clicking on this figure on your BiologyNow CD-ROM.

combinations. Three fourths of all F_2 offspring have the genetic constitution *BB* or *Bb* and are phenotypically black; one fourth have the genetic constitution *bb* and are phenotypically brown. The genetic mechanism that governs the approximate 3:1 F_2 ratios obtained by Mendel in his pea-breeding experiments is again evident. These ratios are called *monohybrid F_2 phenotypic ratios.*

The phenotype of an individual does not always reveal its genotype

As mentioned earlier, an organism's phenotype is its appearance with respect to a certain inherited trait. However, because some alleles may be dominant and others recessive, we can't always determine, simply by examining its phenotype, which alleles are carried by an organism. The *genetic constitution* of that organism, most often expressed in symbols, is its **genotype.** In the cross we have been considering, the genotype of the female parent is homozygous dominant, *BB,* and her phenotype is black. The genotype of the male parent is homozygous recessive, *bb,* and his phenotype is brown. The genotype of all the F_1 offspring is heterozygous, *Bb,* and their phenotype is black. To prevent confusion we always indicate the genotype of a heterozygous individual by writing the symbol for the dominant allele first and the recessive allele second (always *Bb,* never *bB*).

The phenomenon of dominance partly explains why an individual may resemble one parent more than the other, even if the two parents contribute equally to their offspring's genetic constitution. Dominance is not predictable and can be determined only by experiment. In one species of animal, black coat may be dominant to brown; in another species, brown may be dominant to black. In a population, the dominant phenotype is not necessarily more common than the recessive phenotype.

A test cross can detect heterozygosity

Guinea pigs with the genotypes *BB* and *Bb* are alike phenotypically; they both have black coats. How, then, can we know the genotype of a black guinea pig? Geneticists can accomplish this by performing a **test cross,** in which an individual of unknown genotype is crossed with a homozygous recessive individual (Fig. 10-6). In a test cross, the alleles carried by the gametes from the parent of unknown genotype are never "hidden" in the offspring by dominant alleles contributed by the other parent. Therefore, you can deduce the genotypes of all offspring directly from their phenotypes. If all the offspring were black, what inference would you make about the genotype of the black parent? If any of the offspring were brown, what conclusion would you draw regarding the genotype of the black parent? Would you be more certain about one of these inferences than about the other?[1]

PROCESS OF SCIENCE

Mendel conducted several test crosses; for example, he bred F_1 (tall) pea plants with homozygous recessive *(tt)* short ones. He reasoned that the F_1 individuals were heterozygous *(Tt)* and would be expected to produce equal numbers of *T* and *t* gametes. Because the homozygous short parents *(tt)* were expected to produce only *t* gametes, Mendel hypothesized that he would obtain equal numbers of tall *(Tt)* and short *(tt)* offspring. His results agreed with his hypothesis, providing additional evidence for the hypothesis that there is 1:1 segregation of the alleles of a heterozygous parent. Thus Mendel's principle of segregation not only explained the known facts, such as the 3:1 monohybrid F_2 phenotypic ratio, but also let him successfully anticipate the

[1] If all the offspring were black, you could infer that the black parent is probably homozygous, *BB.* If any of the offspring were brown, you could infer that the black parent is heterozygous, *Bb.* You would be more certain that the second inference (about the *Bb* individual) is correct than the first inference (the *BB* individual).

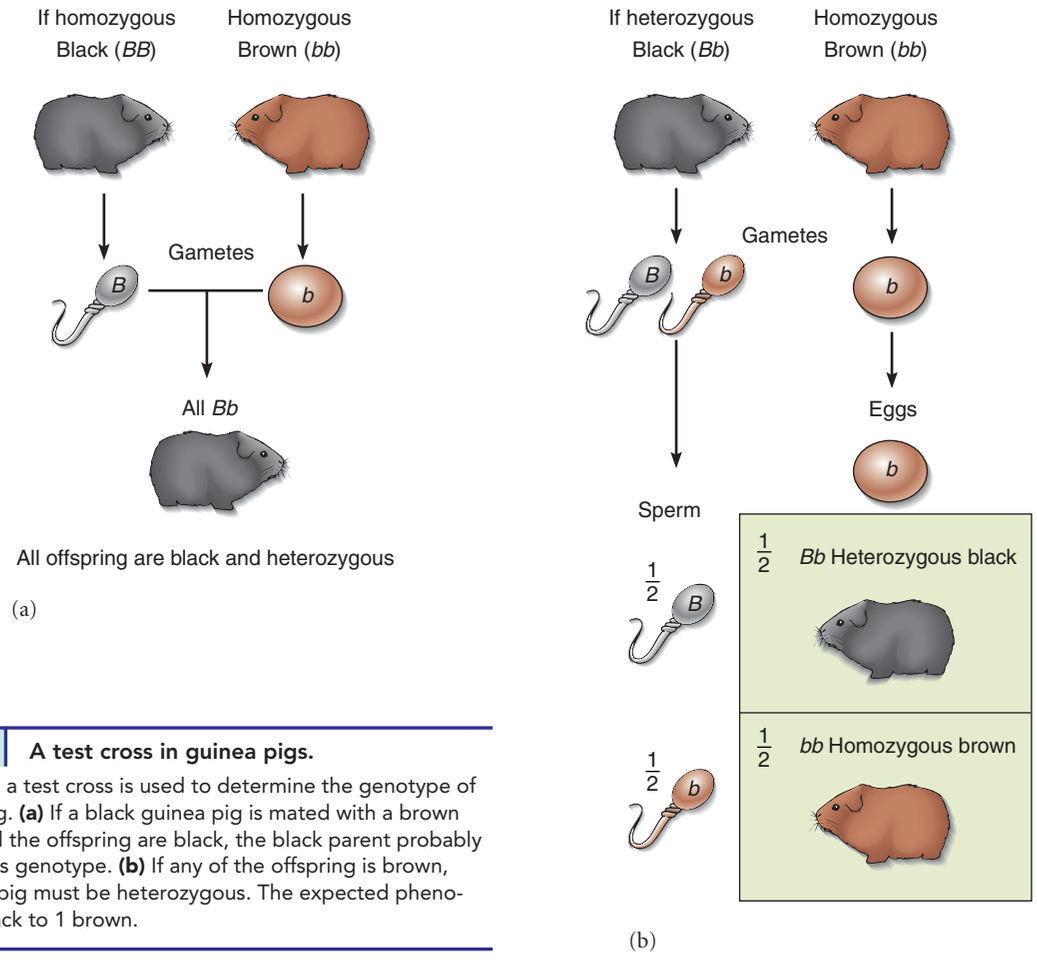


FIGURE **10-6** **A test cross in guinea pigs.**

In this illustration, a test cross is used to determine the genotype of a black guinea pig. **(a)** If a black guinea pig is mated with a brown guinea pig and all the offspring are black, the black parent probably has a homozygous genotype. **(b)** If any of the offspring is brown, the black guinea pig must be heterozygous. The expected phenotypic ratio is 1 black to 1 brown.

results of other experiments—in this case, the 1:1 test cross phenotypic ratio.

A dihybrid cross involves individuals that have different alleles at two loci

Simple monohybrid crosses involve a pair of alleles of a single locus. Mendel also analyzed crosses involving alleles of two or more loci. A mating between individuals with different alleles at two loci is called a **dihybrid cross.** Consider the case when two pairs of alleles lie in nonhomologous chromosomes (that is, one pair of alleles is in one pair of homologous chromosomes, and the other pair of alleles is in a different pair of homologous chromosomes). Each pair of alleles is inherited independently; that is, each pair segregates during meiosis independently of the other.

An example of a dihybrid cross carried through the F_2 generation is shown in Figure 10-7. In this example, black is dominant to brown, and short hair is dominant to long hair. When a homozygous, black, short-haired guinea pig *(BBSS)* and a homozygous, brown, long-haired guinea pig *(bbss)* are mated, the *BBSS* animal produces gametes that are all *BS,* and the *bbss* individual produces gametes that are all *bs.* Each gamete contains one allele for each of the two loci. The union of the *BS* and *bs* gametes yields only individuals with the genotype *BbSs.* All these F_1 offspring are heterozygous for hair color and for hair length, and all are phenotypically black and short-haired.

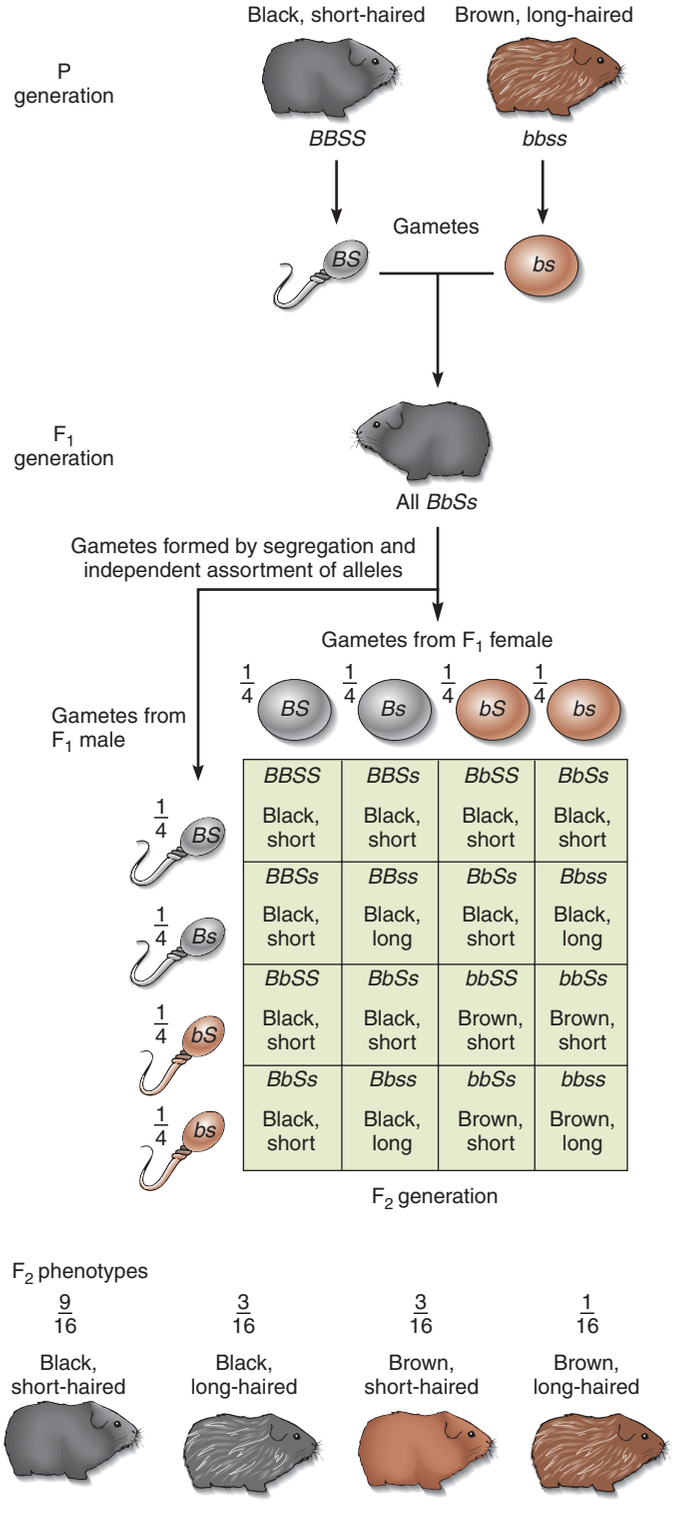
Alleles on nonhomologous chromosomes are randomly distributed into gametes

Each F_1 guinea pig produces four kinds of gametes with equal probability: *BS, Bs, bS,* and *bs.* Hence, the Punnett square has 16 (that is, 4^2) squares representing the zygotes, some of which are genotypically or phenotypically alike. There are 9 chances in 16 of obtaining a black, short-haired individual; 3 chances in 16 of obtaining a black, long-haired individual; 3 chances in 16 of obtaining a brown, short-haired individual; and 1 chance in 16 of obtaining a brown, long-haired individual. This 9:3:3:1 phenotypic ratio is expected in a dihybrid F_2 if the hair color and hair length loci are on nonhomologous chromosomes.

On the basis of similar results, Mendel formulated the principle of inheritance, now known as Mendel's **principle of independent assortment,** which states that members of any gene pair segregate from one another independently of the members of the other gene pairs. This mechanism occurs in a regular way to ensure that each gamete contains one allele for each locus, but the alleles of different loci are assorted at random with respect to each other in the gametes.

FIGURE **10-7** **A dihybrid cross in guinea pigs.**

When a black, short-haired guinea pig is crossed with a brown, long-haired one, all the offspring are black and have short hair. However, when two members of the F_1 generation are crossed, the ratio of phenotypes is 9:3:3:1.



Today we recognize independent assortment is related to the events of meiosis. It occurs because two pairs of homologous chromosomes can be arranged in two different ways at metaphase I of meiosis. These arrangements occur randomly, with approximately half the meiotic cells oriented one way and the other half oriented the opposite way. The orientation of the homologous chromosomes on the metaphase plate then determines the way they subsequently separate and disperse into the haploid cells (Fig. 10-8). (As you will soon see, however, independent assortment does not always occur.)

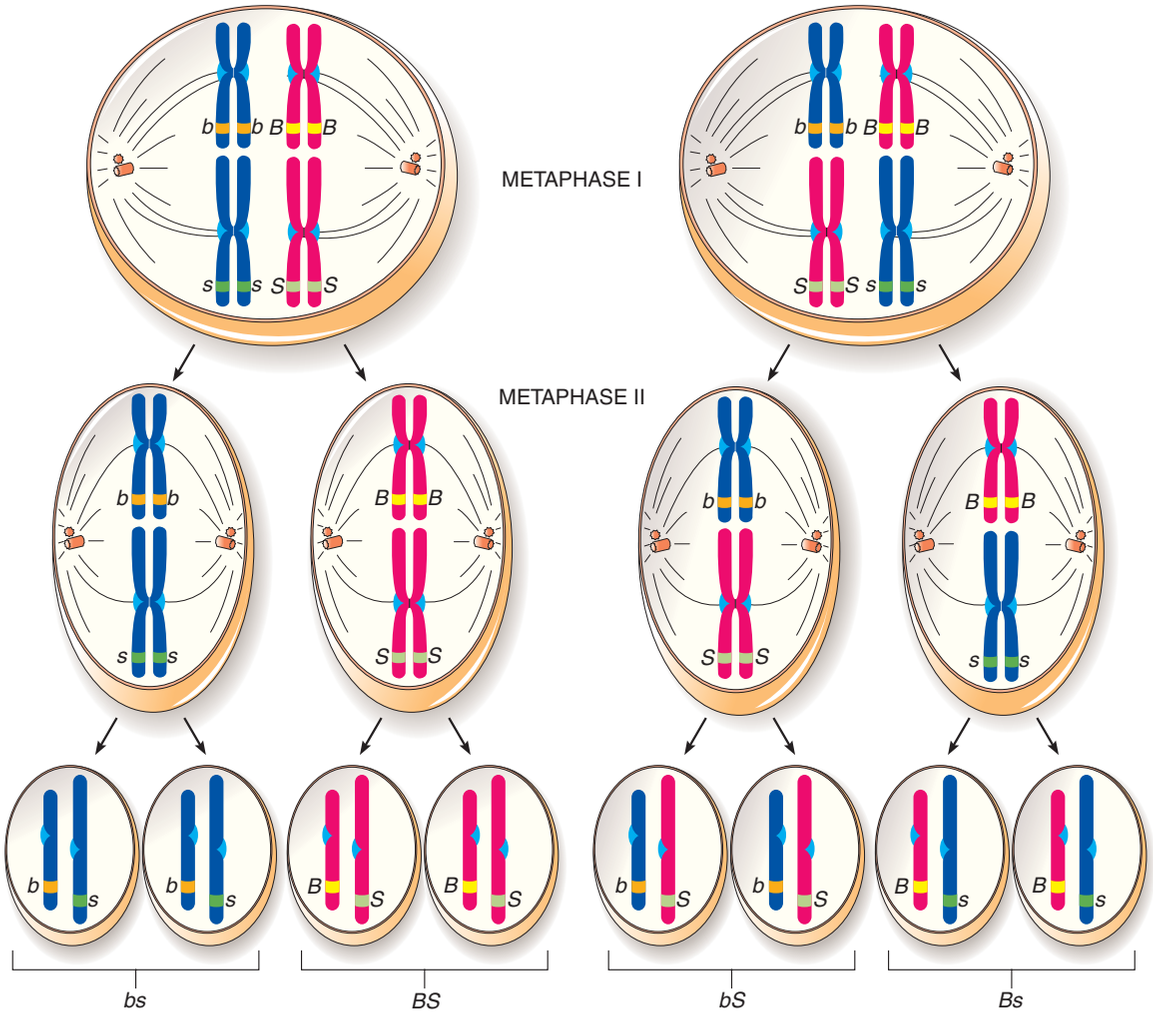
The rules of probability are useful in predicting Mendelian inheritance

All genetic ratios are properly expressed in terms of probabilities. In monohybrid crosses, the expected ratio of the dominant and recessive phenotypes is 3:1. The probability of an event is its expected frequency. Therefore, we can say there are 3 chances in 4 (or $^3/_4$) that any particular individual offspring of two heterozygous individuals will express the dominant phenotype and 1 chance in 4 (or $^1/_4$) that it will express the recessive phenotype. Although we sometimes speak in terms of percentages, probabilities are calculated as fractions (such as $^3/_4$) or decimal fractions (such as 0.75). If an event is certain to occur, its probability is 1; if it is certain *not* to occur, its probability is 0. A probability can be 0, 1, or some number between 0 and 1.

The Punnett square lets you combine two or more probabilities. When you use a Punnett square, you are following two important statistical principles known as the product rule and the sum rule. The **product rule** predicts the combined probabilities of independent events. Events are *independent* if the occurrence of one does not affect the probability that the other will occur. For example, the probability of obtaining heads on the first toss of a coin is $^1/_2$; the probability of obtaining heads on the second toss (an independent event) is also $^1/_2$. If two or more events are independent of each other, the probability of both occurring is the product of their individual probabilities. If this seems strange, keep in mind that when we multiply two numbers that are less than 1, the product is a smaller number. Therefore, the probability of obtaining heads two times in a row is $^1/_2 \times {}^1/_2 = {}^1/_4$, or 1 chance in 4 (Fig. 10-9).

Similarly, we can apply the product rule to genetic events. If both parents are *Bb,* what is the probability they will produce a child who is *bb?* For the child to be *bb,* he or she must receive a *b* gamete from each parent. The probability of a *b* egg is $^1/_2$, and the probability of a *b* sperm is also $^1/_2$. Like the outcomes of the coin tosses, these probabilities are independent, so we combine them by the product rule ($^1/_2 \times {}^1/_2 = {}^1/_4$). You might like to check this result using a Punnett square.

The **sum rule** predicts the combined probabilities of *mutually exclusive* events. In some cases, there is more than one way to obtain a specific outcome. These different ways are mutually exclusive; if one occurs, the other(s) cannot. For example, if both parents are *Bb,* what is the probability that their first child will also have the *Bb* genotype? There are two different ways these parents can have a *Bb* child: Either a *B* egg combines with a *b* sperm (probability $^1/_4$), or a *b* egg combines with a *B* sperm (probability $^1/_4$).



ACTIVE FIGURE **10-8** **Meiosis and independent assortment.**

Two different pairs of homologous chromosomes can line up two different ways at metaphase I and be subsequently distributed. A cell with the orientation shown at the left produces half *BS* and half *bs* gametes. Conversely, the cell at the right produces half *Bs* and half *bS* gametes. Because approximately half of the meiotic cells at metaphase I are of each type, the ratio of the four possible types of gametes is 1:1:1:1.

BiologyNow™ Learn more about **independent assortment** by clicking on this figure on your BiologyNow CD-ROM.

Naturally, if there is more than one way to get a result, the chances of its being obtained improve; we therefore combine the probabilities of mutually exclusive events by summing (adding) their individual probabilities. The probability of obtaining a *Bb* child in our example is therefore $\frac{1}{4} + \frac{1}{4} = \frac{1}{2}$. (Because there is only one way these heterozygous parents can produce a homozygous recessive child, *bb*, that probability is only $\frac{1}{4}$. The probability of a homozygous dominant child, *BB*, is likewise $\frac{1}{4}$.)

The rules of probability can be applied to a variety of calculations

The rules of probability have wide applications. For example, what are the probabilities that a family with two (and only two) children will have two girls, two boys, or one girl and one boy? For purposes of discussion, let's assume male and female births are equally probable. The probability of having a girl first is $\frac{1}{2}$, and the probability of having a girl second is also $\frac{1}{2}$. These are independent events, so we combine their probabilities by multiplying: $\frac{1}{2} \times \frac{1}{2} = \frac{1}{4}$. Similarly, the probability of having two boys is $\frac{1}{4}$.

In families with both a girl and a boy, the girl can be born first or the boy can be born first. The probability that a girl will be born first is $\frac{1}{2}$, and the probability that a boy will be born second is also $\frac{1}{2}$. We use the product rule to combine the probabilities of these two independent events: $\frac{1}{2} \times \frac{1}{2} = \frac{1}{4}$. Similarly, the probability that a boy will be born first and a girl second is also $\frac{1}{4}$. These two kinds of families represent mutually exclusive outcomes, that is, two different ways of obtaining a family with one boy and one girl. Having two different ways of obtaining the desired result improves our chances, so we use the sum rule to combine the probabilities: $\frac{1}{4} + \frac{1}{4} = \frac{1}{2}$.

In working with probabilities, keep in mind a point that many gamblers forget: Chance has no memory. If events are truly independent, past events have no influence on the probability of the occurrence of future events. When working probability problems,

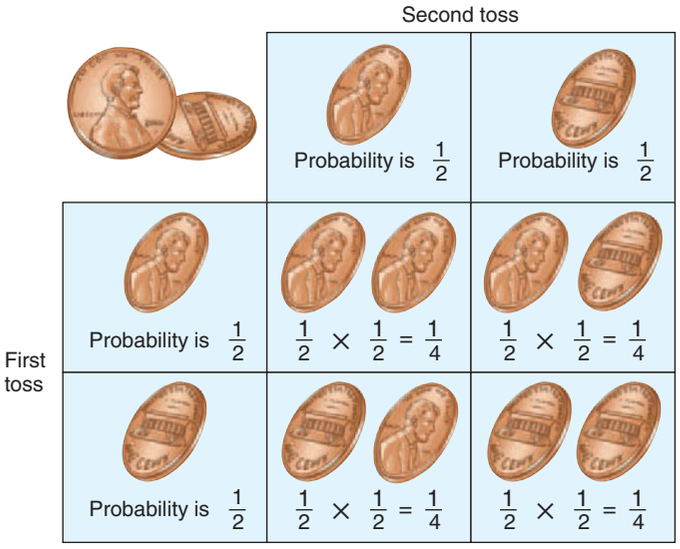


FIGURE **10-9** **The rules of probability.**

For each coin toss, the probability of heads is ½ and the probability of tails is also ½. Because the outcome of the first toss is independent of the outcome of the second, the combined probabilities of the outcomes of successive tosses are calculated by multiplying their individual probabilities (according to the product rule: ½ × ½ = ¼). These same rules of probability predict genetic events.

common sense is more important than blindly memorizing rules. Examine your results to see whether they appear reasonable; if they don't, re-evaluate your assumptions. (See *Focus On: Solving Genetics Problems* on page 206 for step-by-step procedures to solve genetics problems, including when to use the rules of probability.)

MENDELIAN INHERITANCE AND CHROMOSOMES

Learning Objectives

5 Explain Mendel's principles of segregation and independent assortment, given what scientists know about genes and chromosomes.

6 Define *linkage*, and relate it to specific events in meiosis.

7 Show how data from a test cross involving alleles of two loci can be used to distinguish between independent assortment and linkage.

8 Discuss the genetic determination of sex and the inheritance of X-linked genes in mammals.

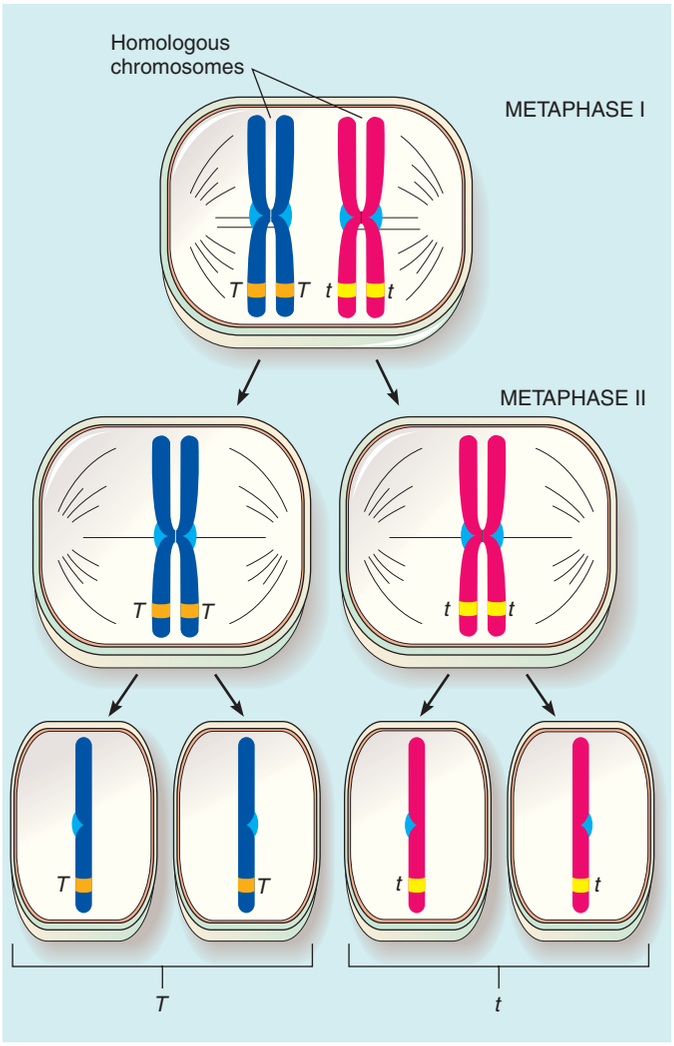

FIGURE **10-10** **The chromosomal basis for segregation.**

The separation of homologous chromosomes during meiosis results in the segregation of alleles in a heterozygote. Note that half of the gametes will carry *T* and half will carry *t*.

It is a measure of Mendel's genius that he worked out the principles of segregation and independent assortment without knowing anything about the chromosomal basis of inheritance. Today we know the segregation of alleles is a direct result of homologous chromosomes separating during meiosis (Fig. 10-10; also see Fig. 9-12). (Recall from Chapter 9 that in all sexual life cycles, meiosis must occur at some point before gamete formation.) Later, at the time of fertilization, each haploid gamete contributes one chromosome from each homologous pair and therefore one allele for each gene pair. Although gametes and fertilization were known at the time Mendel carried out his research, mitosis and meiosis had not yet been discovered. It is truly remarkable that Mendel formulated his ideas mainly on the basis of mathematical abstractions. Today his principles are much easier to understand, because we relate the transmission of genes to the behavior of chromosomes.

The chromosomal basis of inheritance also helps explain certain apparent exceptions to Mendelian inheritance. One of these so-called exceptions involves linked genes.

Linked genes do not assort independently

Beginning around 1910, the research of American geneticist Thomas Hunt Morgan and his graduate students extended the concept of the chromosomal basis of inheritance. Morgan's research organism was the fruit fly (*Drosophila melanogaster*). By carefully analyzing the results of crosses involving fruit flies, Morgan and his students demonstrated that genes are arranged in a linear order on each chromosome.

Morgan also showed that independent assortment does not apply if the two loci lie close together in the same pair of homologous chromosomes. In fruit flies there is a locus controlling wing shape (the dominant allele *V* for normal wings and the recessive allele *v* for abnormally short, or vestigial, wings) and another locus controlling body color (the dominant allele *B* for gray body and the recessive allele *b* for black body). If a homozygous *BBVV* fly is crossed with a homozygous *bbvv* fly, the F_1 flies all have gray bodies and normal wings, and their genotype is *BbVv*.

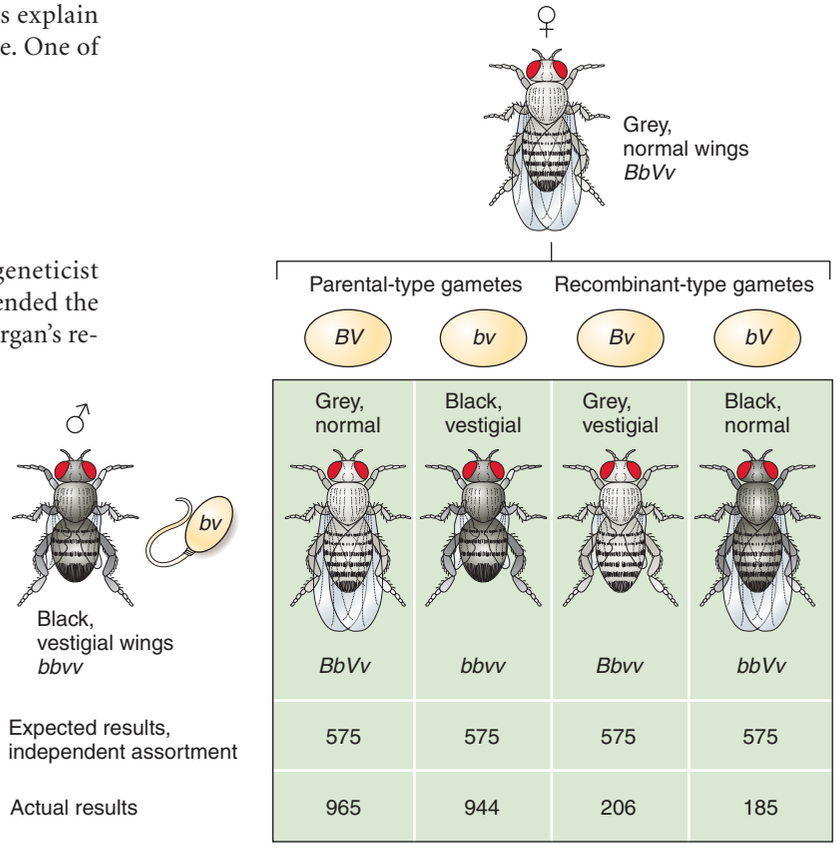

FIGURE **10-11** **A two-point test cross to detect linkage in fruit flies.**

Linkage can be recognized when an excess of parental-type offspring and a deficiency of recombinant-type offspring are produced in a two-point test cross. In this example using data from an actual cross, loci for wing length and body color are linked; they are located on a homologous chromosome pair. This is evident in the 2300 offspring (bottom row). About 920 of the offspring (or 40%) belong to each of the two parental classes (80% total), and 230 offspring (or 10%) belong to each of the two recombinant classes (20% total). The row above the actual results lets you contrast the data with the expected numbers for independent assortment.

Because these loci happen to lie close to one another in the *same pair* of homologous chromosomes, their alleles do not assort independently; instead, they are **linked genes** that tend to be inherited together. **Linkage** is the tendency for a group of genes on the same chromosome to be inherited together in successive generations. You can readily observe linkage in the results of a test cross in which heterozygous F_1 flies *(BbVv)* are mated with homozygous recessive *(bbvv)* flies (Fig. 10-11). Because heterozygous individuals are mated to homozygous recessive individuals, this test cross is similar to the test cross described earlier. However, it is called a **two-point test cross** because alleles of two loci are involved.

If the loci governing these traits were unlinked—that is, on different chromosomes—the heterozygous parent in a test cross would produce four kinds of gametes (*BV, Bv, bV,* and *bv*) in equal numbers. This independent assortment would produce offspring with new gene combinations not present in the parental generation. Any process that leads to new gene combinations is called **recombination.** In our example, gametes *Bv* and *bV* are **recombinant types.** The other two kinds of gametes, *BV* and *bv,* are **parental types** because they are identical to the gametes produced by the P generation. Of course, the homozygous recessive parent produces only one kind of gamete, *bv.* Thus if independent assortment were to occur in the F_1 flies, approximately 25% of the test-cross offspring would be gray-bodied and normal-winged *(BbVv),* 25% black-bodied and normal-winged *(bbVv),* 25% gray-bodied and vestigial-winged *(Bbvv),* and 25% black-bodied and vestigial-winged *(bbvv).* Notice that the two-point test cross lets us determine the genotypes of the offspring directly from their phenotypes.

By contrast, the alleles of the loci in our example do not undergo independent assortment, because they are linked. Alleles at different loci but close to one another on a given chromosome tend to be inherited together; because chromosomes pair and separate during meiosis as units, they therefore tend to be inherited as units. If linkage were complete, only parental-type flies would be produced, with approximately 50% having gray bodies and normal wings *(BbVv),* and 50% having black bodies and vestigial wings *(bbvv).* However, in our example, the offspring also include some gray-bodied, vestigial-winged flies and some black-bodied, normal-winged flies. These are recombinant flies, having received a recombinant-type gamete from the heterozygous F_1 parent. Each recombinant-type gamete arose by **crossing-over** between these loci in a meiotic cell of a het-

erozygous female fly. (Fruit flies are unusual in that crossing-over occurs only in females and not in males; it is far more common for crossing-over to occur in both sexes of a species.) Recall from Chapter 9 that when chromosomes pair and undergo synapsis, crossing-over occurs as homologous (nonsister) chromatids exchange segments of chromosomal material by a process of breakage and rejoining (Fig. 10-12; also see Fig. 9-14).

Calculating the frequency of crossing-over reveals the linear order of linked genes on a chromosome

In our example (see Fig. 10-11), 391 of the offspring are recombinant types: gray flies with vestigial wings, *Bbvv* (206 of the total); and black flies with normal wings, *bbVv* (185 of the total). The remaining 1909 offspring are parental types. These data can be used to calculate the percentage of crossing-over between the loci. You can do this by adding the number of individuals in the two recombinant classes of offspring (206 +185), dividing by the *total number of offspring* (965 + 944 + 206 + 185), and multiplying by 100: 391 ÷ 2300 = 0.17; 0.17 × 100 = 17%. Thus the *V* locus and the *B* locus have 17% recombination between them.

During a single meiotic division, crossing-over may occur at several different points along the length of each homologous chromosome pair. In general, crossing-over is more likely to occur between two loci if they lie far apart on the chromosome and less likely to occur if they lie close together. Because of this rough correlation between the frequency of recombination of two loci and the linear distance between them, a genetic map of the chromosome can be generated by converting the percentage of recombination to **map units.** By convention, 1% recombination between two loci equals a distance of 1 map unit, so the loci in our example are 17 map units apart.

Scientists have determined the frequencies of recombination between specific linked loci in many species. All the experimental results are consistent with the hypothesis that genes are present in a linear order in the chromosomes. Figure 10-13 illustrates the traditional method for determining the linear order of genes in a chromosome.

More than one crossover between two loci in a single tetrad can occur in a given cell undergoing meiosis. (Recall from Chapter 9 that a *tetrad* is a group of four chromatids that make up a pair of synapsed homologous chromosomes.) We can observe only the frequency of offspring receiving recombinant-type gametes from the heterozygous parent, not the actual number of crossovers. In fact, the actual frequency of crossing-over is slightly more than the observed frequency of recombinant-type gametes. This is because the simultaneous occurrence of two crossovers involving the same two homologous chromatids reconstitutes the original combination of genes (Fig. 10-14). When two loci are relatively close together, the effect of double crossing-over is minimized.

By putting together the results of many crosses, scientists developed detailed linkage maps for many eukaryotes, including the fruit fly, the mouse, yeast, *Neurospora* (a fungus), and many plants, especially those that are important crops. In addition, researchers have used genetic methods to develop a detailed map for *Escherichia coli,* a bacterium with a single, circular DNA molecule, and many other prokaryotes and viruses. They have made much more sophisticated maps of chromosomes by means of recombinant DNA technology (see Chapter 14). Using these techniques, the *Human Genome Project* has produced maps of human chromosomes (see Chapter 15).

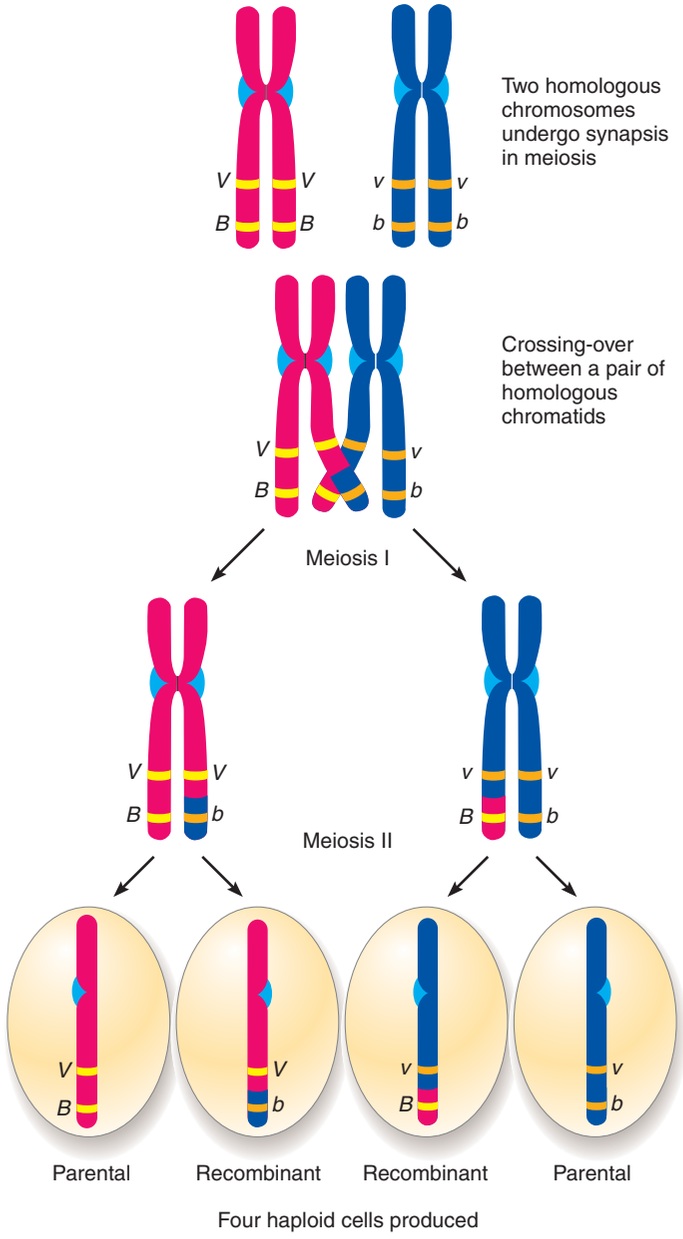

FIGURE **10-12** **Crossing-over.**

The exchange of segments between chromatids of homologous chromosomes facilitates the recombination of linked genes. Genes located far apart on a chromosome have a greater probability of being separated by crossing-over than do genes that are closer together.

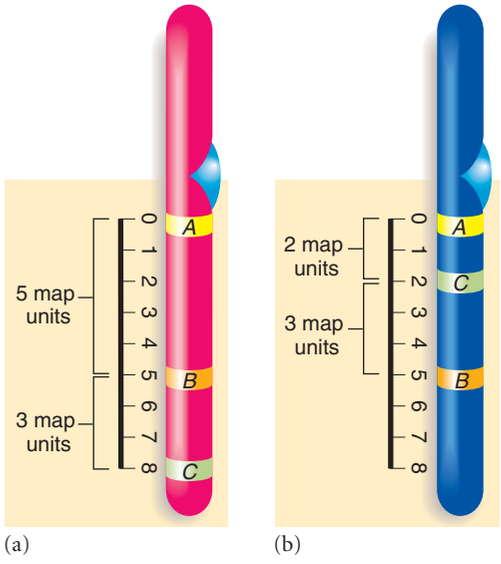

FIGURE **10-13** **Gene mapping.**

Gene order (that is, which locus lies between the other two) is determined by the percentage of recombination between each of the possible pairs. In this hypothetical example, the percentage of recombination between locus *A* and locus *B* is 5% (corresponding to five map units) and that between *B* and *C* is 3% (three map units). There are two alternatives for the linear order of these alleles. **(a)** If the recombination between *A* and *C* is 8% (8 map units), *B* must be in the middle. **(b)** If the recombination between *A* and *C* is 2%, then *C* must be in the middle.

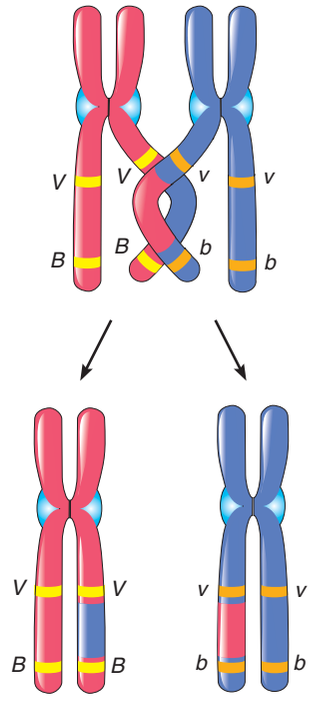

FIGURE **10-14** **Double crossing-over.**

If the same homologous chromatids undergo double crossing-over between the genes of interest, the gametes formed are not recombinant for these genes.

Sex is generally determined by sex chromosomes

In some species, environmental factors exert a large control over an individual's sex. However, genes are the most important sex determinants in most organisms. The major sex-determining genes of mammals, birds, and many insects are carried by **sex chromosomes.** Typically, members of one sex have a pair of similar sex chromosomes and produce gametes that are all identical in sex chromosome constitution. The members of the other sex have two different sex chromosomes and produce two kinds of gametes, each bearing a single kind of sex chromosome.

The cells of females of many animal species, including humans, contain two **X chromosomes.** In contrast, the males have a single X chromosome and a smaller **Y chromosome.** For example, human males have 22 pairs of **autosomes,** which are chromosomes other than the sex chromosomes, plus one X chromosome and one Y chromosome; females have 22 pairs of autosomes plus a pair of X chromosomes. Domestic cats have 19 pairs of autosomes, to which are added a pair of X chromosomes in females, or an X plus a Y in males.

The Y chromosome determines male sex in most species of mammals

Do male humans have a male phenotype because they have only one X chromosome, or because they have a Y chromosome? Much of the traditional evidence bearing on this question comes from studies of people with abnormal sex chromosome constitutions (see Chapter 15). A person with an XXY constitution is a nearly normal male in external appearance, although his testes are underdeveloped (Klinefelter syndrome). A person with one X but no Y chromosome has the overall appearance of a female but has defects such as short stature and undeveloped ovaries (Turner syndrome). An embryo with a Y but no X does not survive. Thus all individuals require at least one X, and the Y is the male-determining chromosome.

Geneticists have identified several genes on the Y chromosomes that are involved in male determination. The *sex reversal on Y (SRY) gene,* the major male-determining gene on the Y chromosome, acts as a "genetic switch" that causes testes to develop in the fetus. The developing testes then secrete the hormone **testosterone,** which causes other male characteristics to develop. A few other genes on the Y chromosome also play a role in sex determination, as do many genes on the X chromosome, which explains why an XXY individual does not have a completely normal male phenotype. Some genes on the autosomes also affect sex development.

The X and Y chromosomes are thought to have originated as a homologous pair. However, they are not truly homologous in their present forms, because they are not similar in size, shape, or genetic constitution. Nevertheless, they have retained a short homologous "pairing region" that lets them synapse and separate from one another during meiosis. Half the sperm contain an X

FOCUS ON: SOLVING GENETICS PROBLEMS

Simple Mendelian genetics problems are like puzzles. They can be fun and easy to work if you follow certain conventions and are methodical in your approach.

1. Always use standard designations for the generations. The generation in which a particular genetic experiment is begun is called the P, or parental, generation. Offspring of this generation are called the F_1, or first filial, generation. The offspring resulting when two F_1 individuals are bred constitute the F_2, or second filial, generation.
2. Write down a key for the symbols you are using for the allelic variants of each locus. Use an uppercase letter to designate a dominant allele and a lowercase letter to designate a recessive allele. Use the same letter of the alphabet to designate both alleles of a particular locus. If you are not told which allele is dominant and which is recessive, the phenotype of the F_1 generation is a good clue.
3. Determine the genotypes of the parents of each cross by using the following types of evidence:
   - Are they from true-breeding lines? If so, they should be homozygous.
   - Can their genotypes be reliably deduced from their phenotypes? This is usually true if they express the recessive phenotype.
   - Do the phenotypes of their offspring provide any information? Exactly how this is done is discussed shortly.
4. Indicate the possible kinds of gametes formed by each of the parents. It is helpful to draw a circle around the symbols for each kind of gamete.
   - If it is a monohybrid cross, we apply the principle of segregation; that is, a heterozygote *Aa* forms two kinds of gametes, *A* and *a*. A homozygote, such as *aa*, forms only one kind of gamete, *a*.
   - If it is a dihybrid cross, we apply the principles of segregation and independent assortment. For example, an individual heterozygous for two loci would have the genotype *AaBb*. Allele *A* segregates from *a*, and *B* segregates from *b*. The assortment of *A* and *a* into gametes is independent of the assortment of *B* and *b*. *A* is equally likely to end up in a gamete with *B* or *b*. The same is true for *a*. Thus an individual with the genotype *AaBb* produces four kinds of gametes in equal amounts: *AB*, *Ab*, *aB*, and *ab*.
5. Set up a Punnett square, placing the possible types of gametes from one parent down the left side and the possible types from the other parent across the top.
6. Fill in the Punnett square. Avoid confusion by consistently placing the dominant allele first and the recessive allele second in heterozygotes (*Aa*, never *aA*). If it is a dihybrid cross, always write the two alleles of one

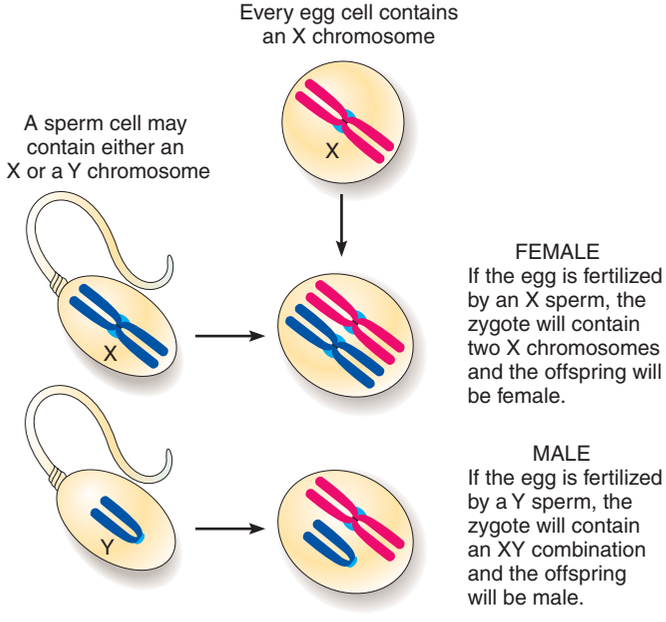

FIGURE **10-15** **Sex determination in mammals.**
The sperm determines sex in mammals. An X-bearing sperm produces a female, and a Y-bearing sperm produces a male.

chromosome and half contain a Y chromosome (Fig. 10-15). All normal eggs bear a single X chromosome. Fertilization of an X-bearing egg by an X-bearing sperm results in an XX (female) zygote; fertilization by a Y-bearing sperm results in an XY (male) zygote.

You might expect to have equal numbers of X- and Y-bearing sperm and a 1:1 ratio of females to males. However, in humans more males are conceived than females, and more males die before birth. Even at birth the ratio is not 1:1; about 106 boys are born for every 100 girls. Although we do not know why this occurs, Y-bearing sperm seem to have some selective advantage.

An XX/XY sex chromosome mechanism, similar to that of humans, operates in many species of animals. However, it is not universal, and many of the details may vary. For example, the fruit fly, *Drosophila*, has XX females and XY males, but the Y does not determine maleness; a fruit fly with only one X chromosome and no Y chromosome has a male phenotype. In birds and butterflies the mechanism is reversed, with males having the equivalent of XX and females the equivalent of XY.

X-linked genes have unusual inheritance patterns

The human X chromosome contains many loci that are required in both sexes. Genes located in the X chromosome, such

locus first and the two alleles of the other locus second. It does not matter which locus you choose to write first, but once you have decided on the order, it is crucial to maintain it consistently. This means that if the individual is heterozygous for both loci, you will always use the form *AaBb*. Writing this particular genotype as *aBbA*, or even as *BbAa*, would cause confusion.

7. If you do not need to know the frequencies of all the expected genotypes and phenotypes, you can use the rules of probability as a shortcut. For example, if both parents are *AaBb*, what is the probability of an *AABB* offspring? To be *AA*, the offspring must receive an *A* gamete from each parent. The probability that a given gamete is *A* is ½ and each gamete represents an independent event, so combine their probabilities by multiplying (½ × ½ = ¼). The probability of *BB* is calculated similarly and is also ¼. The probability of *AA* is independent of the probability of *BB*, so again, use the product rule to obtain their combined probabilities (¼ × ¼ = 1/16).

   Very often the genotypes of the parents can be deduced from the phenotypes of their offspring. In peas, for example, the allele for yellow seeds *(Y)* is dominant to the allele for green seeds *(y)*. Suppose plant breeders cross two plants with yellow seeds, but you don't know whether the yellow-seeded plants are homozygous or heterozygous. You can designate the cross as: *Y_* × *Y_*. The offspring of the cross are allowed to germinate and grow, and their seeds are examined: Of the offspring, 74 produce yellow seeds, and 26 produce green seeds. Knowing that green-seeded plants are recessive, *yy*, the answer is obvious: Each parent contributed a *y* allele to the green-seeded offspring, so the parents' genotypes must have been *Yy* × *Yy*.

   Sometimes it is impossible to determine from the data given whether an individual is homozygous dominant or heterozygous. For example, suppose a cross between a yellow-seeded plant and a green-seeded plant yields offspring that all produce yellow seeds. From the information given about the parents, you can designate the cross as: *Y_* × *yy*. Because all the offspring have yellow seeds, they have the genotype *Yy*. You can deduce this because each parent contributes one allele. (The offspring have yellow seeds so they must have at least one *Y* allele; however, the green seed parent can only contribute a *y* allele to the offspring.) Therefore, the cross is most likely (*YY* × *yy*), but you cannot be absolutely certain about the genotype of the yellow-seeded parent. Further crosses would be necessary to determine this.

as those governing color perception and blood clotting, are sometimes called **sex-linked genes.** It is more appropriate, however, to refer to them as **X-linked genes** because they follow the transmission pattern of the X chromosome and, strictly speaking, are not linked to the sex of the organism per se.

A female receives one X from her mother and one X from her father. A male receives his Y chromosome, which makes him male, from his father. From his mother he inherits a single X chromosome and therefore all his X-linked genes. In the male, every allele present on the X chromosome is expressed, whether that allele was dominant or recessive in the female parent. A male is neither homozygous nor heterozygous for his X-linked alleles; instead, he is always **hemizygous**—that is, he has only one copy of each X-linked gene.

We will use a simple system of notation for problems involving X linkage, indicating the X chromosome and incorporating specific alleles as superscripts. For example, the symbol X^c signifies a recessive X-linked allele for colorblindness and X^C the dominant X-linked allele for normal color vision. The Y chromosome is written without superscripts because it does not carry the locus of interest. Two recessive X-linked alleles must be present in a female for the abnormal phenotype to be expressed (X^cX^c), whereas in the hemizygous male a single recessive allele (X^cY) causes the abnormal phenotype. As a consequence, these abnormal alleles are much more frequently expressed in male offspring. A heterozygous female may be a *carrier,* an individual who possesses one copy of a mutant recessive allele but does not express it in the phenotype (X^CX^c).

To be expressed in a female, a recessive X-linked allele must be inherited from both parents. A colorblind female, for example, must have a colorblind father and a mother who is homozygous or heterozygous for a recessive colorblindness allele (Fig. 10-16). The homozygous combination is unusual, because the frequency of alleles for colorblindness is relatively low. In contrast, a colorblind male need only have a mother who is heterozygous for colorblindness; his father can have normal vision. Therefore, X-linked recessive traits are generally much more common in males than in females, a fact that may partially explain why human male embryos are more likely to die.

Dosage compensation equalizes the expression of X-linked genes in males and females

The X chromosome contains numerous genes required by both sexes, yet a normal female has two copies ("doses") for each locus, whereas a normal male has only one. **Dosage compensation** is a mechanism that makes equivalent the two doses in the female and the single dose in the male. Male fruit flies accomplish this by making their single X chromosome more active. In most tissues, the metabolic activity of a single male X chromosome is equal to the combined metabolic activity of the two X chromosomes present in the female.

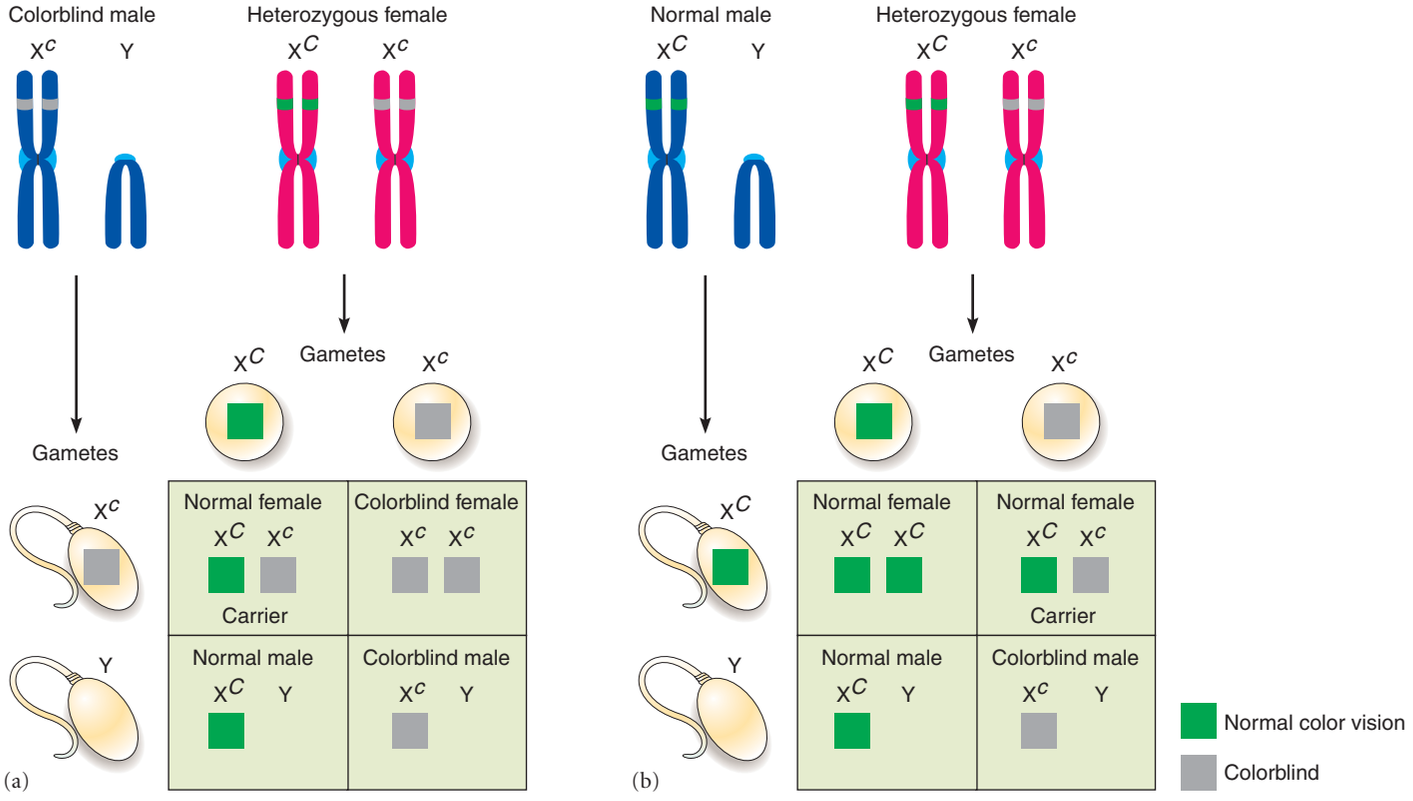

FIGURE **10-16** **X-linked red–green colorblindness.**

Note that the Y chromosome does not carry a gene for color vision. **(a)** To be colorblind, a female must inherit alleles for colorblindness from both parents. **(b)** If a normal male mates with a carrier (heterozygous) female, half of their sons would be expected to be colorblind and half of their daughters would be expected to be carriers.

Dosage compensation in mammals generally involves the inactivation of one of the two X chromosomes in the female (Fig. 10-17a). During interphase, a dark spot of chromatin is visible at the edge of the nucleus of each female mammalian cell when stained and observed with a microscope. This dark spot, known as a **Barr body,** is a dense, metabolically inactive X chromosome. The other X chromosome resembles the metabolically active autosomes; during interphase, it is a greatly extended thread that is not evident in light microscopy. From this and other evidence, the British geneticist Mary Lyon hypothesized in 1961 that in most cells of a female mammal, only one of the two X chromosomes is active; the other is inactive and is condensed as a Barr body. (Actually, X chromosome inactivation is never complete; a small fraction of the genes are active.)

X chromosome inactivation is a random event in each somatic (body) cell of the female embryo. A female mammal that is heterozygous at an X-linked locus expresses one of the alleles in about half her cells and the other allele in the other half. This is sometimes evident in the phenotype. Mice and cats have several X-linked genes for certain coat colors. Females that are heterozygous for such genes may show patches of one coat color in the middle of areas of the other coat color. This phenomenon, termed **variegation,** is evident in tortoiseshell and calico cats (Fig. 10-17b). Early in development, when relatively few cells are present, X chromosome inactivation occurs randomly in each cell. When any one of these cells divides by mitosis, the cells of the resulting *clone* (a group of genetically identical cells) all have the same active X chromosome, and, therefore, a patch develops of cells that all express the same color.

Why, you might ask, is variegation not always apparent in females heterozygous at X-linked loci? The answer is that, although variegation usually occurs, we may need to use special techniques to observe it. For example, colorblindness is caused by a defect involving the pigments in the cone cells in the retina of the eye (see Chapter 41). In at least one type of red-green colorblindness, the retina of a heterozygous female actually contains patches of abnormal cones, but the patches of normal cones are enough to provide normal color vision. Variegation can be very hard to observe in cases where cell products become mixed in bodily fluids. For instance, in females heterozygous for the allele that causes hemophilia, only half the cells responsible for producing a specific blood-clotting factor do so, but they produce enough to ensure that the blood clots normally.

Review

- What are linked genes?
- How do geneticists use a two-point test cross to detect linkage?
- Which chromosome determines the male sex in humans and most species of mammals?
- What is dosage compensation, and what does it generally involve in mammals?

FIGURE **10-17** **Dosage compensation in female mammals.**

(a) Inactivation of one X chromosome in female cells. (1) The zygote and early embryonic cells have two X chromosomes, one from each parent. (2) The random inactivation of one X chromosome occurs early in development. Roughly half the cells inactivate one X chromosome, like the left cell, and the other half inactivate the second X chromosome, as in the right cell. The inactive X chromosome is visible as a Barr body near the nuclear envelope. (3) Chromosomal inactivation persists through subsequent mitotic divisions, resulting in patches of cells in the adult body. **(b)** Persian calico cat. A calico cat has X-linked genes for both black and yellow (or orange) pigmentation of the fur, but because of random X chromosome inactivation, black is expressed in some groups of cells and orange is expressed in others. (The patches of white fur are due to the presence of other genes that affect fur color.)

EXTENSIONS OF MENDELIAN GENETICS

Learning Objectives

9 Explain some of the ways genes may interact to affect the phenotype; discuss how a single gene can affect many features of the organism simultaneously.

10 Solve genetics problems involving incomplete dominance, codominance, multiple alleles, epistasis, and polygenes.

11 Describe *norm of reaction*, and give an example.

The relationship between a given locus and the trait it controls may or may not be simple. A single pair of alleles of a locus may regulate the appearance of a single trait (such as tall versus short in garden peas). Alternatively, a pair of alleles may participate in the control of several traits, or alleles of many loci may interact to affect the phenotypic expression of a single character. Not surprisingly, these more complex relationships are quite common.

You can assess the phenotype on one or many levels. It may be a morphological trait, such as shape, size, or color. It may be a physiological trait or even a biochemical trait, such as the presence or absence of a specific enzyme required for the metabolism of some specific molecule. In addition, changes in the environmental conditions under which the organism develops may alter the phenotypic expression of genes.

Dominance is not always complete

Studies of the inheritance of many traits in a wide variety of organisms have shown that one member of a pair of alleles may not be completely dominant over the other. In such instances, it is inaccurate to use the terms *dominant* and *recessive*.

PROCESS OF SCIENCE

The plants commonly known as four o'clocks (*Mirabilis jalapa*) may have red or white flowers. Each color breeds true when these plants are self-pollinated. What flower color might you expect in the offspring of a cross between a red-flowering plant and a white-flowering one? Without knowing which is dominant, you might predict that all would have red flowers or all would have white flowers. German botanist Carl Correns, one of the rediscoverers of Mendel's work, first performed this cross and found that all F_1 offspring have pink flowers! Does this result in any way indicate that Mendel's assumptions about inheritance are wrong? Did the parental traits blend inseparably

in the offspring? Quite the contrary, for when two of these pink-flowered plants are crossed, red-flowered, pink-flowered, and white-flowered offspring appear in a ratio of 1:2:1 (Fig. 10-18). In this instance, as in all other aspects of the scientific process, results that differ from those hypothesized prompt scientists to re-examine and modify their hypotheses to account for the exceptional results. The pink-flowered plants are clearly the heterozygous individuals, and neither the red allele nor the white allele is completely dominant. When the heterozygote has a phenotype intermediate between those of its two parents, the genes are said to show **incomplete dominance.** In these crosses, the genotypic and phenotypic ratios are identical.

Incomplete dominance is not unique to four o'clocks, and additional examples of incomplete dominance are known in both plants and animals. For example, true-breeding white chickens and true-breeding black chickens produce bluish-gray offspring, known as Andalusian blues, when crossed.

In both cattle and horses, reddish coat color is not completely dominant to white coat color. Heterozygous individuals have a mixture of reddish hairs and white hairs, which is called *roan.* If you saw a white mare nursing a roan foal, what would you guess was the coat color of the foal's father? Because the red-dish and white colors are expressed independently (hair by hair) in the roan heterozygote, scientists sometimes refer to this as a case of **codominance.** Strictly speaking, the term *incomplete dominance* refers to instances in which the heterozygote is intermediate in phenotype, and *codominance* refers to instances in which the heterozygote simultaneously expresses the phenotypes of both types of homozygotes.

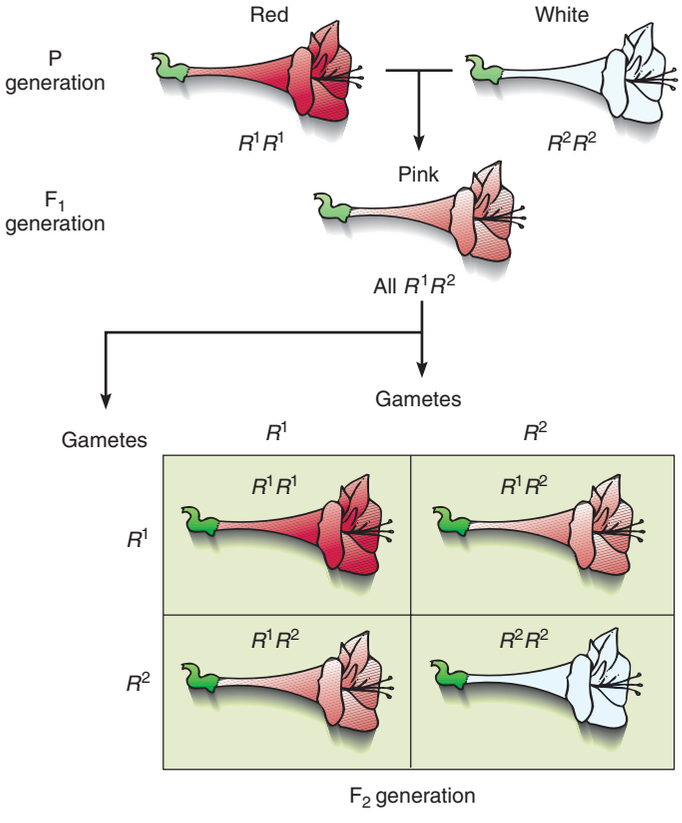

FIGURE **10-18** **Incomplete dominance in four o'clocks.**
If a pair of alleles is incompletely dominant to each other, a heterozygote has a phenotype intermediate between its parents. Two incompletely dominant alleles, R^1 and R^2, are responsible for red, white, and pink flower colors. Red-flowered plants are R^1R^1, white-flowered plants are R^2R^2, and heterozygotes (R^1R^2) are pink. Note that uppercase letters are used for both alleles, because neither is recessive to the other.

TABLE **10-1** **ABO Blood Types***

Phenotype (blood type)	Genotypes	Antigen on RBC	Antibodies to A or B Antigens in Plasma
A	I^AI^A, I^Ai	A	Anti-B
B	I^BI^B, I^Bi	B	Anti-A
AB	I^AI^B	A, B	None
O	ii		Anti-A, anti-B

*This table and the discussion of the ABO system have been simplified somewhat. Note that the body produces antibodies against the antigens *lacking* on its own red blood cells (RBCs). Because of their specificity for the corresponding antigens, these antibodies are used in standard tests to determine blood types.

Humans have four blood types (A, B, AB, and O), collectively called the **ABO blood group.** The human ABO blood group is an excellent example of codominant alleles. Blood types A, B, AB, and O are controlled by three alleles representing a single locus (Table 10-1). Allele I^A codes for the synthesis of a specific glycoprotein, antigen A, which is expressed on the surface of red blood cells. (Immune responses are discussed in Chapter 43; for now, we define antigens simply as substances capable of stimulating an immune response.) Allele I^B leads to the production of antigen *B,* a different (but related) glycoprotein. Allele i is allelic to I^A and I^B, but it does not code for an antigen. Individuals with the genotype I^AI^A or I^Ai have blood type A. People with genotype I^BI^B or I^Bi have blood type B. Those with genotype I^AI^B have blood type AB, whereas those with genotype ii have blood type O. These results show that neither allele I^A nor allele I^B is dominant to the other. Both alleles are expressed phenotypically in the heterozygote and are therefore codominant to each other, although each is dominant to allele i.

At one time, determining blood types was used to settle cases of disputed parentage. Although blood type tests can *exclude* someone as a possible parent of a particular child, they can never prove a certain person is the parent; they only determine he or she *could* be. Could a man with blood type AB be the father of a child with blood type O? Could a woman with blood type O be the mother of a child with blood type AB? Could a type B child with a type A mother have a type A father or a type O father?[2]

Multiple alleles for a locus may exist in a population

Most of our examples so far have dealt with situations in which each locus was represented by a maximum of two allelic variants. It is true that a single diploid individual has a maximum of two

[2] The answer to all these questions is no.

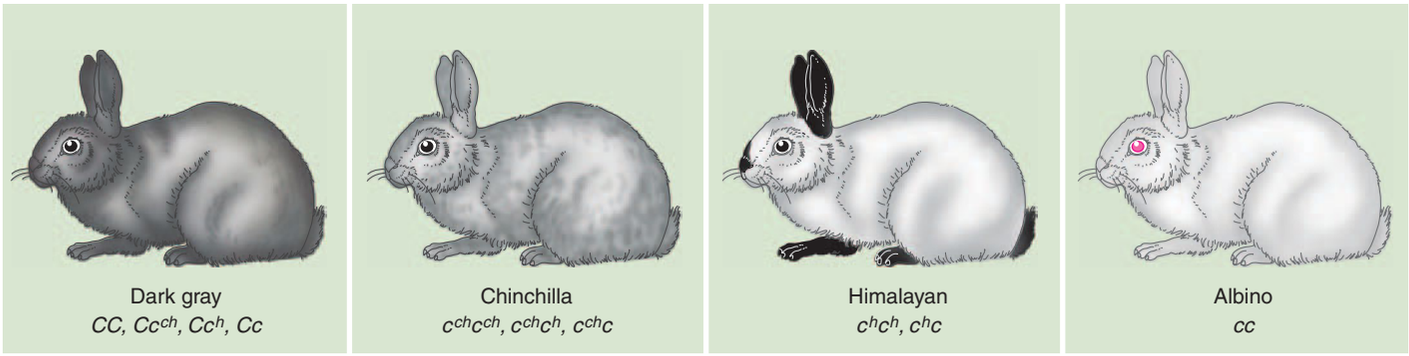

FIGURE **10-19** **Multiple alleles in rabbits.**

In rabbits the locus for coat color has four alleles, designated *C*, c^{ch}, c^h, and *c*. An individual rabbit, being diploid, may have any two alleles of this series. The phenotypes and their associated genotypes are shown.

different alleles for a particular locus and that a haploid gamete has only one allele for each locus. However, if you survey a population you may find more than two alleles for a particular locus, as you saw with the ABO blood group. If three or more alleles for a given locus exist within the population, we say that locus has **multiple alleles.** Research has shown that many loci have multiple alleles. Some alleles can be identified by the activity of a certain enzyme or by some other biochemical feature but do not produce an obvious phenotype. Others produce a readily recognizable phenotype, and certain patterns of dominance can be discerned when the alleles are combined in various ways.

In rabbits, four alleles occur at the locus for coat color (Fig. 10-19). A *C* allele causes a fully colored dark gray coat. The homozygous recessive genotype, *cc,* causes albino (white) coat color. There are two additional allelic variants of the same locus, c^{ch} and c^h. An individual with the genotype $c^{ch}c^{ch}$ has the chinchilla pattern, in which the entire body has a light, silvery gray color. The genotype c^hc^h causes the Himalayan pattern, in which the body is white but the tips of the ears, nose, tail, and legs are colored, like the color pattern of a Siamese cat. On the basis of the results of genetic crosses, these alleles can be arranged in the following series:

$$C > c^{ch} > c^h > c$$

Each allele is dominant to those following it and recessive to those preceding it. For example, a $c^{ch}c^{ch}$, $c^{ch}c^h$, or $c^{ch}c$ rabbit has the chinchilla pattern, whereas a c^hc^h or c^hc rabbit has the Himalayan pattern. (We revisit the Himalayan coat pattern later in the chapter when we discuss the influence of environment on gene expression.)

In other series of multiple alleles, certain alleles may be codominant and others incompletely dominant. In such cases, the heterozygotes commonly have phenotypes intermediate between those of their parents.

A single gene may affect multiple aspects of the phenotype

In our examples, the relationship between a gene and its phenotype has been direct, precise, and exact, and the loci have controlled the appearance of single traits. However, the relationship of gene to trait may not have such a simple genetic basis. Most genes have several effects on different characters. The ability of a single gene to have multiple effects is known as **pleiotropy.** Most cases of pleiotropy can be traced to a single fundamental cause. For example, a defective enzyme may affect the functioning of many types of cells. Pleiotropy is evident in many genetic diseases in which a single pair of alleles causes multiple symptoms. For example, people who are homozygous for the recessive allele that causes cystic fibrosis produce abnormally thick mucus in many parts of the body, including the respiratory, digestive, and reproductive systems (see Chapter 15).

Alleles of different loci may interact to produce a phenotype

Several pairs of alleles may interact to affect a single phenotype, or one pair may inhibit or reverse the effect of another pair. One example of gene interaction is illustrated by the inheritance of combs in chickens, where two genes may interact to produce a novel phenotype (Fig. 10-20). The allele for a rose comb, *R,* is dominant to that for a single comb, *r.* A second, unlinked pair of alleles governs the inheritance of a pea comb, *P,* versus a single comb, *p.* A single-comb chicken is homozygous for the recessive allele at both loci *(pprr).* A rose comb chicken is either *ppRR* or *ppRr,* and a pea comb chicken is either *PPrr* or *Pprr.* When an *R* and *P* occur in the same individual, the phenotype is neither a pea nor a rose comb but a completely different type, a walnut comb. The walnut comb phenotype is produced whenever a chicken has one or two *R* alleles, plus one or two *P* alleles (that is, *PPRR, PpRR, PPRr,* or *PpRr*). What would you hypothesize about the types of combs among the offspring of two heterozygous walnut comb chickens, *PpRr?* How does this form of gene interaction affect the ratio of phenotypes in the F_2 generation? Is it the typical Mendelian 9:3:3:1 ratio?[3]

[3] The offspring of two heterozygous walnut comb chickens will have four genotypes in what appears to be a Mendelian 9:3:3:1 ratio: 9 walnut comb, 3 pea comb, 3 rose comb, and 1 single comb. This example is not a typical Mendelian 9:3:3:1 ratio because it involves a single character (comb shape) coded by alleles at two different loci. In Mendelian inheritance, the 9:3:3:1 ratio involves *two* characters (such as seed color and seed shape) coded by alleles at two loci.

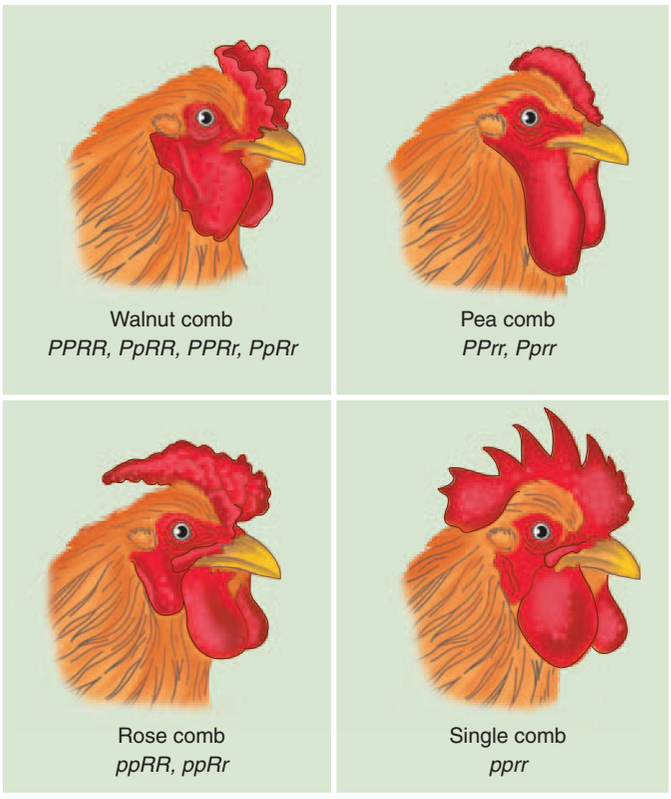

FIGURE **10-20** **Gene interaction in chickens.**

Two gene pairs govern four chicken comb phenotypes. Chickens with walnut combs have the genotype *P_R_*. Chickens with pea combs have the genotype *P_rr,* and those with rose combs have the genotype *ppR_*. Chickens that are recessive for both genes, *pprr,* have a single comb. (The blanks can be either dominant or recessive alleles.)

Epistasis is a common type of gene interaction in which the presence of certain alleles of one locus can prevent or mask the expression of alleles of a different locus and express its own phenotype instead. (The term epistasis means "standing on.") Unlike the chicken example, no novel phenotypes are produced in epistasis.

Coat color in Labrador retrievers is an example of epistasis that involves a gene for pigment and a gene for depositing color in the coat (Fig. 10-21). The two alleles for the pigment gene are *B* for black coat and its recessive counterpart *b* for brown coat. The gene for depositing color in the coat has two alleles, *E* for the expression of black and brown coats and *e,* which is epistatic and blocks the expression of the *B/b* gene. The epistatic allele is recessive and therefore is only expressed as a yellow coat in the homozygous condition (*ee*), regardless of the combination of *B* and *b* alleles in the genotype.

Polygenes act additively to produce a phenotype

Many human characters—such as height, body form, and skin pigmentation—are not inherited through alleles at a single locus. The same holds true for many commercially important characters in domestic plants and animals, such as milk and egg production. Alleles at several, perhaps many, loci affect each character. The term **polygenic inheritance** is applied when multiple independent pairs of genes have similar and additive effects on the same character.

Polygenes—as many as 60 loci—account for the inheritance of skin pigmentation in humans. To keep things simple in this example, we illustrate the principle of polygenic inheritance in human skin pigmentation with pairs of alleles at three unlinked loci (Fig. 10-22). These can be designated *A* and *a,* B and *b,* and *C* and *c.* The capital letters represent incompletely dominant alleles producing dark skin. The more capital letters, the darker the skin, because the alleles affect skin pigmentation in an additive fashion. A person with the darkest skin possible would have the genotype *AABBCC,* and a person with the lightest skin possible would have the genotype *aabbcc.* The F_1 offspring of an *aabbcc* person and an *AABBCC* person are all *AaBbCc* and have an intermediate skin color. The F_2 offspring of two such triple heterozygotes (*AaBbCc* × *AaBbCc*) would have skin pigmentation ranging from very dark to very light.

Polygenic inheritance is characterized by an F_1 generation that is intermediate between the two completely homozygous parents and by an F_2 generation that shows wide variation between the two parental types. When the number of individuals in a population is plotted against the amount of skin pigmentation and the points are connected, the result is a bell-shaped curve, a **normal distribution curve.** Most of the F_2 generation individuals have one of the intermediate phenotypes; only a few show the extreme phenotypes of the original P generation (that is, the grandparents). On average, only 1 of 64 is as dark as the very dark grandparent, and only 1 of 64 is as light as the very light grandparent. The alleles *A, B,* and *C* each produce about the same amount of darkening of the skin; hence the genotypes *AaBbCc, AABbcc, AAbbCc, AaBBcc, aaBBCc, AabbCC,* and *aaBbCC* all produce similar intermediate phenotypes.

Genes interact with the environment to shape phenotype

Imagine taking two cuttings from a coleus plant. You place one cutting in a growth chamber where it receives a lot of light and the other in a growth chamber programmed to deliver dim light. Although the cuttings are genetically identical (they came from the same plant), the appearance of the two plants would be dramatically different in a very short period. The plant with adequate light would thrive and grow vigorously, whereas the plant with inadequate light would be spindly and weak. During an organism's development, both genotype and environmental factors affect the expression of phenotype, and genetically identical individuals may develop differently in different environments.

Consider another example of the effect of environment on gene expression, this one involving the Himalayan rabbits discussed earlier. Recall that the phenotype of these rabbits is white fur except for dark patches on the ears, nose, and paws. The local surface temperature of a rabbit's ears, nose, and paws is colder in the rabbit's natural environment, and this temperature difference causes the production of dark fur. If you raise rabbits

Black	Yellow	Chocolate

FIGURE **10-21** **Epistasis in Labrador retrievers.**

Two gene pairs interact to govern coat color in Labrador retrievers. Black Labs have the genotype *B_E_;* yellow Labs have the genotype *B_ee* or *bbee;* and chocolate Labs have the genotype *bbE_*. The blanks represent either dominant or recessive alleles.

with the Himalayan genotype at a warm temperature (30°C), the rabbits are completely white, with no dark patches on the ears, nose, or paws. If you raise Himalayan rabbits at a cooler temperature (25°C), however, they develop the characteristic dark patches of fur.

Now let's examine a human example—height—in the context of genes and the environment. The inheritance of height in humans is polygenic and involves alleles representing 10 or more loci. Because many genes are involved and because height

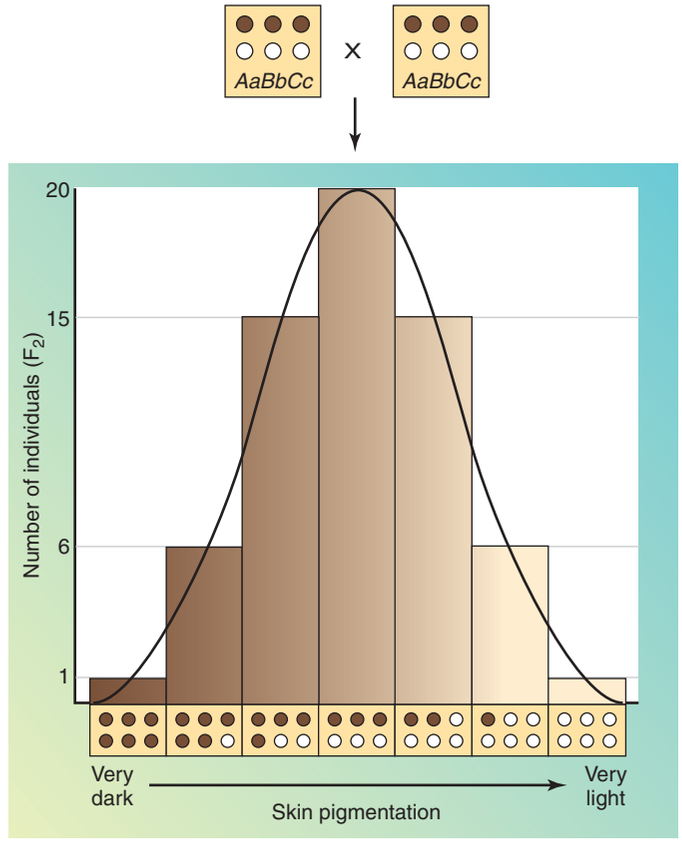

FIGURE **10-22** **Polygenic inheritance in human skin pigmentation.**

This simplified example assumes that skin pigmentation in humans is governed by alleles of three unlinked loci. The alleles producing dark skin (*A, B,* and *C*) are represented by capital letters, but they are not dominant. Instead their effects are additive. The number of dark dots, each signifying an allele producing dark skin, is counted to determine the phenotype. A wide range of phenotypes is possible when individuals of intermediate phenotype mate and have offspring (*AaBbCc* × *AaBbCc*). The expected distribution of phenotypes is consistent with the superimposed normal distribution curve.

is modified by a variety of environmental conditions, such as diet and general health, the height of most adults ranges from 4 ft 2 in (1.25 m) to 7 ft 2 in (2.15 m). The genes that affect height set limits for the phenotype—no human is 12 ft tall, for example—but the environment shapes the phenotype within its genetic limits. The range of phenotypic possibilities that can develop from a single genotype under different environmental conditions is known as the **norm of reaction.** In certain genotypes, such as the human ABO blood group, the norm of reaction is quite limited. In other genotypes, such as those involved in human height, the norm of reaction is quite broad.

Although the phenotypes of many characters are influenced by interactions between genes and the environment, it is impossible to determine the exact contributions of genes and the environment to a given phenotype. This subject, known as the *nature–nurture question,* is particularly controversial, because it relates to human characters ranging from intelligence to the tendency to abuse alcohol. For example, intelligence has a genetic component, but environment is also an important influence. To test for the relative effects of genes and environment on intelligence, we would have to separate and raise genetically identical children in different environments. Because it is ethically unacceptable to manipulate humans in this way, such tests cannot be performed. All we can say with certainty is that an individual's genes provide the potential for developing a particular phenotype but that environmental influences also shape the phenotype.

Review

- What is the difference between incomplete dominance and codominance?
- What is the difference between multiple alleles and polygenes?
- What is the difference between pleiotropy and epistasis?
- What is a norm of reaction?

BiologyNow™ Assess your understanding of **extensions of Mendelian genetics** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Define the terms *phenotype, genotype, locus, allele, dominant allele, recessive allele, homozygous,* and *heterozygous.*

- **Genes** are in chromosomes; the site a gene occupies in the chromosome is its **locus.** Different forms of a particular gene are **alleles;** they occupy corresponding loci on homologous chromosomes. Therefore, genes exist as pairs of alleles in diploid individuals.
- An individual that carries two identical alleles is said to be **homozygous** for that locus. If the two alleles are different, that individual is said to be **heterozygous** for that locus.
- One allele, the **dominant allele,** may mask the expression of the other allele, the **recessive allele,** in a heterozygous individual. For this reason two individuals with the same appearance, or **phenotype,** may differ from each other in genetic constitution, or **genotype.**

2 Describe Mendel's principles of segregation and independent assortment.

- According to Mendel's **principle of segregation,** during meiosis the alleles for each locus separate, or segregate, from each other. When haploid gametes are formed, each contains only one allele for each locus.
- According to Mendel's **principle of independent assortment,** alleles of different loci are distributed randomly into the gametes. This can result in **recombination,** the production of new gene combinations that were not present in the **parental (P) generation.**

3 Solve genetics problems involving monohybrid, dihybrid, and test crosses.

- A cross between homozygous parents (P generation) that differ from each other with respect to their alleles at one locus is called a **monohybrid cross;** if they differ at two loci, it is called a **dihybrid cross.**
- The first generation of offspring is heterozygous and is called the first filial, or **F_1, generation;** the generation produced by a cross of two F_1 individuals is the second filial, or **F_2, generation.**
- A **test cross** is between an individual of unknown genotype and a homozygous recessive individual.

4 Apply the product rule and sum rule appropriately when predicting the outcomes of genetic crosses.

- Genetic ratios can be expressed in terms of probabilities. Any probability is expressed as a fraction or decimal fraction, calculated as the number of favorable events divided by the total number of events. This can range from 0 (an impossible event) to 1 (a certain event).
- According to the **product rule,** the probability of two independent events occurring together can be calculated by multiplying the probabilities of each event occurring separately.
- According to the **sum rule,** the probability of an outcome that can be obtained in more than one way can be calculated by adding the separate probabilities.

5 Explain Mendel's principles of segregation and independent assortment, given what scientists know about genes and chromosomes.

- Segregation of alleles is a direct result of homologous chromosomes separating during meiosis.
- Independent assortment occurs because there are two ways in which two pairs of homologous chromosomes can be arranged at metaphase I of meiosis. The orientation of homologous chromosomes on the metaphase plate determines the way chromosomes are distributed into haploid cells.

6 Define *linkage,* and relate it to specific events in meiosis.

- Each chromosome behaves genetically as if it consisted of genes arranged in a linear order. **Linkage** is the tendency for a group of genes on the same chromosome to be inherited together. Groups of genes on the same chromosome are **linked genes.** Indepen-

SUMMARY WITH KEY TERMS *(continued)*

dent assortment does not apply if two loci are linked close together on the same pair of homologous chromosomes.

- Recombination of linked genes can result from **crossing-over** (breaking and rejoining of homologous chromatids) in meiotic prophase I.
- By measuring the frequency of recombination between linked genes, it is possible to construct a linkage map of a chromosome.

7 Show how data from a test cross involving alleles of two loci can be used to distinguish between independent assortment and linkage.

- To distinguish between independent assortment and linked genes, perform a **two-point test cross** between an individual that is heterozygous for the linked genes and an individual that is homozygous recessive for both characters.
- Linkage is recognized when an excess of parental type offspring and a deficiency of recombinant type offspring are produced in a two-point test cross.

8 Discuss the genetic determination of sex and the inheritance of X-linked genes in mammals.

- The sex of humans and many other animals is determined by the **X** and **Y chromosomes** or their equivalents. Normal female mammals have two X chromosomes; normal males have one X and one Y. The fertilization of an X-bearing egg by an X-bearing sperm results in a female (XX) zygote. The fertilization of an X-bearing egg by a Y-bearing sperm results in a male (XY) zygote.
- The Y chromosome determines male sex in mammals. The X chromosome contains many important genes unrelated to sex determination that are required by both males and females. A male receives all his **X-linked genes** from his mother. A female receives X-linked genes from both parents.
- A female mammal shows **dosage compensation** of X-linked genes. Only one of the two X chromosomes is expressed in each cell; the other is inactive and is seen as a dark-staining **Barr body** at the edge of the interphase nucleus.

9 Explain some of the ways genes may interact to affect the phenotype; discuss how a single gene can affect many features of the organism simultaneously.

- The relationship between genotype and phenotype may be quite complex. **Pleiotropy** is the ability of one gene to have several effects on different characters. Most cases of pleiotropy can be traced to a single cause, such as a defective enzyme. Alternatively, alleles of many loci may interact to affect the phenotypic expression of a single character.

10 Solve genetics problems involving incomplete dominance, codominance, multiple alleles, epistasis, and polygenes.

- Dominance does not always apply, and some alleles demonstrate **incomplete dominance,** in which the heterozygote is intermediate in phenotype, or **codominance,** in which the heterozygote simultaneously expresses the phenotypes of both homozygotes.
- **Multiple alleles,** three or more alleles that can potentially occupy a particular locus, may exist in a population. A diploid individual has any two of the alleles; a haploid individual or gamete has only one.
- In **epistasis,** an allele of one locus can mask the expression of alleles of a different locus.
- In **polygenic inheritance,** multiple independent pairs of genes may have similar and additive effects on the phenotype.

11 Describe *norm of reaction,* and give an example.

- The range of phenotypic possibilities that can develop from a single genotype under different environmental conditions is known as the **norm of reaction.**
- Many genes are involved in the inheritance of height in humans. Also, height is modified by a variety of environmental conditions, such as diet and general health. The genes that affect height set the norm of reaction—that is, the limits—for the phenotype, and the environment molds the phenotype within its norm of reaction.

POST-TEST

1. One reason Mendel discovered the basic principles of inheritance is that he (a) understood the behavior of chromosomes in mitosis and meiosis (b) studied a wide variety of experimental organisms (c) began by establishing true-breeding lines (d) studied various types of linkage (e) studied hybrids between parents that differed in many, often not clearly defined, ways
2. One of the autosomal loci controlling eye color in fruit flies has two alleles, one for brown eyes and the other for red eyes. Fruit flies from a true-breeding line with brown eyes were crossed with flies from a true-breeding line with red eyes. The F_1 flies had red eyes. What conclusion can be drawn from this experiment? (a) these alleles underwent independent assortment (b) these alleles underwent segregation (c) these genes are X-linked (d) the allele for red eyes is dominant to the allele for brown eyes (e) all of the above are true
3. The F_1 flies described in question 2 were mated with brown-eyed flies from a true-breeding line. What phenotypes would you expect the offspring to have? (a) all red eyes (b) all brown eyes (c) half red eyes and half brown eyes (d) red-eyed females and brown-eyed males (e) brown-eyed females and red-eyed males
4. The type of cross described in question 3 is a(an) (a) F_2 cross (b) dihybrid cross (c) test cross (d) two-point test cross (e) none of the preceding

Use the following information to answer questions 5 through 8:

In peas, the allele for round seeds *(R)* is dominant to that for wrinkled seeds *(r);* the allele for yellow seeds *(Y)* is dominant to that for green seeds *(y)*. These loci are unlinked. Plants from a true-breeding line with round, green seeds are crossed with plants from a true-breeding line with wrinkled, yellow seeds. These parents constitute the P generation.

5. The genotypes of the P generation are (a) *RRrr* and *Yyyy* (b) *RrYy* (c) *RRYY* and *rryy* (d) *RRyy* and *rrYY* (e) *RR* and *YY*
6. What are the expected genotypes of the F_1 hybrids produced by the described cross? (a) *RRrr* and *YYyy* (b) all *RrYy* (c) *RRYY* and *rryy* (d) *RRyy* and *rrYY* (e) *RR* and *YY*
7. What kinds of gametes can the F_1 individuals produce? (a) *RR* and *YY* (b) *Rr* and *Yy* (c) *RR, rr, YY,* and *yy* (d) *R, r, Y,* and *y* (e) *RY, Ry, rY,* and *ry*
8. What is the expected proportion of F_2 wrinkled, yellow seeds? (a) $^9/_{16}$ (b) $^1/_{16}$ (c) $^3/_{16}$ (d) $^1/_4$ (e) zero

9. Individuals of genotype *AaBb* were crossed with *aabb* individuals. Approximately equal numbers of the following classes of offspring were produced: *AaBb, Aabb, aaBb,* and *aabb.* These results illustrate Mendel's principle(s) of (a) linkage (b) independent assortment (c) segregation (d) a and c (e) b and c
10. Assume that the ratio of females to males is 1:1. A couple already has two daughters and no sons. If they plan to have a total of six children, what is the probability they will have four more girls? (a) ¼ (b) ⅛ (c) 1/16 (d) 1/32 (e) 1/64
11. Red-green colorblindness is an X-linked recessive disorder in humans. Your friend is the daughter of a colorblind father. Her mother had normal color vision, but her maternal grandfather was colorblind. What is the probability your friend is colorblind? (a) 1 (b) ½ (c) ¼ (d) ¾ (e) zero
12. When homozygous, a particular allele of a locus in rats causes abnormalities of the cartilage throughout the body, an enlarged heart, slow development, and death. This is an example of (a) pleiotropy (b) polygenic inheritance (c) epistasis (d) codominance (e) dosage compensation
13. In peas, yellow seed color is dominant to green. Determine the phenotypes (and their proportions) of the offspring of the following crosses: (a) homozygous yellow X green (b) heterozygous yellow X green (c) heterozygous yellow X homozygous yellow (d) heterozygous yellow X heterozygous yellow
14. If two animals heterozygous for a single pair of alleles are mated and have 200 offspring, about how many would be expected to have the phenotype of the dominant allele (that is, to look like the parents)?
15. When two long-winged flies were mated, the offspring included 77 with long wings and 24 with short wings. Is the short-winged condition dominant or recessive? What are the genotypes of the parents?
16. Outline a breeding procedure whereby a true-breeding strain of red cattle could be established from a roan bull and a white cow.
17. What is the probability of rolling a seven with a pair of dice? Which is a more likely outcome, rolling a six with a pair of dice or rolling an eight?
18. In rabbits, spotted coat *(S)* is dominant to solid color *(s),* and black *(B)* is dominant to brown *(b).* These loci are not linked. A brown, spotted rabbit from a pure line is mated to a solid black one, also from a pure line. What are the genotypes of the parents? What would be the genotype and phenotype of an F_1 rabbit? What would be the expected genotypes and phenotypes of the F_2 generation?
19. The long hair of Persian cats is recessive to the short hair of Siamese cats, but the black coat color of Persians is dominant to the brown-and-tan coat color of Siamese. Make up appropriate symbols for the alleles of these two unlinked loci. If a pure black, long-haired Persian is mated to a pure brown-and-tan, short-haired Siamese, what will be the appearance of the F_1 offspring? If two of these F_1 cats are mated, what is the chance that a long-haired, brown-and-tan cat will be produced in the F_2 generation? (Use the shortcut probability method to obtain your answer; then check it with a Punnett square.)
20. Mr. and Mrs. Smith are concerned because their own blood types are A and B respectively, but their new son, Richard, is blood type O. Could Richard be the child of these parents?
21. The expression of an allele called *frizzle* in fowl causes abnormalities of the feathers. As a consequence, the animal's body temperature is lowered, adversely affecting the functions of many internal organs. When one gene affects many traits of the organism in this way, we say that gene is _____.
22. A walnut comb rooster is mated to three hens. Hen A, which is walnut comb, has offspring in the ratio of 3 walnut to 1 rose. Hen B, which has a pea comb, has offspring in the ratio of 3 walnut to 3 pea to 1 rose to 1 single. Hen C, which has a walnut comb, has only walnut comb offspring. What are the genotypes of the rooster and the three hens?
23. What kinds of matings result in the following phenotypic ratios? (a) 3:1 (b) 1:1 (c) 9:3:3:1 (d) 1:1:1:1
24. The weight of the fruit in a certain variety of squash is determined by allelic pairs for two loci: *AABB* produces fruits that average 2 kg each, and *aabb* produces fruits that weigh 1 kg each. Each allele represented by a capital letter adds 0.25 kg. When a plant that produces 2-kg fruits is crossed with a plant that produces 1-kg fruits, all the offspring produce fruits that weigh 1.5 kg each. If two of these F_1 plants were crossed, how much would the fruits produced by the F_2 plants weigh?
25. The X-linked *barred* locus in chickens controls the pattern of the feathers, with the alleles *B* for barred pattern and *b* for no bars. If a barred female (X^BY) is mated to a nonbarred male (X^bX^b), what will be the appearance of the male and female progeny? (Recall that in birds males are XX and females are XY.) Do you see any commercial usefulness for this result? (*Hint:* It is notoriously difficult to determine the sex of newly hatched chicks.)
26. Individuals of genotype *AaBb* were mated to individuals of genotype *aabb.* One thousand offspring were counted, with the following results: 474 *Aabb,* 480 *aaBb,* 20 *AaBb,* and 26 *aabb.* What type of cross is this known as? Are these loci linked? What are the two parental classes and the two recombinant classes of offspring? What is the percentage of recombination between these two loci? How many map units apart are they?
27. Genes *A* and *B* are 6 map units apart, and *A* and *C* are 4 map units apart. Which gene is in the middle if *B* and *C* are 10 map units apart? Which is in the middle if *B* and *C* are 2 map units apart?

CRITICAL THINKING

1. Would the science of genetics in the 20th century have developed any differently if Gregor Mendel had never lived?
2. Sketch a series of diagrams showing each of the following, making sure to end each series with haploid gametes:
   a. How a pair of alleles for a single locus segregates in meiosis
   b. How the alleles of two unlinked loci assort independently in meiosis
   c. How the alleles of two linked loci undergo genetic recombination
3. Can you always ascertain an organism's genotype for a particular locus if you know its phenotype? Conversely, if you are given an organism's genotype for a locus, can you always reliably predict its phenotype? Explain.

14. 150
15. The short-winged condition is recessive. Both parents are heterozygous.
16. Repeated matings of the roan bull and the white cow will yield an approximate 1:1 ratio of roan-to-white offspring. Repeated matings among roan offspring will yield red, roan, and white offspring in an approximate 1:2:1 ratio. The mating of two red individuals will yield only red offspring.
17. There are 36 possible outcomes when a pair of dice is rolled. There are six ways of obtaining a seven: 1,6; 6,1; 2,5; 5,2; 3,4; and 4,3. There are five ways of rolling a six: 1,5; 5,1; 2,4; 4,2; and 3,3. There are also five ways of rolling an eight: 2,6; 6,2; 3,5; 5,3; and 4,4.
18. The genotype of the brown spotted rabbit is *bbSS.* The genotype of the black, solid rabbit is *BBss.* An F_1 rabbit would be black, spotted *(BbSs).* The F_2 is expected to be $^9/_{16}$ black, spotted *(B_S_),* $^3/_{16}$ black, solid *(B_ss),* $^3/_{16}$ brown, spotted *(bbS_),* and $^1/_{16}$ brown, solid *(bbss).*
19. The F_1 offspring are expected to be black, short-haired. There is a $^1/_{16}$ chance of brown and tan, long-haired offspring in the F_2 generation.
20. Yes
21. Pleiotropic
22. The rooster is *PpRr;* hen A is *PpRR;* hen B is *Pprr;* and hen C is *PPRR.*
23. a. Both parents are heterozygous for a single locus.
    b. One parent is heterozygous and the other parent homozygous recessive (for a single locus).
    c. Both parents are heterozygous (for two loci).
    d. One parent is heterozygous and the other is homozygous recessive (for two loci).
24. The expected types of F_2 plants are $^1/_{16}$ of the plants produce 2-kg fruits; $^1/_4$ of the plants produce 1.75-kg fruits, $^3/_8$ of the plants produce 1.5-kg fruits, $^1/_4$ of the plants produce 1.25-kg fruits, and $^1/_{16}$ of the plants produce 1-kg fruits.
25. All male offspring of this cross are barred, and all females are nonbarred, thus allowing the sex of the chicks to be determined by their phenotypes.
26. This is a two-point test cross involving linked loci. The parental class of offspring are *Aabb* and *aaBb;* the recombinant classes are *AaBb* and *aabb.* There is 4.6% recombination, which corresponds to 4.6 map units between the loci.
27. If genes B and C are 10 map units apart, gene A is in the middle. If genes B and C are 2 map units apart, gene C is in the middle.

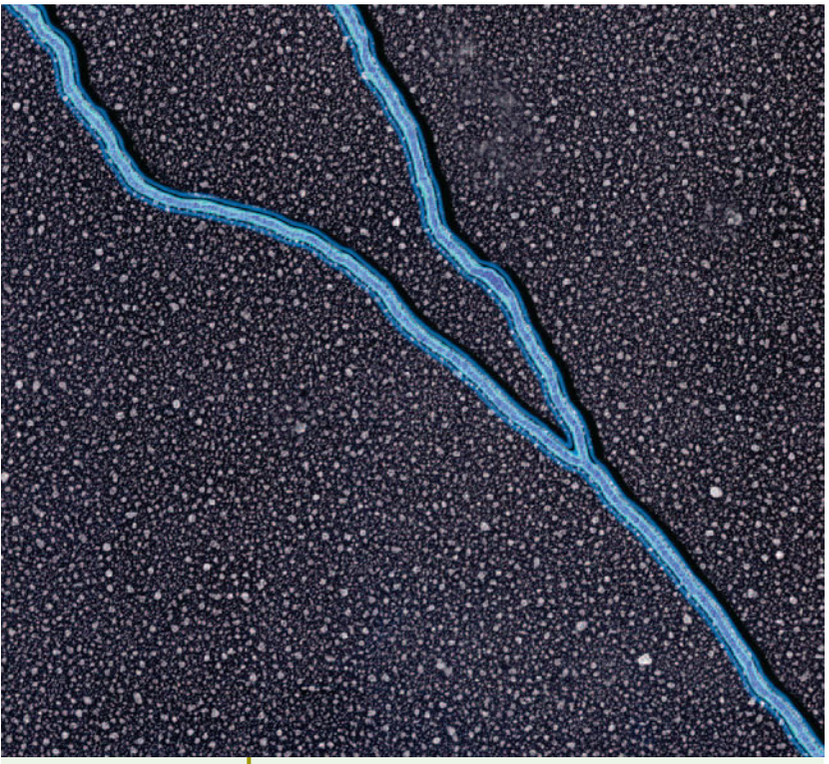
DNA: The Carrier of Genetic Information



Dr. Gopal Murti/Science Photo Library/Photo Researchers, Inc.

Electron micrograph of DNA replication. During replication, two DNA molecules are synthesized from the original parent molecule. Replication is occurring at the Y-shaped structure, which is called a *replication fork*.

CHAPTER OUTLINE

- **Evidence of DNA as the Hereditary Material**
- **The Structure of DNA**
- **DNA Replication**

After the rediscovery of Mendel's principles in 1900, geneticists conducted a variety of elegant experiments to learn how genes are arranged in chromosomes and how they are transmitted from generation to generation. However, the basic questions remained unanswered through most of the first half of the 20th century: What are genes made of? How do genes work? The studies of inheritance patterns described in Chapter 10 did not answer these questions. However, they provided a foundation of knowledge that enabled scientists to make predictions about the molecular (chemical) nature of genes and how genes function.

Scientists generally agreed that the function of genes must be to provide information; therefore, the molecules of which genes are made would have to store information in a form that the cell could retrieve and use. But genes had other properties that also had to be accounted for. For example, countless experiments on a variety of organisms had demonstrated that genes are usually stable, being passed unchanged from generation to generation. However, occasionally a gene converted to a different form; such genetic changes, called *mutations,* were then transmitted unchanged to future generations.

As the science of genetics was developing, the science of biochemistry was flourishing as well, and scientists were making a growing effort to correlate the known properties of genes with the nature of various biological molecules. What kind of molecule could store information? How could that information be retrieved and used to direct cell functions? What kind of molecule could be relatively stable but have the capacity to change, resulting in a mutation, under certain conditions?

Some scientists thought they could never answer these questions. They thought the information a cell requires is so complex that no one type of molecule could function as the genetic material. As they learned more about the central role of proteins in virtually every aspect of cell structure and metabolism, other scientists considered proteins the prime candidates for the genetic material. However, protein did not turn out to be the molecule that governs inheritance. In this chapter we discuss

how researchers discovered that **deoxyribonucleic acid (DNA),** a nucleic acid once thought unremarkable, is the molecular basis of inheritance. We explore the unique features of DNA, including its replication (see photograph), that enable it to carry out this role. ■

EVIDENCE OF DNA AS THE HEREDITARY MATERIAL

Learning Objective

1 Summarize the evidence that accumulated during the 1940s and early 1950s demonstrating that DNA is the genetic material.

PROCESS OF SCIENCE

During the 1930s and early 1940s, most geneticists paid little attention to DNA, convinced that the genetic material must be protein. Given the accumulating evidence that genes control production of proteins (discussed in Chapter 12), it certainly seemed likely that genes themselves must also be proteins. Scientists knew proteins consisted of more than 20 different kinds of amino acids in many different combinations, which conferred unique properties on each type of protein. Given their complexity and diversity compared with other molecules, proteins seemed to be the "stuff" of which genes are made.

In contrast, scientists had established that DNA and other nucleic acids were made of only four nucleotides, and what was known about their arrangement made them relatively uninteresting to most researchers. For this reason, several early clues to the role of DNA were not widely noticed.

DNA is the transforming principle in bacteria

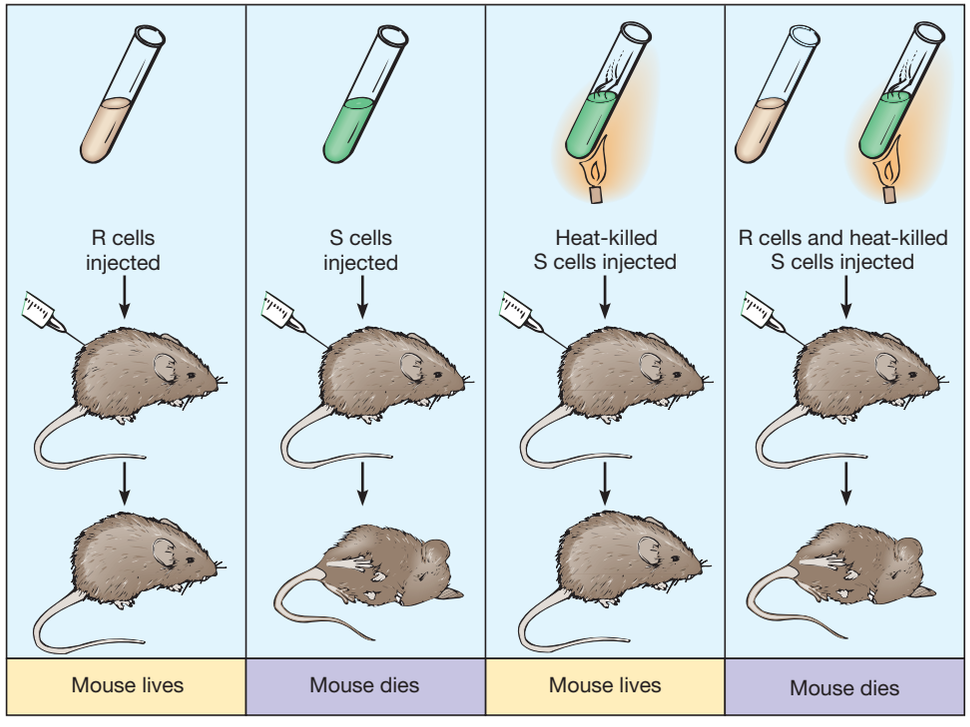
One of these clues had its origin in 1928, when Frederick Griffith, a British medical officer, made a curious observation concerning two strains of pneumococcus bacteria (Fig. 11-1). A smooth (S) strain, named for its formation of smooth colonies on a solid growth medium, was known to exhibit **virulence,** the ability to cause disease, and often death, in its host. When living cells of this strain were injected into mice, the animals contracted pneumonia and died. Not surprisingly, the injected animals survived if the cells were first killed with heat. A related rough (R) strain of bacteria, which forms colonies with a rough surface, was known to exhibit **avirulence,** or inability to produce pathogenic effects; mice injected with either living or heat-killed cells of this strain survived. However, when Griffith injected mice with a mixture of *heat-killed* virulent S cells and live avirulent R cells, a high proportion of the mice died. Griffith then isolated living S cells from the dead mice.

Because neither the heat-killed S strain nor the living R strain could be converted to the living virulent form when injected by itself in the control experiments, it seemed that something in the heat-killed cells converted the avirulent cells to the lethal form. This type of permanent genetic change in which the properties of one strain of dead cells are conferred on a different strain of living cells became known as **transformation.** Scientists hypothesized that some chemical substance (the "transforming principle") was transferred from the dead bacteria to the living cells and caused transformation.

In 1944, American biologist Oswald T. Avery and his colleagues Colin M. MacLeod and Maclyn McCarty chemically identified Griffith's transforming principle as DNA. They did this through a series of careful experiments in which they lysed (split open) S cells and separated the cell contents into several fractions: lipids, proteins, polysaccharides, and nucleic acids (DNA and RNA). They tested each fraction to see if it could transform living R cells into S cells. The experiments using lipids, polysaccharides, and proteins did not cause transformation. However,

FIGURE **11-1** **Griffith's transformation experiments.**

Although neither the rough (R) strain nor the heat-killed smooth (S) strain could kill a mouse, a combination of the two did. Autopsy of the dead mouse showed the presence of living S-strain pneumococci. These results indicated that some substance in the heat-killed S cells had transformed the living R cells into a virulent form. Avery and his colleagues later showed that purified DNA isolated from the S cells confers virulence on the R cells, establishing that DNA carries the necessary information for bacterial transformation.



when Avery treated living R cells with nucleic acids extracted from S cells, the R cells were transformed into S cells.

Although today scientists consider their results to be the first definitive demonstration that DNA is the genetic material, not all scientists of the time were convinced. Many thought the findings might apply only to bacteria and might not have any relevance for the genetics of eukaryotes. During the next few years, new evidence accumulated that the haploid nuclei of pollen grains and gametes such as sperm contain only half the amount of DNA found in diploid somatic cells of the same species. (Somatic cells are body cells and never become gametes.) Because scientists generally accepted that genes are on chromosomes, these findings correlating DNA content with chromosome number provided strong circumstantial evidence for DNA's importance in eukaryotic inheritance.

DNA is the genetic material in certain viruses

In 1952, American geneticists Alfred Hershey and Martha Chase performed a series of elegant experiments (Fig. 11-2) on the reproduction of viruses that infect bacteria, known as **bacteriophages** (see Chapter 23). When they planned their experiments, they knew bacteriophages reproduce inside a bacterial cell, eventually causing the cell to break open, releasing large numbers of new viruses. Because electron microscopic studies had shown that only part of an infecting bacteriophage actually enters the cell, they reasoned the genetic material should be included in that portion.

They labeled the viral protein of one sample of bacteriophages with ^{35}S, a radioactive isotope of sulfur, and the viral DNA of a second sample with ^{32}P, a radioactive isotope of phosphorus. (Recall from Chapter 3 that proteins contain sulfur as part of the amino acids cysteine and methionine and that nucleic acids contain phosphate groups.) The bacteriophages in each sample attached to bacteria, and the researchers then shook them off by agitating them in a blender. Then they centrifuged the cells.

In the sample in which they had labeled the proteins with ^{35}S, they subsequently found the label in the supernatant, indicating that the protein had not entered the cells. In the sample in which they had labeled the DNA with ^{32}P, they found the label associated with the bacterial cells (in the pellet): DNA had actually entered the cells. Hershey and Chase concluded that bacteriophages inject their DNA into bacterial cells, leaving most of their protein on the outside. This finding emphasized the significance of DNA in viral reproduction, and many scientists saw it as an important demonstration of DNA's role as the hereditary material.

Review

- How did the experiments of Avery and his colleagues point to DNA as the essential genetic material?
- Did the Hershey-Chase experiment establish that DNA is the genetic material in all organisms? Explain your answer.

BiologyNow™ Assess your understanding of the **evidence of DNA as the hereditary material** by taking the pretest on your BiologyNow CD-ROM.

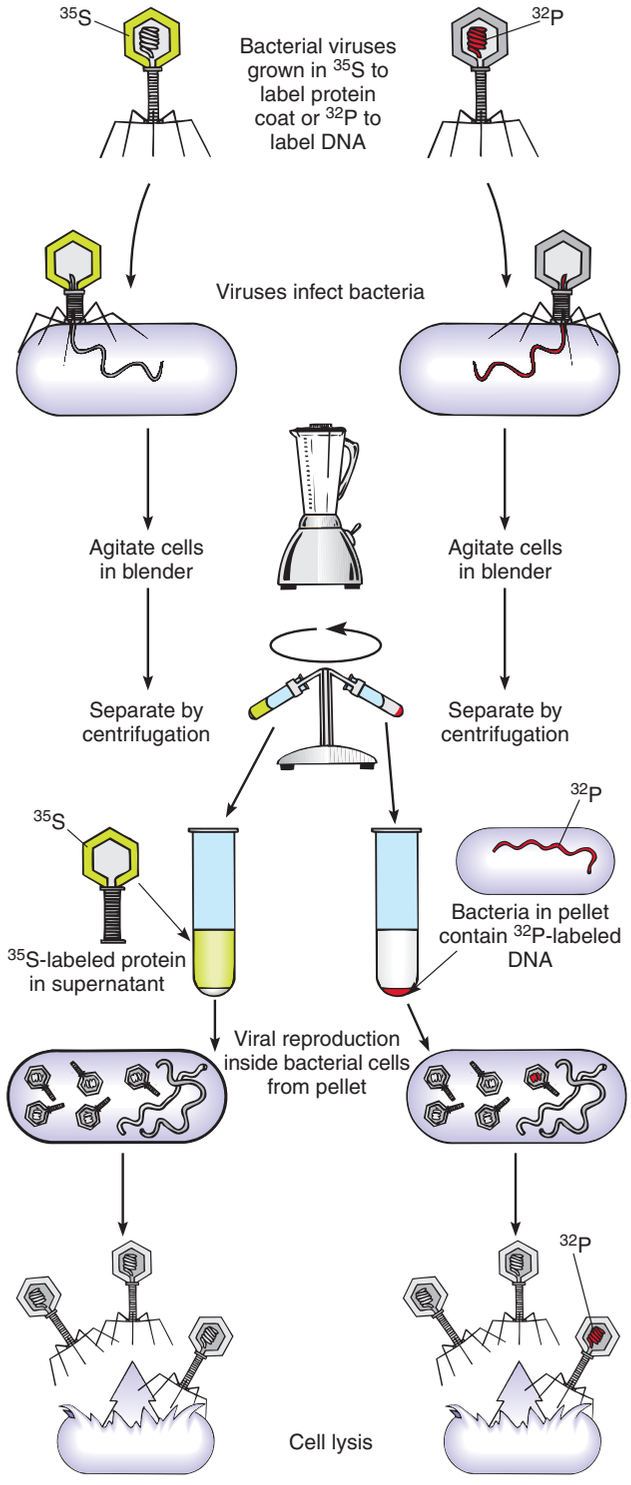


FIGURE **11-2** **The Hershey-Chase experiments.**

The researchers could separate bacteriophage protein coats labeled with the radioactive isotope ^{35}S *(left side)* from infected bacterial cells without affecting viral reproduction. However, they could not separate viral DNA labeled with the radioactive isotope ^{32}P *(right side),* from infected bacterial cells. This demonstrated that viral DNA enters the bacterial cells and is required for the synthesis of new viral particles.

THE STRUCTURE OF DNA

Learning Objectives

2 Sketch how nucleotide subunits link together to form a single DNA strand.

3 Illustrate how the two strands of DNA are oriented with respect to each other.

4 State the base-pairing rules for DNA, as determined by Chargaff and coworkers, and describe how complementary bases bind to each other.

Scientists did not generally accept DNA as the genetic material until 1953, when American scientist James Watson and British scientist Francis Crick, both working in England, proposed a model for its structure that had extraordinary explanatory power. The story of how the structure of DNA was figured out is one of the most remarkable chapters in the history of modern biology (Table 11-1). As you will see in the following discussion, scientists already knew a great deal about DNA's physical and chemical properties when Watson and Crick became interested in the problem; in fact, they did not conduct any experiments or gather any new data. Their all-important contribution was to integrate all the available information into a model that demonstrated how the molecule can both carry information for making proteins and serve as its own **template** (pattern or guide) for its duplication.

Nucleotides can be covalently linked in any order to form long polymers

As discussed in Chapter 3, each DNA building block is a **nucleotide** consisting of the pentose sugar **deoxyribose,** a phosphate, and one of four nitrogenous bases (Fig. 11-3). It is conventional to number the atoms in a molecule using a system devised by organic chemists. Accordingly, in nucleic acid chemistry the individual carbons in each sugar and each base are numbered. The carbons in a base are designated by numerals, but the carbons in a sugar are distinguished from those in the base by prime symbols, such as 2′. The nitrogenous base is attached to the 1′ carbon of the sugar, and the phosphate is attached to the 5′ carbon. The bases include two **purines, adenine (A)** and **guanine (G),** and two **pyrimidines, thymine (T)** and **cytosine (C).**

The nucleotides are linked by covalent bonds to form an alternating sugar–phosphate backbone. The 3′ carbon of one sugar is bonded to the 5′ phosphate of the adjacent sugar to form a 3′,5′ **phosphodiester linkage.** A polymer of indefinite length forms, with the nucleotides linked in any order. Scientists now know that

PROCESS OF SCIENCE

TABLE 11-1 A Timeline of Selected Historical DNA Discoveries

Date	Discovery
1928	**Federick Griffith** finds a substance in heat-killed bacteria that "transforms" living bacteria.
1944	**Oswald Avery, Colin MacLeod,** and **Maclyn McCarty** chemically identify Griffith's transforming principle as DNA.
1949	**Erwin Chargaff** reports relationships among DNA bases that provide a clue to the structure of DNA.
1952	**Alfred Hershey** and **Martha Chase** demonstrate that DNA, not protein, is involved in viral reproduction.
1952	**Rosalind Franklin** produces an x-ray diffraction image of DNA.
1953	**James Watson** and **Francis Crick** propose a model of the structure of DNA.
1958	**Matthew Meselson** and **Franklin Stahl** demonstrate that DNA replication is semiconservative.
1962	**James Watson, Francis Crick,** and **Maurice Wilkins** are awarded the Nobel Prize in Medicine for discoveries about the molecular structure of nucleic acids.
1969	**Alfred Hershey** is awarded the Nobel Prize in Medicine for discovering the replication mechanism and genetic structure of viruses.

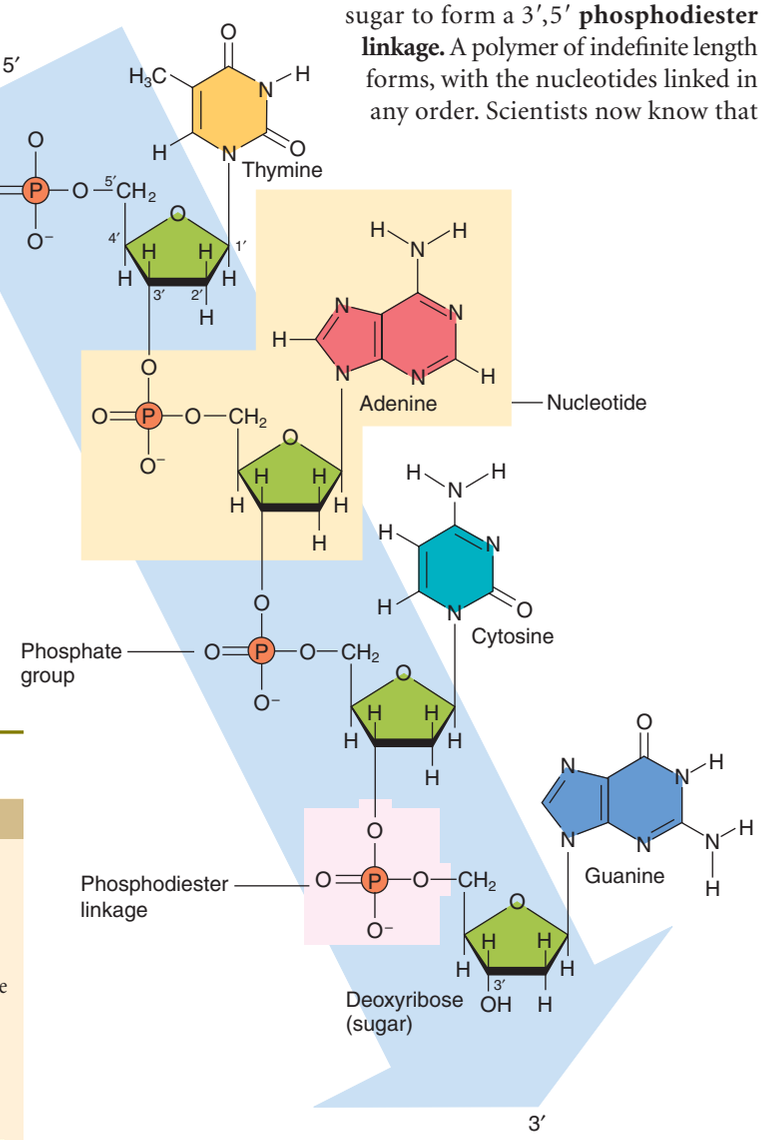

FIGURE 11-3 The nucleotide subunits of DNA.

A single strand of DNA consists of a backbone made of phosphate groups alternating with the sugar deoxyribose *(green).* Phosphodiester linkages *(pink)* join sugars of adjacent nucleotides. Linked to the 1′ carbon of each sugar is one of four nitrogenous bases: adenine, guanine, thymine, and cytosine. Note the polarity of the polynucleotide chain, with the 5′ end at the top of the figure and the 3′ end at the bottom.

most DNA molecules found in cells are millions of bases long. Figure 11-3 also shows that a single polynucleotide chain is directional. No matter how long the chain may be, one end, the **5′ end,** has a 5′ carbon attached to a phosphate and the other, the **3′ end,** has a 3′ carbon attached to a hydroxyl group.

In 1949, Erwin Chargaff and his colleagues at Columbia University had determined the base composition of DNA from several organisms and tissues. They found a simple relationship among the bases that turned out to be an important clue to the structure of DNA. Regardless of the source of the DNA, in Chargaff's words the "ratios of purines to pyrimidines and also of adenine to thymine and of guanine to cytosine were not far from 1" (Table 11-2). In other words, in double-stranded DNA molecules, the number of purines equals the number of pyrimidines, the number of adenines equals the number of thymines (A equals T), and the number of guanines equals the number of cytosines (G equals C). These equalities became known as **Chargaff's rules.**

TABLE **11-2** **Base Compositions in DNA from Selected Organisms**

	Percentage of DNA Bases				Ratios	
Source of DNA	**A**	**T**	**G**	**C**	**A/T**	**G/C**
E. coli	26.1	23.9	24.9	25.1	1.09	0.99
Yeast	31.3	32.9	18.7	17.1	0.95	1.09

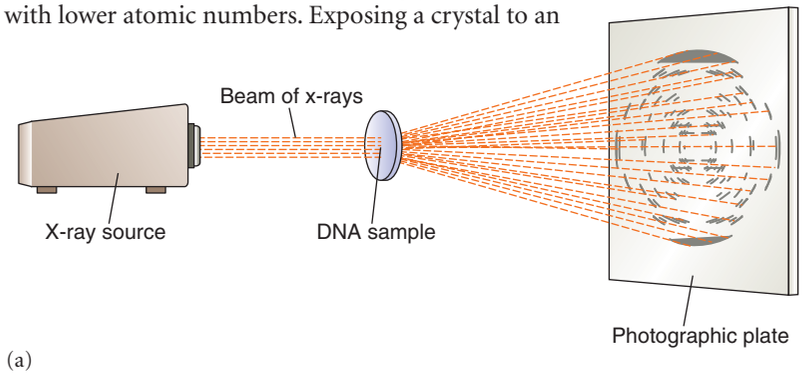
Herring sperm	27.8	27.5	22.2	22.6	1.01	0.98
Human liver	30.3	30.3	19.5	19.9	1.00	0.98
Corn (*zea mays*)	25.6	25.3	24.5	24.6	1.01	1.00

DNA is made of two polynucleotide chains intertwined to form a double helix

PROCESS OF SCIENCE

Key information about the structure of DNA came from x-ray diffraction studies on crystals of purified DNA, carried out by British scientist Rosalind Franklin from 1951 to 1953 in the laboratory of Maurice Wilkins in England. **X-ray diffraction,** a powerful method for elucidating the 3-D structure of a molecule, can determine the distances between the atoms of molecules arranged in a regular, repeating crystalline structure (Fig. 11-4a). X-rays have such short wavelengths that they can be scattered by the electrons surrounding the atoms in a molecule. Atoms with dense electron clouds (such as phosphorus and oxygen) tend to deflect electrons more strongly than atoms with lower atomic numbers. Exposing a crystal to an intense beam of x-rays causes the regular arrangement of its atoms to diffract, or scatter, the x-rays in specific ways. The pattern of diffracted x-rays appears on photographic film as dark spots. Mathematical analysis of the pattern and distances between the spots yields the precise distances between atoms and their orientation within the molecules.



(a)

FIGURE **11-4** **X-ray diffraction of DNA.**

(a) The basic technique. Researchers direct a narrow beam of x-rays at a single crystal of DNA. Important clues about DNA structure are provided by detailed mathematical analysis of measurements of the spots, which are formed by x-rays hitting the photographic plate.

Franklin had already produced x-ray crystallographic films of DNA patterns when Watson and Crick began to pursue the problem of DNA structure. Her pictures clearly showed that DNA has a type of helical structure, and three major types of regular, repeating patterns in the molecule (with the dimensions 0.34 nm, 3.4 nm, and 2.0 nm) were evident (Fig. 11-4b). Franklin and Wilkins had inferred from these patterns that the nucleotide bases (which are flat molecules) are stacked like the rungs of a ladder. Using this information, Watson and Crick began to build scale models of the DNA components and then fit them together to correlate with the experimental data.

After several trials, they worked out a model that fit the existing data (Fig. 11-5). The nucleotide chains conformed to the dimensions of the x-ray data only if each DNA molecule consisted of *two* polynucleotide chains arranged in a coiled **double helix.** In their model, the sugar–phosphate backbones of the two chains form the out-

Image not available due to copyright restrictions

side of the helix. The bases belonging to the two chains associate as pairs along the central axis of the helix. The reasons for the repeating patterns of 0.34-nm and 3.4-nm measurements are readily apparent from the model: Each pair of bases is exactly 0.34 nm from the adjacent pairs above and below. Because exactly 10 base pairs are present in each full turn of the helix, each turn constitutes 3.4 nm of length. To fit the data, the two chains must run in opposite directions; therefore, each end of the double helix must have an exposed 5′ phosphate on one strand and an exposed 3′ hydroxyl group (—OH) on the other. Because the two strands run in opposite directions, they are said to be **antiparallel** to each other (Fig. 11-6a).

In double-stranded DNA, hydrogen bonds form between A and T and between G and C

Other features of the Watson and Crick model integrated critical information about the chemical composition of DNA with the x-ray diffraction data. The x-ray diffraction studies indicated that the double helix has a precise and constant width, as shown by the 2.0-nm measurements. This finding is actually consistent with Chargaff's rules. As Figure 11-3 shows, each pyrimidine (cytosine or thymine) contains only one ring of atoms, whereas each purine (guanine or adenine) contains two rings. Study of the models made it clear to Watson and Crick that if each rung of the ladder contained one purine and one pyrimidine, the width of the helix at each base pair would be exactly 2.0 nm. By contrast, the combination of two purines (each of which is 1.2 nm wide) would be wider than 2.0 nm and that of two pyrimidines would be narrower, so the diameter would not be constant. Further examination of the model showed that adenine can pair with thymine (and guanine with cytosine) in such a way that hydrogen bonds form between them; the opposite combinations, cytosine with adenine and guanine with thymine, do not lead to favorable hydrogen bonding.

The nature of the hydrogen bonding between adenine and thymine and between guanine and cytosine is shown in Figure 11-6b. Two hydrogen bonds form between adenine and thymine, and three between guanine and cytosine. This concept of specific base pairing neatly explains Chargaff's rules. The amount of cytosine must equal the amount of guanine, because every cytosine in one chain must have a paired guanine in the other chain. Similarly, every adenine in the first chain must have a thymine in the second chain. The sequences of bases in the two chains are **complementary** to each other—that is, the sequence of nucleotides in one chain dictates the complementary sequence of nucleotides in the other. For example, if one strand has this sequence,

3′—AGCTAC—5′

then the other strand has the complementary sequence:

5′—TCGATG—3′

The double-helix model strongly suggested that the sequence of bases in DNA provides for the storage of genetic information and that this sequence ultimately relates to the sequences of amino acids in proteins. Although restrictions limit how the bases pair with each other, the number of possible sequences of bases in a strand is virtually unlimited. Because a DNA molecule

DNA REPLICATION

Learning Objectives

5 Cite experimental evidence that enabled scientists to differentiate between semiconservative replication of DNA and alternative models (conservative and dispersive replication).

6 Summarize how DNA replicates, and identify some unique features of the process.

7 Explain the complexities of DNA replication that make it (a) bidirectional and (b) continuous in one strand and discontinuous in the other.

8 Define *telomere;* describe the possible connections between telomerase and cell aging and between telomerase and cancer.

Two immediately apparent and distinctive features of the Watson-Crick model made it seem plausible that DNA is the genetic material. We have already mentioned that the sequence of bases in DNA can carry coded information. The model also suggested a way in which the sequence of nucleotides in DNA could be precisely copied, a process known as **DNA replication.** The connection between DNA replication and the behavior of chromosomes in mitosis was obvious to Watson and Crick. A chromosome becomes duplicated so that it consists of two identical sister chromatids that later separate at anaphase; the genetic material must be precisely duplicated and distributed to the daughter cells. They noted, in a classic and now famous understatement at the end of their first brief paper, "It has not escaped our notice that the specific pairing we have postulated immediately suggests a possible copying mechanism for the genetic material."

The model suggested that, because the nucleotides pair with each other in complementary fashion, each strand of the DNA molecule could serve as a template for synthesizing the opposite strand. It would simply be necessary for the hydrogen bonds between the two strands to break (recall that hydrogen bonds are relatively weak) and the two chains to separate. Each strand of the double helix could then pair with new complementary nucleotides to replace its missing partner. The result would be two DNA double helices, each identical to the original one and consisting of one original strand from the parent molecule and one newly synthesized complementary strand. This type of information copying is known as **semiconservative replication** (Fig. 11-7a).

Meselson and Stahl verified the mechanism of semiconservative replication

PROCESS OF SCIENCE

Although the semiconservative replication mechanism suggested by Watson and Crick was (and is) a simple and compelling model, experimental proof was needed to establish that DNA in fact duplicates in that manner. Researchers first needed to rule out other possibilities. With *conservative replication,* both parent (or old) strands would remain together, and the two newly synthesized strands would form a second double helix (Fig. 11-7b). As a third hypothesis, the parental and newly synthesized strands might become randomly mixed during the replication process; this possibility was known as *dispersive replication* (Fig. 11-7c). To discriminate among semiconservative replication and the other models, investigators had to distinguish between old and newly synthesized strands of DNA.

One technique is to use a heavy isotope of nitrogen, ^{15}N (ordinary nitrogen is ^{14}N), to label the bases of the DNA strands, making them more dense. Using **density gradient centrifugation,** scientists can separate large molecules such as DNA on the basis of differences in their density. When DNA is mixed with a solution containing cesium chloride (CsCl) and centrifuged at high speed, the solution forms a density gradient in the centrifuge tube, ranging from a region of lowest density at the top to one of highest density at the bottom. During centrifugation, the DNA molecules migrate to the region of the gradient identical to their own density.

In 1958, Matthew Meselson and Franklin Stahl at the California Institute of Technology grew the bacterium *Escherichia coli* on a medium that contained ^{15}N in the form of ammonium chloride (NH_4Cl). The cells used the ^{15}N to synthesize bases, which then became incorporated into DNA (Fig. 11-7d). The resulting DNA molecules, which contained heavy nitrogen, were extracted from some of the cells. When the researchers subjected them to density gradient centrifugation, they accumulated in the high-density region of the gradient. The team transferred the rest of the bacteria (which also contained ^{15}N-labeled DNA) to a different growth medium in which the NH_4Cl contained the naturally abundant, lighter ^{14}N isotope and then allowed them to undergo additional cell divisions.

Meselson and Stahl expected the newly synthesized DNA strands to be less dense, because they incorporated bases containing the lighter ^{14}N isotope. Indeed, double-stranded DNA from cells isolated after one generation had an intermediate density, indicating they contained half as many ^{15}N atoms as the "parent" DNA. This finding supported the semiconservative replication model, which predicted that each double helix would contain a previously synthesized strand (heavy in this case) and a newly synthesized strand (light in this case). It was also consistent with the dispersive model, which would also yield one class of molecules, all with intermediate density. It was inconsistent with the conservative model, which predicted two classes of double-stranded molecules, those with two heavy strands and those with two light strands.

After another cycle of cell division in the medium with the lighter ^{14}N isotope, two types of DNA appeared in the density gradient, exactly as predicted by the semiconservative replication model. One consisted of DNA with a density intermediate between ^{15}N-labeled DNA and ^{14}N-labeled DNA, whereas the other contained only DNA with a density of ^{14}N-labeled DNA. This finding refuted the dispersive model, which predicted that all strands would have an intermediate density.

Semiconservative replication explains the perpetuation of mutations

The recognition that DNA could be copied by a semiconservative mechanism suggested how DNA could explain a third

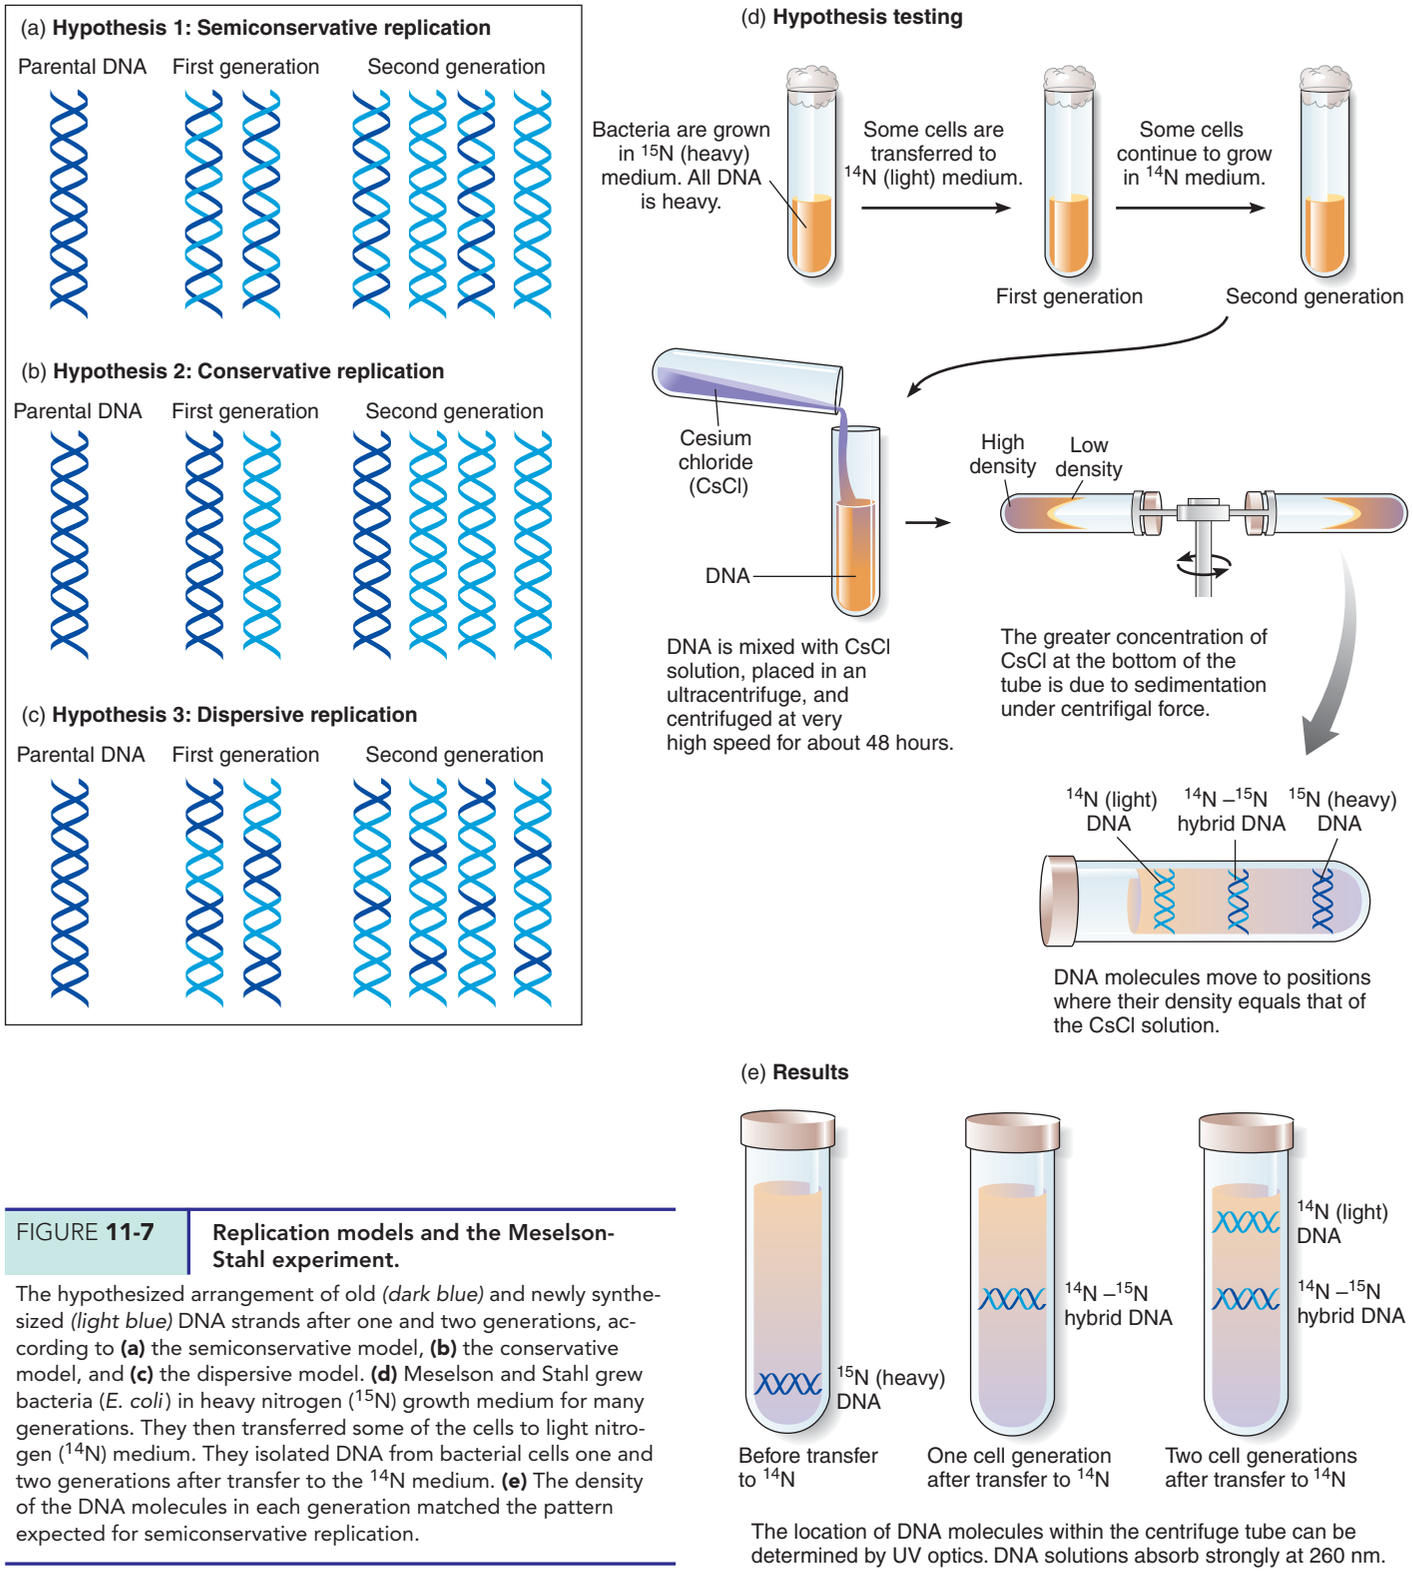

FIGURE **11-7** **Replication models and the Meselson-Stahl experiment.**

The hypothesized arrangement of old *(dark blue)* and newly synthesized *(light blue)* DNA strands after one and two generations, according to **(a)** the semiconservative model, **(b)** the conservative model, and **(c)** the dispersive model. **(d)** Meselson and Stahl grew bacteria (*E. coli*) in heavy nitrogen (^{15}N) growth medium for many generations. They then transferred some of the cells to light nitrogen (^{14}N) medium. They isolated DNA from bacterial cells one and two generations after transfer to the ^{14}N medium. **(e)** The density of the DNA molecules in each generation matched the pattern expected for semiconservative replication.

essential characteristic of genetic material—the ability to mutate. It was long known that **mutations,** or genetic changes, could arise in genes and then be transmitted faithfully to succeeding generations. For example, a mutation in the fruit fly (*Drosophila melanogaster*) produces vestigial wings (see Fig. 10-11).

When the double-helix model was proposed, it seemed plausible that mutations could represent a change in the sequence of bases in the DNA. You could predict that if DNA is copied by a mechanism involving complementary base pairing, any change in the sequence of bases on one strand would produce a new sequence of complementary bases during the next replication cycle. The new base sequence would then transfer to daughter molecules by the same mechanism used to copy the original genetic material, as if no change had occurred.

For the example in Figure 11-8, an adenine base in one of the DNA strands has been changed to guanine. This could occur by a rare error in DNA replication or by one of several other known mechanisms. Certain enzymes correct errors when they occur, but not all errors are corrected properly. By one estimate, the rate of uncorrected errors that occurs during DNA replication is equal to about one nucleotide in a billion. When the DNA molecule containing an error replicates (left side of Fig. 11-8), one of the strands gives rise to a molecule exactly like its parent strand; the other (mutated) strand gives rise to a molecule with a new combination of bases that is transmitted generation after generation.

DNA replication is a complex process that requires protein "machinery"

Although semiconservative replication by base pairing appears simple and straightforward, the actual process is highly regulated and requires a "replication machine" containing many protein and enzyme molecules. Many essential features of DNA replication are common to all organisms, although prokaryotes and eukaryotes differ somewhat because their DNA is organized differently. In most bacterial cells, such as *E. coli,* most or all of the DNA is in the form of a single, *circular,* double-stranded DNA molecule. In contrast, each unreplicated eukaryotic chromosome contains a single, *linear,* double-stranded molecule associated with at least as much protein (by mass) as DNA.

We now present DNA replication, based on the current understanding of the process. Figure 11-9 shows a simplified overview, and Figures 11-10 and 11-11 outline the steps. Although scientists know much about DNA replication, many aspects of the process remain unclear. For example, in the unicellular yeast *Saccharomyces cerevisiae,* which is considered a relatively "simple" eukaryote, 88 genes are involved in DNA replication! Determining the roles and interactions of all those genes in DNA replication will require the efforts of many scientists over a long time.

DNA strands must be unwound during replication

Watson and Crick recognized that in their double-helix model, the two DNA strands wrap around each other like the strands of a rope. If you tried to pull the strands apart, the rope must either rotate or twist into tighter coils. You could expect similar results when complementary DNA strands are separated for replication. **DNA helicases** are enzymes that separate the two strands of DNA by traveling along the helix, opening the double helix like a zipper as they move (Table 11-3). Once the strands are separated, **single-strand binding proteins (SSBs),** also called *helix-destabilizing proteins,* bind to single DNA strands and stabilize them; this prevents the double helix from reforming until the strands are copied. As the DNA strands unwind to open for replication, excessive twisting occurs in another part of the DNA molecule. Enzymes called **topoisomerases** produce breaks in the DNA molecules and then rejoin the strands, relieving strain and effectively preventing excessive coiling and knot formation during replication.

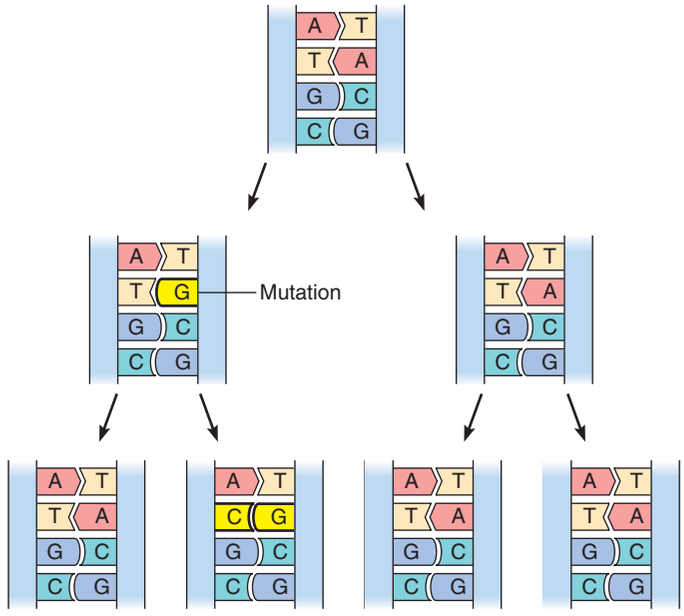

FIGURE **11-8** **The perpetuation of a mutation.**
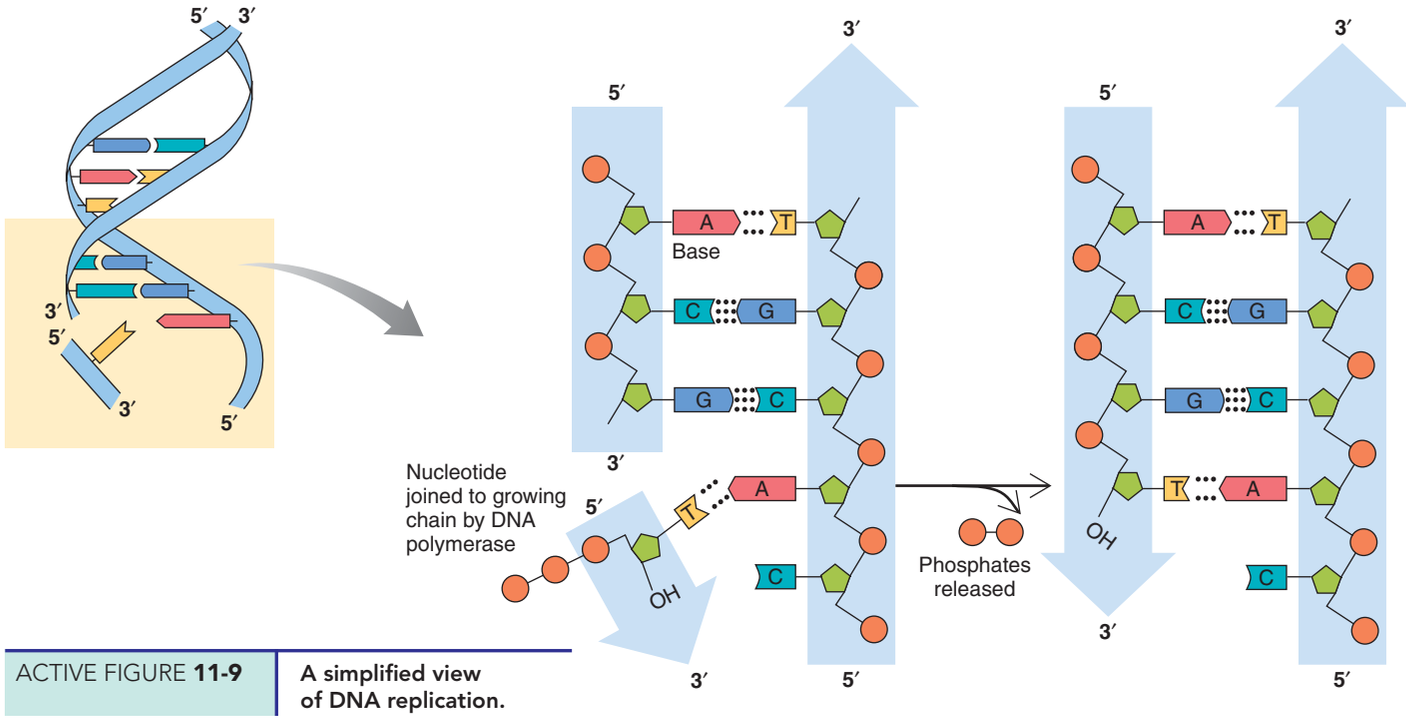
The process of DNA replication can stabilize a mutation *(bright yellow)* so that it is transmitted to future generations.

DNA synthesis always proceeds in a 5′ ⟶ 3′ direction

The enzymes that catalyze the linking together of the nucleotide subunits are called **DNA polymerases.** They add nucleotides only to the 3′ end of a growing polynucleotide strand, and this strand must be paired with the strand being copied (see Fig. 11-9). Nucleotides with three phosphate groups, as in ATP and GTP, are substrates for the polymerization reaction. As the nucleotides link together, two of the phosphates are removed. These reactions are strongly exergonic and do not need additional energy. Because the polynucleotide chain is elongated by the linkage of the 5′ phosphate group of the next nucleotide subunit to the 3′ hydroxyl group of the sugar at the end of the pre-existing strand, the new strand of DNA always grows in the 5′ ⟶ 3′ direction.

TABLE **11-3** **Enzymes Involved in DNA Replication**

Enzyme	Function
DNA helicases	Open the double helix by disrupting the hydrogen bonds that hold the two strands together.
Topoisomerases	Break one or both DNA strands, preventing excessive coiling during replication, and rejoin them.
DNA polymerases	Link nucleotide subunits together.
DNA primase	Synthesizes short RNA primers on the lagging strand. Begins replication of the leading strand.
DNA ligase	Links Okazaki fragments by joining the 3′ end of the new DNA fragment to the 5′end of the adjoining DNA.
Telomerase	Lengthens telomeric DNA.



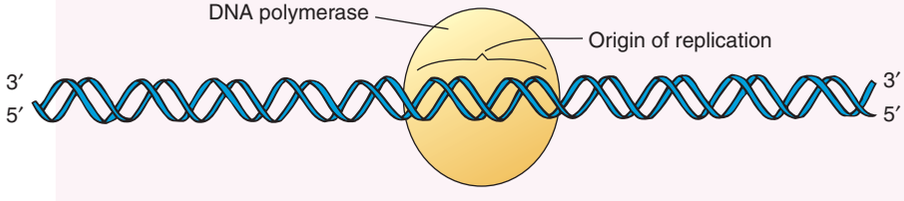
ACTIVE FIGURE **11-9** **A simplified view of DNA replication.**

DNA polymerase adds one nucleotide at a time to the 3′ end of a growing chain.

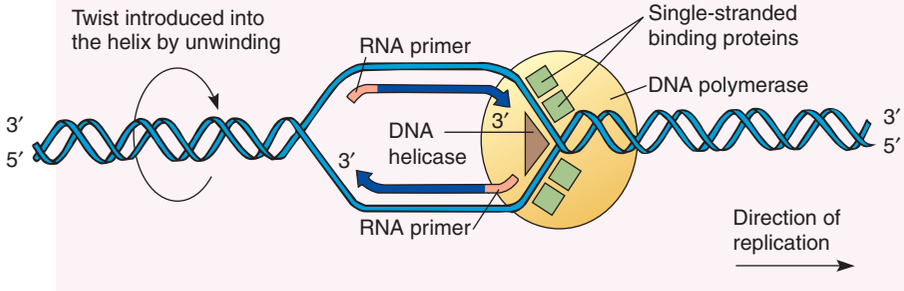
Biology Now™ Watch the **process of replication** by clicking on this figure on your BiologyNow CD-ROM.

FIGURE **11-10** **An overview of DNA replication.**

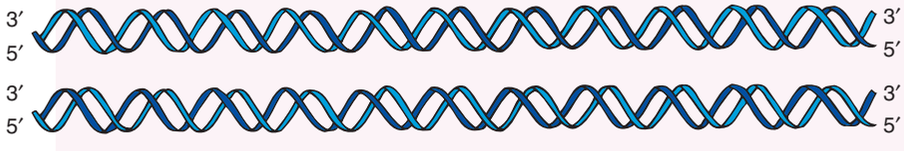
This process requires several steps involving several enzymes, proteins, and RNA primers.



① DNA synthesis begins at origin of replication.



② Strands are separated at origin of replication and unwound by DNA helicase, which "walks" along DNA molecule preceding the DNA-synthesizing enzymes. Single-stranded regions are prevented from reforming into double strands by single-strand binding proteins, which bind to single-stranded DNA. Region of active DNA synthesis is associated with replication fork, formed at junction of single strands and double-stranded region. Both strands are synthesized in vicinity of fork (in 5′→3′ direction).



③ Completion of replication results in formation of two daughter molecules, each containing one old and one newly synthesized strand. Each double helix is chromatid of duplicated eukaryotic chromosome.

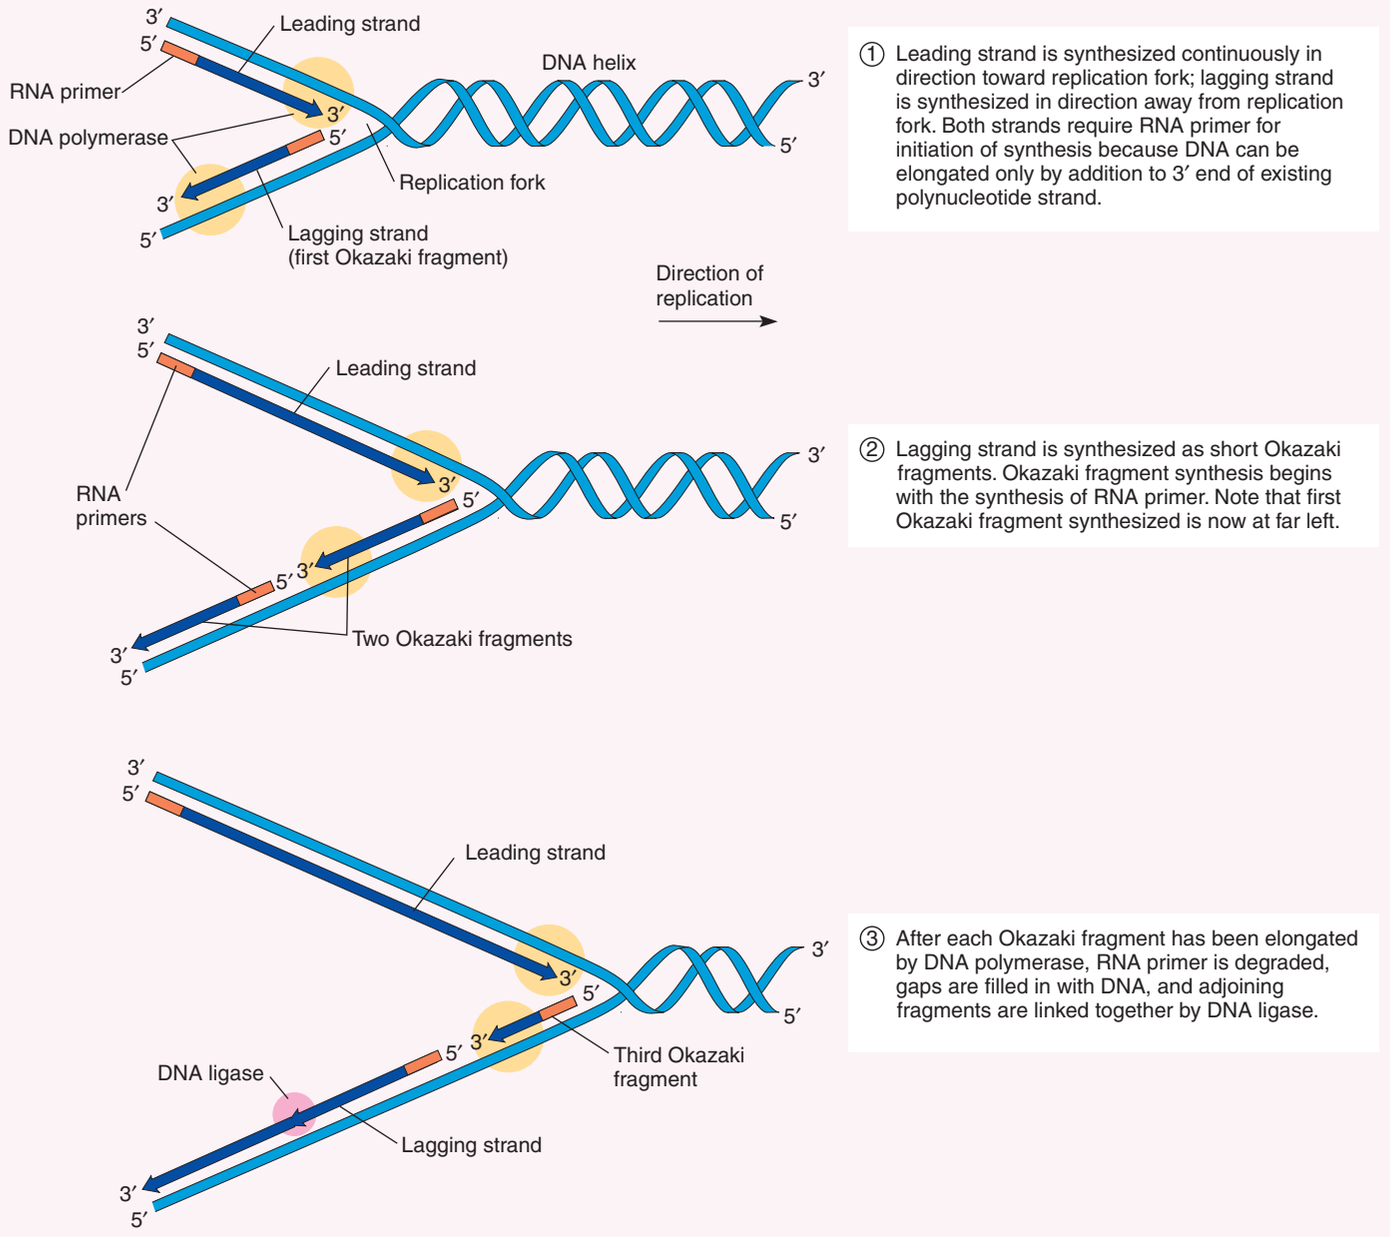


FIGURE **11-11** **Leading and lagging DNA strands.**
Because elongation can proceed only in the 5′ ⟶ 3′ direction, the two strands at the replication fork are copied in different ways, each by a separate DNA polymerase molecule.

DNA synthesis requires an RNA primer

As mentioned, DNA polymerases add nucleotides only to the 3′ end of an *existing* polynucleotide strand. Then how can DNA synthesis be initiated once the two strands are separated? The answer is that first a short piece of RNA (5 to 14 nucleotides) called an **RNA primer** is synthesized at the point where replication begins (Fig. 11-10).

RNA, or **ribonucleic acid** (see Chapters 3 and 12), is a nucleic acid polymer consisting of nucleotide subunits that can associate by complementary base pairing with the single-stranded DNA template. The RNA primer is synthesized by **DNA primase,** an enzyme that starts a new strand of RNA opposite a DNA strand. After a few nucleotides have been added, DNA polymerase displaces the primase and subsequently adds subunits to the 3′ end of the short RNA primer. Specific enzymes later degrade the primer, and the space fills in with DNA.

DNA replication is discontinuous in one strand and continuous in the other

We mentioned earlier that the complementary DNA strands are antiparallel. DNA synthesis proceeds only in the 5′ ⟶ 3′ direction, which means that the strand being copied is being read in the 3′ ⟶ 5′ direction. Thus it may seem necessary to copy one of the strands starting at one end of the double helix and the other strand starting at the opposite end. Some viruses replicate their DNA in this way, but this replication method is not workable in the extremely long DNA molecules in eukaryotic chromosomes.

Instead, DNA replication begins at specific sites on the DNA molecule, called **origins of replication,** and both strands replicate at the same time at a Y-shaped structure called the **replication fork** (see Fig. 11-11 and chapter introduction photograph). The position of the replication fork is constantly moving as replication proceeds. Two identical DNA polymerase molecules catalyze replication. One of these adds nucleotides to the 3′ end of the new strand that is always growing *toward* the replication fork. Because this strand can be formed smoothly and continuously, it is called the **leading strand.**

A separate (but identical) DNA polymerase molecule adds nucleotides to the 3′ end of the other new strand. Called the **lagging strand,** it is always growing *away* from the replication fork. Only short pieces can be synthesized, because if the DNA polymerase were to add continuously to the 3′ end of that strand, it would need to move far away from the replication fork. These 100- to 2000-nucleotide pieces are called **Okazaki fragments** after their discoverer, Japanese molecular biologist Reiji Okazaki.

A separate RNA primer initiates each Okazaki fragment, which DNA polymerase then extends toward the 5′ end of the previously synthesized fragment. When the RNA primer of the previously synthesized fragment is reached, DNA polymerase degrades and replaces the primer with DNA. The fragments are then joined together by **DNA ligase,** an enzyme that links the 3′ hydroxyl of one Okazaki fragment to the 5′ phosphate of the DNA immediately next to it, forming a phosphodiester linkage.

DNA synthesis is bidirectional

When double-stranded DNA separates, two replication forks form, and the molecule replicates in both directions from the origin of replication. In bacteria, each circular DNA molecule usually has only one origin of replication, so the two replication forks proceed around the circle and eventually meet at the other side to complete the formation of two new DNA molecules (Fig. 11-12a).

A eukaryotic chromosome consists of one long, linear DNA molecule, so having multiple origins of replication expedites the replication process (Fig. 11-12b,c). Synthesis continues at each replication fork until it meets a newly synthesized strand coming from the opposite direction. This results in a chromosome containing two DNA double helices, each corresponding to a chromatid.

Telomeres cap eukaryotic chromosome ends

Unlike bacterial DNA, which is circular, eukaryotic chromosomes have free ends. Because DNA replication is discontinu-

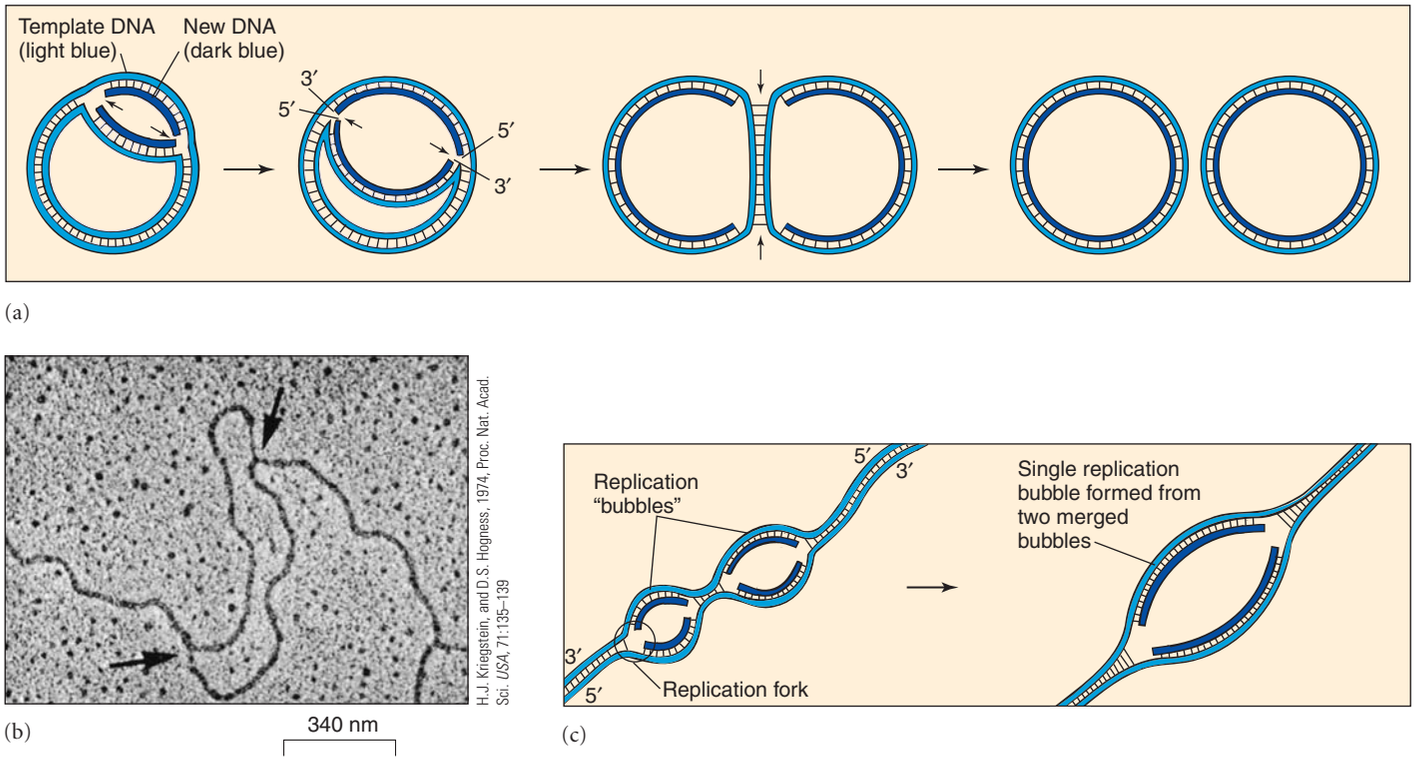

FIGURE **11-12** **Bidirectional DNA replication in bacteria and eukaryotes.**

The illustrations do not show leading strands and lagging strands. **(a)** The circular DNA in the prokaryote *E. coli* has only one origin of replication. Because DNA synthesis proceeds from that point in both directions, two replication forks form *(small black arrows),* travel around the circle, and eventually meet. **(b)** This TEM shows two replication forks *(arrows)* in a segment of a eukaryotic chromosome that has partly replicated. **(c)** Eukaryotic chromosomal DNA contains multiple origins of replication. DNA synthesis proceeds in both directions from each origin until adjacent replication "bubbles" eventually merge.

ous in the lagging strand, DNA polymerases do not complete replication of the strand neatly. At the end of the DNA, a small portion is left unreplicated, and a small, single-stranded segment of the DNA is lost with each cell cycle (Fig. 11-13a). The important genetic information is retained because chromosomes have end caps known as **telomeres** that do not contain protein-coding genes. Telomeres consist of short, simple, noncoding DNA sequences that repeat many times (Fig. 11-13b). Therefore, although a small amount of telomeric DNA fails to replicate each time the cell divides, a cell can divide many times before it starts losing essential genetic information.

Telomerase, a special DNA replication enzyme, can lengthen telomeric DNA. This enzyme, which researchers discovered in 1984, is typically present in cells that divide an unlimited number of times, including protozoa and other unicellular eukaryotes, and most types of **cancer cells,** which proliferate in a rapid and uncontrolled manner. In humans and other mammals, active telomerase is usually present in germ line cells (the cells that give rise to eggs and sperm) but not in normal somatic cells.

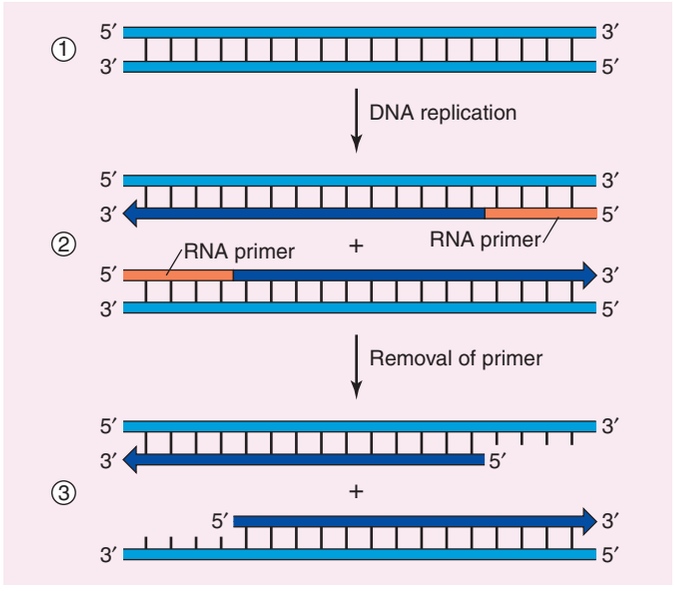
Research evidence suggests that the shortening of telomeres may contribute to **cell aging** and *apoptosis,* which is programmed cell death. Scientists have analyzed cell aging since the 1960s, following the pioneering studies of American biologist Leonard Hayflick, who showed that when normal somatic cells of the human body are grown in culture, they lose their ability to divide after a limited number of cell divisions. Furthermore, the number of cell divisions is determined by the age of the individual from whom the cells were taken. Cells from a 70-year-old divide only 20 to 30 times, compared with those from an infant, which divide 80 to 90 times.

PROCESS OF SCIENCE

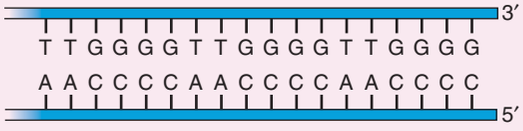
Many investigators have observed correlations between telomerase activity and the ability of cells to undergo unlimited divisions without showing signs of the aging process. However, they couldn't find evidence of a causal relationship until the early 2000s, when scientists at the Geron Corporation and the University of Texas Southwestern Medical Center conducted a direct test. Using recombinant DNA technology (see Chapter 14), they infected cultured normal human cells with a virus that carried the genetic information coding for the catalytic subunit of telomerase. The infected cells not only produced active telomerase, which elongated the telomeres significantly, but also continued to divide long past the point at which cell divisions would normally cease.

Telomeres and telomerase are an active focus of current research, for both theoretical and practical reasons. The ability to give somatic cells telomerase so they can divide many times more than they ordinarily would, has many potential therapeutic applications, especially if lost or injured cells must be replaced. However, giving such cells the property of unlimited cell division also has potentially serious consequences. For example, if transplanted into the body, cells with active telomerase might behave like cancer cells.

Cancer cells have the ability to divide hundreds of times in culture; in fact, they are virtually immortal. Most cancer cells, including human cancers of the breast, lung, colon, prostate



(a)



(b)

FIGURE 11-13 **Replication at chromosome ends.**

(a) Why one strand of DNA is shorter than that of the preceding generation. ① This is the unwound DNA of a eukaryotic chromosome before replication. ② When DNA replication occurs, the 5′ end of each newly synthesized strand contains a short segment of RNA that functioned as a primer on the lagging strand. ③ Removal of the 5′ RNA primer results in DNA molecules with shorter 5′ ends than in the original chromosome because there is no way to prime the last section at the 5′ end. **(b)** The telomeres of chromosomes have short noncoding DNA sequences that repeat many times. Shown is TTGGGG, which is the segment repeated some 20 to 70 times in telomeres of the protozoon *Tetrahymena,* the unicellular organism in which telomerase was first discovered.

gland, and pancreas, have telomerase to maintain telomere length and possibly to resist apoptosis. Research is underway to develop anticancer drugs that inhibit telomerase activity. An alternative treatment for cancer is also under study—directing the body's immune system to recognize and attack cancer cells that contain telomerase.

Review

- How did Meselson and Stahl verify that DNA replication is semiconservative?
- What are some of the complexities of DNA replication?
- Why is DNA replication continuous for one strand but discontinuous for the other?

BiologyNow™ Assess your understanding of **DNA replication** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Summarize the evidence that accumulated during the 1940s and early 1950s demonstrating that DNA is the genetic material.

- Many early geneticists thought genes were made of proteins. They knew proteins are complex and variable, whereas they thought of nucleic acids as simple molecules with a limited ability to store information.
- Several lines of evidence supported the idea that **DNA (deoxyribonucleic acid)** is the genetic material. In **transformation** experiments, the DNA of one strain of bacteria can endow related bacteria with new genetic characteristics.
- When a bacterial cell becomes infected with a **bacteriophage** (virus), only the DNA from the virus enters the cell; this DNA is sufficient for the virus to reproduce and form new viral particles.
- Watson and Crick's model of the structure of DNA demonstrated how information can be stored in the molecule's structure and how DNA molecules can serve as **templates** for their own replication.

2 Sketch how nucleotide subunits link together to form a single DNA strand.

- DNA is a very regular polymer of **nucleotides.** Each nucleotide subunit contains a nitrogenous base, which may be one of the **purines** (**adenine** or **guanine**) or one of the **pyrimidines** (**thymine** or **cytosine**). Each base covalently links to a pentose sugar, **deoxyribose,** which covalently bonds to a phosphate group.
- The backbone of each single DNA chain is formed by alternating sugar and phosphate groups, joined by covalent **phosphodiester linkages.** Each phosphate group attaches to the 5′ carbon of one deoxyribose and to the 3′ carbon of the neighboring deoxyribose.

3 Illustrate how the two strands of DNA are oriented with respect to each other.

- Each DNA molecule consists of two polynucleotide chains that associate as a **double helix.** The two chains are **antiparallel** (running in opposite directions); at each end of the DNA molecule one chain has a phosphate attached to a 5′ deoxyribose carbon, the **5′ end,** and the other has a hydroxyl group attached to a 3′ deoxyribose carbon, the **3′ end.**

4 State the base-pairing rules for DNA, as determined by Chargaff and coworkers, and describe how complementary bases bind to each other.

- Hydrogen bonding between specific base pairs holds together the two chains of the helix. Adenine (A) forms two hydrogen bonds with thymine (T); guanine (G) forms three hydrogen bonds with cytosine (C).
- **Complementary** base pairing between A and T and between G and C is the basis of Chargaff's rules, which state that A equals T and G equals C.
- Because complementary base pairing holds together the two strands of DNA, it is possible to predict the base sequence of one strand if you know the base sequence of the other strand.

5 Cite experimental evidence that enabled scientists to differentiate between semiconservative replication of DNA and alternative models (conservative and dispersive replication).

- When *E. coli* cells are grown for many generations in a medium containing heavy nitrogen (^{15}N), they incorporate the ^{15}N into their DNA. When researchers transfer cells from a ^{15}N medium to a ^{14}N medium and isolate them after either one or two generations, the density of the DNA in each group is what would be expected if DNA replication were semiconservative. In **semiconservative replication,** each daughter double helix consists of an original strand from the parent molecule and a newly synthesized complementary strand.

6 Summarize how DNA replicates, and identify some unique features of the process.

- During **DNA replication,** the two strands of the double helix unwind. Each strand serves as a template for forming a new, complementary strand. The enzyme that adds new nucleotide subunits to a growing DNA strand is **DNA polymerase.**
- Additional enzymes and other proteins are required to unwind and stabilize the separated DNA helix. **DNA helicases** open the double helix and **topoisomerases** prevent tangling and knotting. **DNA primase** synthesizes short **RNA primers** on the lagging strand, and **DNA ligase** links together **Okazaki fragments** of newly synthesized DNA.

7 Explain the complexities of DNA replication that cause it to be (a) bidirectional and (b) discontinuous in one strand and continuous in the other.

- DNA replication is bidirectional, starting at the **origin of replication** and proceeding in both directions from that point. A eukaryotic chromosome may have multiple origins of replication and may be replicating at many points along its length at any one time.
- DNA synthesis always proceeds in a 5′ ⟶ 3′ direction. This requires that one DNA strand, the **lagging strand,** be synthesized discontinuously, as short Okazaki fragments. The opposite strand, the **leading strand,** is synthesized continuously.

8 Define *telomere;* describe the possible connections between telomerase and cell aging and between telomerase and cancer.

- Eukaryotic chromosome ends, known as **telomeres,** are short, noncoding, repetitive DNA sequences. Telomeres shorten slightly with each cell cycle but can be extended by the enzyme **telomerase.**
- The absence of telomerase activity in certain cells may be a cause of **cell aging,** in which cells lose their ability to divide after a limited number of cell divisions.
- Most **cancer cells,** including human cancers of the breast, lung, colon, prostate gland, and pancreas, have telomerase to maintain telomere length and possibly to resist apoptosis.

POST-TEST

1. When Griffith injected mice with a combination of live rough-strain and heat-killed smooth-strain pneumococci, he discovered that (a) the mice were unharmed (b) the dead mice contained living rough-strain bacteria (c) the dead mice contained living smooth-strain bacteria (d) DNA had been transferred from the smooth-strain bacteria to the mice (e) DNA had

POST-TEST *(continued)*

been transferred from the rough-strain bacteria to the smooth-strain bacteria

2. Which of the following inspired Avery and his colleagues to perform the experiments demonstrating that the transforming principle in bacteria is DNA? (a) the fact that A is equal to T, and G is equal to C (b) Watson and Crick's model of DNA structure (c) Meselson and Stahl's studies on DNA replication in *E. coli* (d) Griffith's experiments on smooth and rough strains of pneumococci (e) Hershey and Chase's experiments on the reproduction of bacteriophages
3. In the Hershey-Chase experiment with bacteriophages (a) harmless bacterial cells permanently transformed into virulent cells (b) DNA was shown to be the transforming principle of earlier bacterial transformation experiments (c) the replication of DNA was conclusively shown to be semiconservative (d) viral DNA was shown to enter bacterial cells and cause the production of new viruses within the bacteria (e) viruses injected their proteins, not their DNA, into bacterial cells
4. The two complementary strands of the DNA double helix are held to one another by (a) ionic bonds between deoxyribose molecules (b) ionic bonds between phosphate groups (c) covalent bonds between nucleotide bases (d) covalent bonds between deoxyribose molecules (e) hydrogen bonds between nucleotide bases
5. If a segment of DNA is 5′—CATTAC—3′, the complementary DNA strand is
   (a) 3′—CATTAC—5′ (b) 3′—GTAATG—5′
   (c) 5′—CATTAC—3′ (d) 5′—GTAATG—3′
   (e) 5′—CATTAC—5′
6. Each DNA strand has a backbone that consists of alternating (a) purines and pyrimidines (b) nucleotide bases (c) hydrogen bonds and phosphodiester linkages (d) deoxyribose and phosphate (e) phosphate and phosphodiester linkages
7. The experiments in which Meselson and Stahl grew bacteria in heavy nitrogen conclusively demonstrated that DNA (a) is a double helix (b) replicates semiconservatively (c) consists of repeating nucleotide subunits (d) has complementary base pairing (e) is always synthesized in the 5′ to 3′ direction
8. The statement "DNA replicates by a semiconservative mechanism" means that (a) only one DNA strand is copied (b) first one DNA strand is copied, and then the other strand is copied (c) the two strands of a double helix have identical base sequences (d) some portions of a single DNA strand are old, and other portions are newly synthesized (e) each double helix consists of one old and one newly synthesized strand
9. What technique did Franklin use to determine many of the physical characteristics of DNA? (a) x-ray diffraction (b) transformation (c) radioisotope labeling (d) density gradient centrifugation (e) transmission electron microscopy
10. Multiple origins of replication (a) speed up replication of eukaryotic chromosomes (b) enable the lagging strands and leading strands to be synthesized at different replication forks (c) help to relieve strain as the double helix unwinds (d) prevent mutations (e) are necessary for the replication of a circular DNA molecule in bacteria
11. Topoisomerases (a) synthesize DNA (b) synthesize RNA primers (c) join Okazaki fragments (d) break and rejoin DNA to resolve knots that have formed (e) prevent single DNA strands from joining to form a double helix
12. A phosphate in DNA (a) hydrogen-bonds to a base (b) covalently links to two bases (c) covalently links to two deoxyriboses (d) hydrogen-bonds to two additional phosphates (e) covalently links to a base, a deoxyribose, and another phosphate
13. Which of the following depicts the relative arrangement of the complementary strands of a DNA double helix?
    (a) 5′—5′ / 3′—3′ (b) 3′—5′ / 3′—5′ (c) 3′—3′ / 3′—3′ (d) 5′—5′ / 5′—5′ (e) 3′—5′ / 5′—3′
14. A lagging strand forms by (a) joining primers (b) joining Okazaki fragments (c) joining leading strands (d) breaking up a leading strand (e) joining primers, Okazaki fragments, and leading strands
15. The immediate source of energy for DNA replication is (a) the hydrolysis of the nucleotides, with the release of two phosphates (b) the oxidation of NADPH (c) the hydrolysis of ATP (d) electron transport (e) the breaking of hydrogen bonds
16. Which of the following statements about eukaryotic chromosomes is *false?* (a) Eukaryotic chromosomes have free ends (b) Telomeres contain protein-coding genes (c) Telomerase lengthens telomeric DNA (d) Telomere shortening may contribute to cell aging (e) Cells with active telomerase may undergo many cell divisions

CRITICAL THINKING

1. What characteristics must a molecule have to function as genetic material?
2. What important features of the structure of DNA are consistent with its role as the chemical basis of heredity?

CHAPTER OUTLINE

- Discovery of the Gene–Protein Relationship
- Information Flow from DNA to Protein: An Overview
- Transcription
- Translation
- Variations in Protein Synthesis in Different Organisms
- Mutations and Genes

In Chapter 11, we discussed how the cell accurately replicates the nucleotide sequence in DNA to pass the genetic material unaltered to the next generation. Watson and Crick originally described the basic features of the DNA double helix, which scientists now know to be the same in all cells studied to date—from the simplest bacteria to highly complex human cells.

By the mid-1950s, researchers had determined that the sequence of bases in DNA contains the information that specifies all the proteins the cell needs. However, more than a decade of intense investigation by many scientists preceded a fundamental understanding of how cells convert DNA information into the amino acid sequences of proteins. Much of that understanding came from studying the functions of bacterial genes. After Watson and Crick discovered the structure of DNA, researchers chose bacterial cells as the organisms of choice for these studies because bacteria grew quickly and easily, and because they contained the minimal amount of DNA needed for growth and reproduction. As researchers learned that all organisms have fundamental genetic similarities, the validity, as well as the utility, of this approach was repeatedly confirmed.

In this chapter we examine the evidence that accumulated in the first half of the 20th century indicating that most genes specify the structure of proteins. We then consider how DNA affects the phenotype of the organism at the molecular level through the process of gene expression. **Gene expression** involves a series of steps in which the information in the sequence of bases in DNA specifies the makeup of the cell's proteins. The proteins affect the phenotype in some way; these effects range from readily observable physical traits to subtle changes detectable only at the biochemical level. The first major step of gene expression is **transcription,** the synthesis of RNA molecules complementary to the DNA (see photograph). The second major step is **translation,** in which RNA becomes a coded template to direct protein synthesis. In Chapter 13 we consider some of the ways gene expression is regulated. ■

DISCOVERY OF THE GENE–PROTEIN RELATIONSHIP

Learning Objective

1 Summarize the early evidence indicating that most genes specify the structure of proteins.

PROCESS OF SCIENCE

The idea that genes and proteins are connected originated early in the 20th century, shortly after scientists rediscovered Mendel's principles. In the first edition of his book, *Inborn Errors of Metabolism* (1908), Archibald Garrod, an English physician and biochemist, discussed a rare genetic disease called **alkaptonuria,** which scientists hypothesized had a simple recessive inheritance pattern. The condition involves the metabolic pathway that breaks down the amino acid tyrosine, ultimately converting it to carbon dioxide and water. An intermediate in this pathway, homogentisic acid, accumulates in the urine of affected people, turning it black when exposed to air (Fig. 12-1). Other symptoms of alkaptonuria include the later development of arthritis and, in men, stones in the prostate gland.

In Garrod's time, scientists knew about enzymes but didn't recognize they were proteins. Garrod hypothesized that people with alkaptonuria lack the enzyme that normally oxidizes homogentisic acid. Before the second edition of his book had been published, in 1923, researchers found that affected people do indeed lack the enzyme that oxidizes homogentisic acid. Garrod's hypothesis was correct: A mutation in this specific gene is associated with the absence of a specific enzyme. Shortly thereafter, in 1926, U.S. biochemist James Sumner purified a different enzyme, urease, and showed it to be a protein. This was the first clear identification of an enzyme as a protein. In 1946 Sumner was awarded the Nobel Prize in Chemistry for being the first to crystallize an enzyme.

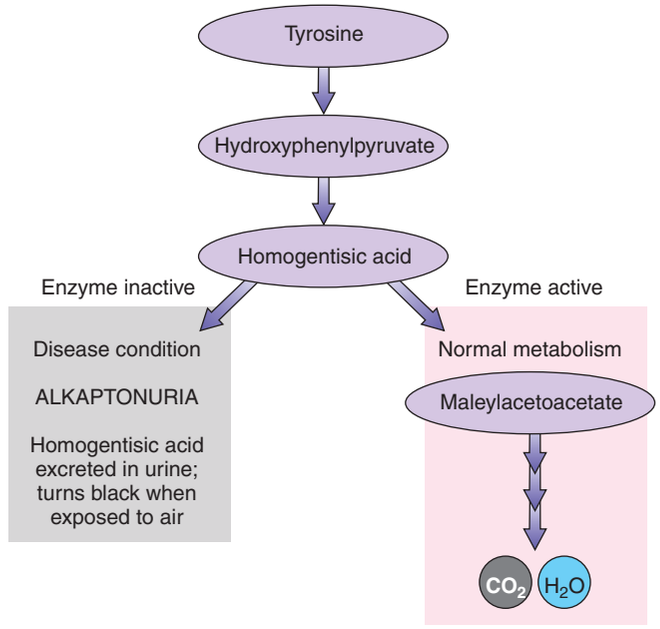

FIGURE **12-1** **An "inborn error of metabolism."**

Garrod proposed that the alkaptonuria allele causes the inactivation of the enzyme homogentisic acid oxidase, which normally converts homogentisic acid to maleylacetoacetate. Thus the acid accumulates in the blood and is excreted in the urine, which turns black on contact with the air.

Beadle and Tatum proposed the one-gene, one-enzyme hypothesis

A major advance in understanding the relationship between genes and enzymes came in the early 1940s, when U.S. geneticists George Beadle and Edward Tatum and their associates developed a new approach to the problem. Most efforts until that time had focused on studying known loci and seeking to determine what biochemical reactions they affected. Researchers examined previously identified loci, such as those controlling eye color in *Drosophila* or pigments in plants. They found that a series of biosynthetic reactions control specific phenotypes, but it was not clear whether the genes themselves were acting as enzymes or if they determined the workings of the enzymes in more complex ways.

Beadle and Tatum decided to take the opposite approach. Rather than try to identify the enzymes affected by single genes, they decided to look for mutations interfering with known metabolic reactions that produce essential molecules, such as amino acids and vitamins. They chose a fungus, *Neurospora,* a common bread mold, as an experimental organism, for several important reasons. First, wild-type *Neurospora* is easy to grow in culture. The adjective **wild-type** refers to an individual with the normal phenotype. *Neurospora* manufactures all its essential biological molecules when grown on a simple growth medium (minimal medium) containing only sugar, salts, and the vitamin biotin. However, a mutant *Neurospora* strain that cannot make a substance such as an amino acid, can still grow if that substance is simply added to the growth medium.

Second, the life cycle of *Neurospora* includes both sexual and asexual reproduction, which facilitates certain types of manipulations and genetic analysis. Third, *Neurospora* grows primarily as a haploid organism, allowing a recessive mutant allele to be immediately identified because there is no homologous chromosome that could carry a dominant allele that would mask its expression. (For an illustration of the generalized life cycles of simple organisms such as fungi, see Fig. 9-16b; a more detailed life cycle of organisms similar to *Neurospora* is given in Fig. 25-9.)

Beadle and Tatum began by exposing thousands of haploid wild-type *Neurospora* asexual spores to x-rays or ultraviolet radiation to induce mutant strains. They first grew each irradiated strain on a complete growth medium, which contained all the amino acids and vitamins normally made by *Neurospora*. Then they tested each strain on the minimal medium described previously. About 1% to 2% of the strains that grew on the complete medium failed to grow after transfer to the minimal medium. Beadle and Tatum reasoned that such a strain carried a mutation preventing the fungus from producing one of the chemicals essential for growth. Further testing of the mutant

strain on media containing different combinations of amino acids, purines, and vitamins enabled the investigators to determine the exact compound required (Fig. 12-2).

The work on *Neurospora* revealed that each mutant strain had a mutation in only one gene locus and that each gene locus affected only one enzyme. Beadle and Tatum stated this one-to-one correspondence between genes and enzymes as the *one-gene, one-enzyme hypothesis.* In 1958, they received the Nobel Prize in Medicine for discovering that genes regulate specific chemical events. The work of Beadle, Tatum, and others led to a more precise understanding of what a gene is and to additional predictions about the chemical nature of genes. The idea that a gene encodes the information to produce a single enzyme held for almost a decade, until additional findings required a modification of this definition.

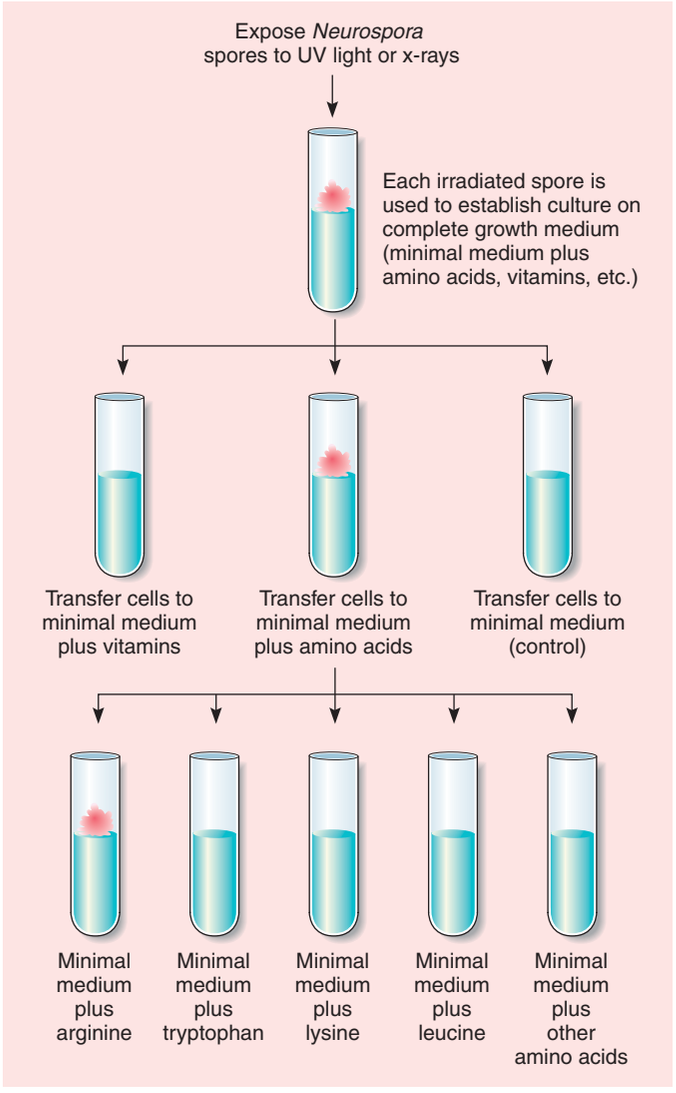

FIGURE **12-2** **Mutations affecting biochemical pathways.**

Beadle and Tatum irradiated *Neurospora* spores to induce mutations. Cultures derived from these spores were grown on a complete growth medium that contained all the amino acids, vitamins, and other nutrients that *Neurospora* normally makes for itself. They hypothesized that any strain that failed to grow when transferred to a minimal medium carried a mutation that blocked a step in a biochemical pathway. They identified the specific nutritional requirement in the mutant strain by testing for growth on minimal media supplemented with individual vitamins or amino acids. In this example, only the medium containing the amino acid arginine supports growth, indicating the mutation affects some part of the arginine biosynthetic pathway.

In the late 1940s, researchers began to understand that genes control not only enzymes but other proteins as well. The U.S. chemist Linus Pauling and his colleagues demonstrated in 1949 that a mutation of a single locus alters the structure of hemoglobin. This particular mutant form of hemoglobin is associated with the genetic disease sickle cell anemia (see Chapter 15). In 1954, Pauling received the Nobel Prize in Chemistry for his work on the genetic aspects of the molecular structure of hemoglobin. In addition, studies by other scientists showed that many proteins are constructed from two or more polypeptide chains, each of which is under the control of a different locus. For example, hemoglobin contains two types of polypeptide chains, the α and β subunits (see Fig. 3-22a). Sickle cell anemia results from a mutation affecting the β subunits.

Scientists therefore extended the definition of a gene to say that one gene is responsible for one polypeptide chain. Even this definition has proved only partially correct, although as you will see later in this chapter, scientists still define a gene in terms of its product.

Although the elegant work of Beadle and Tatum and others demonstrated that genes are expressed in the form of proteins, the mechanism was completely unknown. After Watson and Crick's discovery of the structure of DNA, many scientists worked to understand exactly how gene expression takes place. We begin with an overview of gene expression and then consider the various steps in more detail.

Review

- What is the one-gene, one-enzyme hypothesis?
- What were the contributions of each of the following scientists—A. Garrod, G. Beadle and E. Tatum, and L. Pauling—to our understanding of the relationship between genes and proteins?

BiologyNow™ Assess your understanding of **the discovery of the gene–protein relationship** by taking the pretest on your BiologyNow CD-ROM.

INFORMATION FLOW FROM DNA TO PROTEIN: AN OVERVIEW

Learning Objectives

2 Outline the flow of genetic information in cells, from DNA to protein.

3 Compare the structures of DNA and RNA.

4 Explain why the genetic code is said to be redundant and virtually universal, and discuss how these features may reflect its evolutionary history.

Although the sequence of bases in DNA determines the sequence of amino acids in polypeptides, cells do not use the information in DNA directly. Instead, a related nucleic acid, **ribonucleic acid (RNA),** is the link between DNA and protein. When a protein-coding gene is expressed, first an RNA copy is made of the information in the DNA. It is this RNA copy that provides the information that directs protein synthesis.

Like DNA, RNA is a polymer of nucleotides, but it has some important differences (Fig. 12-3). RNA is usually single-stranded, although internal regions of some RNA molecules may have complementary sequences that allow the strand to fold back and pair to form short, double-stranded segments. As shown in Figure 12-3, the sugar in RNA is **ribose,** which is similar to deoxyribose of DNA but has a hydroxyl group at the 2′ position. (Compare ribose with the deoxyribose of DNA, shown in Fig. 11-3, which has only a hydrogen at the 2′ position.) The base **uracil** substitutes for thymine and, like thymine, is a pyrimidine that can form two hydrogen bonds with adenine. Hence uracil and adenine are a complementary pair.

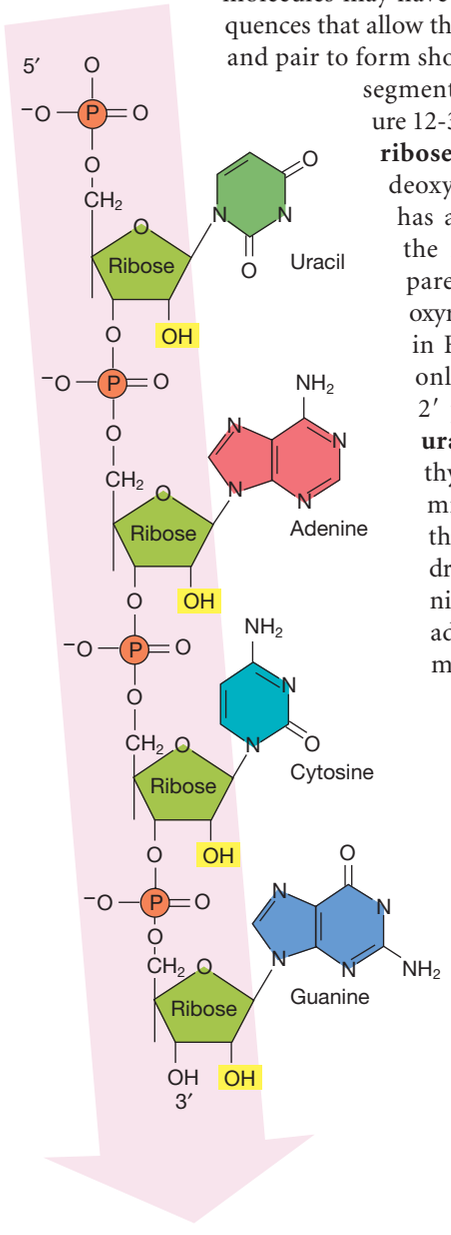

FIGURE **12-3** **The nucleotide structure of RNA.**

The nucleotide subunits of RNA are joined by 5′ ⟶ 3′ phosphodiester linkages, like those found in DNA. Adenine, guanine, and cytosine are present, as in DNA, but the base uracil replaces thymine. All four nucleotide types contain the five-carbon sugar ribose, which has a hydroxyl group *(yellow)* on its 2′ carbon atom.

DNA is transcribed to form RNA

The process by which RNA is synthesized resembles DNA replication in that the sequence of bases in the RNA strand is determined by complementary base-pairing with one of the DNA strands, the **template strand** (Fig. 12-4). Because RNA synthesis takes the information in one kind of nucleic acid (DNA) and copies it as another nucleic acid (RNA), this process is called **transcription** ("copying").

Three specific kinds of RNA molecules are transcribed: messenger RNA, transfer RNA, and ribosomal RNA. **Messenger RNA (mRNA)** is a single, uncoiled strand of RNA that carries the specific information for making a protein. Each of the 20 or so **transfer RNAs (tRNAs)** is a single strand of RNA that folds back on itself to form a specific shape. Each tRNA bonds with only one specific amino acid and carries it to the ribosome. **Ribosomal RNA (rRNA),** which is in a globular form, is an important part of the structure of ribosomes and has catalytic functions needed during protein synthesis.

RNA is translated to form a polypeptide

Figure 12-4 also shows the second step of gene expression, in which the transcribed information in the mRNA is used to specify the amino acid sequence of a polypeptide. This process is called **translation,** because it involves conversion of the "nucleic acid language" in the mRNA molecule into the "amino acid language" of protein.

A sequence of three consecutive bases in mRNA, called a **codon,** specifies one amino acid. For example, one codon that corresponds to the amino acid threonine is 5′— ACG—3′. Because each codon consists of three nucleotides, the code is described as a **triplet code.** The assignments of codons for amino acids and for start and stop signals are collectively named the **genetic code** (Fig. 12-5).

Transfer RNAs are crucial parts of the decoding machinery, because they act as "adapters" that connect amino acids and nucleic acids. This mechanism is possible because each tRNA can (1) link with a specific amino acid and (2) recognize the appropriate mRNA codon for that particular amino acid. A particular tRNA can recognize a specific codon because it has a sequence of three bases, called the **anticodon,** that hydrogen bonds with the mRNA codon by complementary base-pairing. The exact anticodon that is complementary to the codon for threonine in our example is 3′—UGC—5′.

Translation requires that (1) each tRNA anticodon is hydrogen-bonded to the complementary mRNA codon, and (2) the amino acids carried by the tRNAs are linked together in the order specified by the sequence of codons in the mRNA. **Ribosomes,** the site of translation, are organelles composed of two different subunits, each containing protein and rRNA. Ribosomes attach to one end of the mRNA and travel along it, allowing the tRNAs to attach sequentially to the codons of mRNA. In this way the amino acids carried by the tRNAs take up the proper position to be joined by *peptide bonds* in the correct sequence to form a polypeptide.

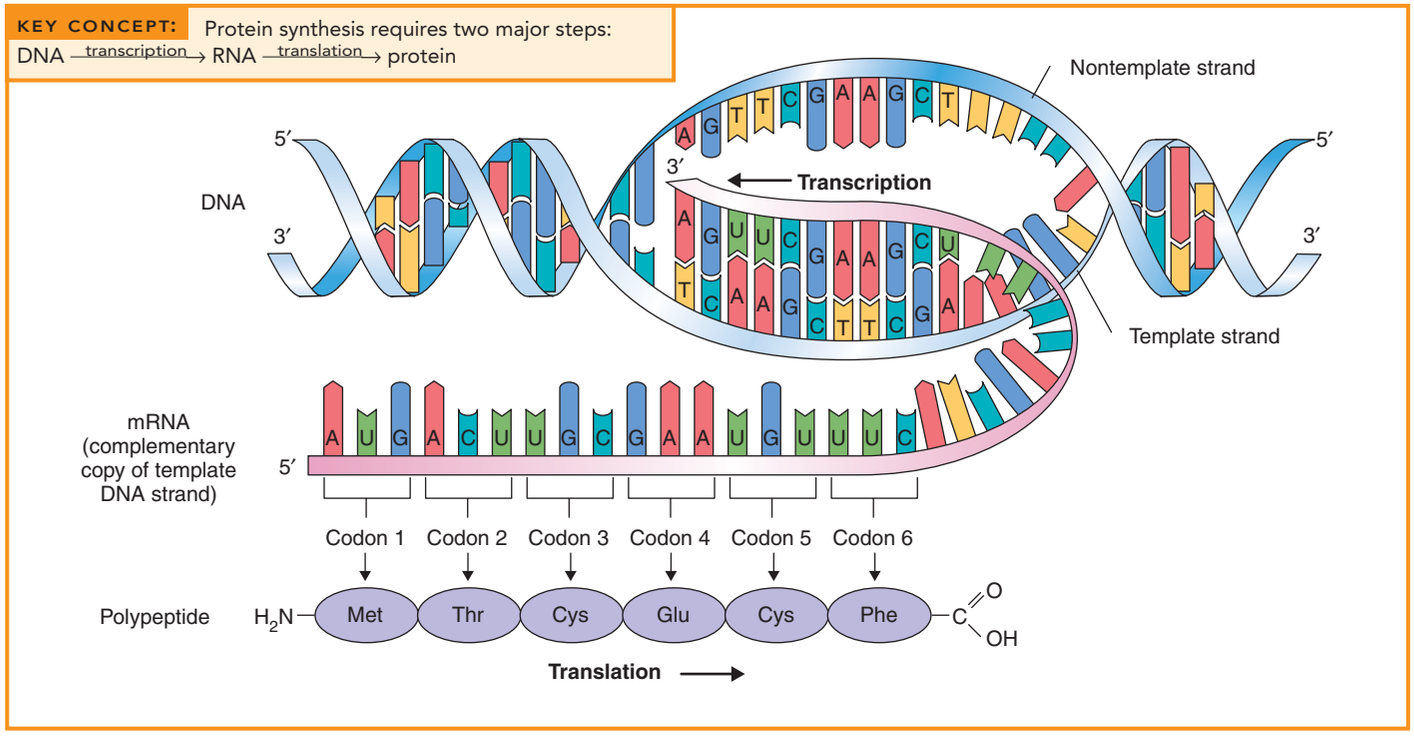

FIGURE **12-4** **An overview of transcription and translation.**

In transcription, messenger RNA is synthesized as a complementary copy of one of the DNA strands, the template strand. Messenger RNA carries genetic information in the form of sets of three bases, or codons, each of which specifies one amino acid. Codons are translated consecutively, thus specifying the linear sequence of amino acids in the polypeptide chain. Translation requires tRNA and ribosomes *(not shown)*. The figure depicts transcription and translation in bacteria. In eukaryotes, transcription takes place in the nucleus and translation occurs in the cytosol.

Biologists cracked the genetic code in the 1960s

PROCESS OF SCIENCE

Before the genetic code was deciphered, scientists had become interested in how a genetic code might work. The Watson and Crick model of DNA showed it to be a linear sequence of four nucleotides. If each nucleotide coded for a single amino acid, the genetic code could specify only 4 amino acids, not the 20 found in the vast variety of proteins in the cell. Scientists saw that the DNA bases could serve as a four-letter "alphabet" and hypothesized that three-letter combinations of the four bases would make it possible to form a total of 64 "words," more than enough to specify all the naturally occurring amino acids. In 1961, Crick and British scientist Sydney Brenner concluded from experimental evidence that the code used nonoverlapping triplets of bases. They predicted the code is read, one triplet at a time, from a fixed starting point that establishes the **reading frame.** Because no "commas" separate the triplets, an alteration in the reading frame results in the incorporation of incorrect amino acids.

Marshall Nirenberg, a U.S. biochemist, and his postdoctoral researcher, Heinrich Matthaei, first obtained experimental evidence indicating the assignment of specific triplets to specific amino acids. By constructing artificial mRNA molecules with known base sequences, they determined which amino acids would be incorporated into protein in purified in vitro protein synthetic systems derived from *E. coli*. For example, when they added the synthetic mRNA polyuridylic acid (UUUUUUUUU . . .) to a mixture of purified ribosomes, aminoacyl-tRNAs (amino acids linked to their respective tRNAs), and essential cofactors needed to synthesize protein, only phenylalanine was incorporated into the resulting polypeptide chain. The inference was inescapable that the UUU triplet codes for phenylalanine. Similar experiments showed that polyadenylic acid (AAAAAAAAA . . .) codes for a polypeptide of lysine and polycytidylic acid (CCCCCCCCC . . .) codes for a polypeptide of proline. In 1968, Nirenberg received the Nobel Prize in Medicine for his work in deciphering the genetic code.

By using mixed nucleotide polymers (such as a random polymer of A and C) as artificial messengers, researchers assigned the other codons to specific amino acids. However, three of the codons—UAA, UGA, and UAG—did not specify any amino acids. These codons are now known to be the signals that terminate the coding sequence for a polypeptide chain. By 1967 the genetic code was completely "cracked," and scientists had identified the coding assignments of all 64 possible codons shown in Figure 12-5.

Remember that the genetic code we define and use is an mRNA code. The tRNA anticodon sequences, as well as the

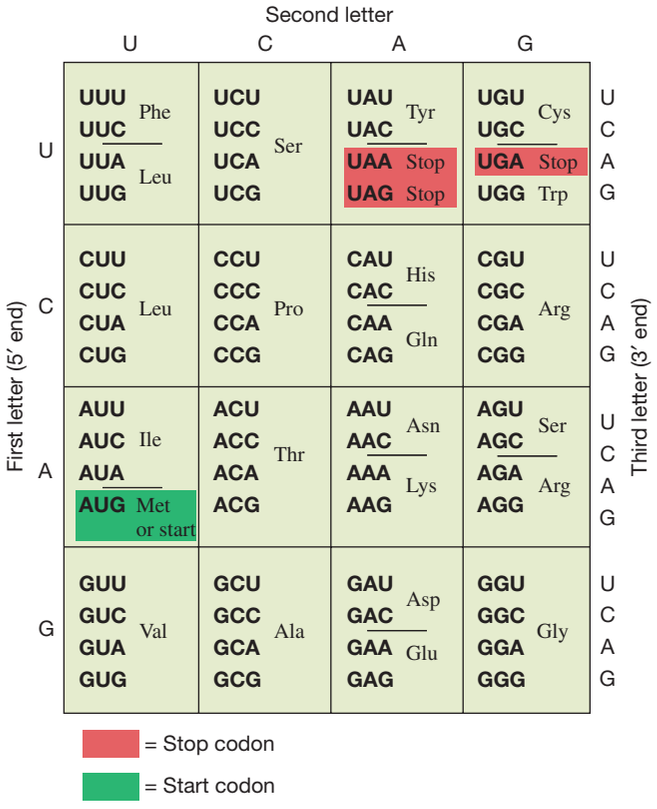

FIGURE **12-5** **The genetic code.**

The genetic code specifies all possible combinations of the three bases that comprise codons in mRNA. Of the 64 possible codons, 61 specify amino acids (see Fig. 3-16 for an explanation of abbreviations). The codon AUG specifies the amino acid methionine and also signals the ribosome to initiate translation ("start"). Three codons—UAA, UGA, and UAG—do not specify amino acids; they terminate protein synthesis ("stop").

DNA sequence from which the message is transcribed, are complementary to the sequences in Figure 12-5. For example, the mRNA codon for the amino acid methionine is 5′—AUG—3′. It is transcribed from the DNA base sequence 3′—TAC—5′, and the corresponding tRNA anticodon is 3′—UAC—5′.

The genetic code is virtually universal

Perhaps the single most remarkable feature of the code is that it is essentially universal. Over the years, biologists have examined the genetic code in a diverse array of species and found it the same in organisms as different as the bacterium *E. coli,* redwood trees, jellyfish, and humans. These findings strongly suggest the code is an ancient legacy that evolved very early in the history of life (see Chapter 20).

Scientists have discovered some very minor exceptions to the universality of the genetic code. In several unicellular protozoa, UAA and UGA code for the amino acid glutamine instead of functioning as stop signals. Other exceptions are found in mitochondria, which contain their own DNA and protein synthesis machinery for some genes (see Chapters 4 and 20). These slight coding differences vary with the organism, but keep in mind that in each case, all the other coding assignments are identical to the standard genetic code.

The genetic code is redundant

Given 64 possible codons and only 20 common amino acids, it is not surprising that more than 1 codon specify certain amino acids. This redundancy in the genetic code has certain characteristic patterns. The codons CCU, CCC, CCA, and CCG are "synonymous" in that they all code for the amino acid proline. The only difference among the 4 codons involves the nucleotide at the 3′ end of the triplet. Although the code may be read three nucleotides at a time, only the first two nucleotides seem to contain specific information for proline. A similar pattern can be seen for several other amino acids. Only methionine and tryptophan are specified by single codons. Each of the other amino acids is specified by 2 to 6 different codons.

Crick first proposed this apparent breach of the base-pairing rules as the **wobble hypothesis.** He reasoned that the third nucleotide of a tRNA anticodon (which is the 5′ base of the anticodon sequence) may sometimes form hydrogen bonds with more than one kind of third nucleotide (the 3′ base) of a codon. Investigators later established this experimentally by determining the anticodon sequences of tRNA molecules and testing their specificities in artificial systems. Some tRNA molecules can recognize as many as three separate codons differing in their third nucleotide but specifying the same amino acid.

Review

- Sketch a simple flow diagram that shows the relationships among the following: RNA, translation, DNA, transcription, and protein.
- How was the genetic code deciphered?

BiologyNow™ Assess your understanding of **information flow from DNA to protein** by taking the pretest on your BiologyNow CD-ROM.

TRANSCRIPTION

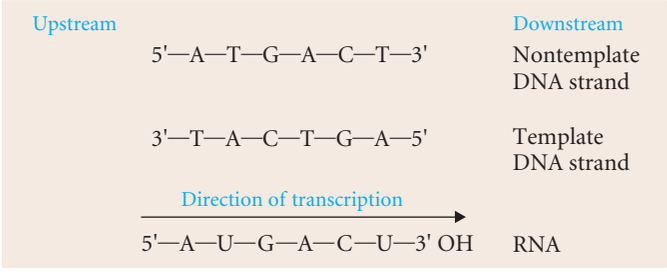
Learning Objective

5 Compare the processes of transcription and DNA replication, identifying both similarities and differences.

Now that we have presented an overview of information flow from DNA to RNA to protein, let's examine the entire process more closely. In transcription, most RNA is synthesized by **DNA-dependent RNA polymerases,** enzymes present in all cells. These enzymes require DNA as a template and have many similarities to the DNA polymerases discussed in Chapter 11. Like DNA polymerases, they carry out synthesis in the 5′ ⟶ 3′ direction; that is, they begin at the 5′ end of the RNA molecule being synthesized and then continue to add nucleotides at the 3′ end until the molecule is complete (Fig. 12-6). DNA-dependent RNA polymerases use nucleotides with three phosphate groups as substrates, removing two of the phosphates as the nucleotides are covalently linked to the 3′ end of the RNA. Like DNA replication and the hydrolysis of ATP, these reactions are strongly exergonic (see Chapter 6).

Whenever nucleic acid molecules associate by complementary base pairing, the two strands are **antiparallel.** Just as the two paired strands of DNA are antiparallel, the template strand of the DNA and the complementary RNA strand are also antiparallel. Therefore, as shown in Fig. 12-6, when transcription takes place, as RNA is synthesized in its 5′ ⟶ 3′ direction, the DNA template is read in its 3′ ⟶ 5′ direction.

Scientists conventionally refer to a sequence of bases in a gene or the mRNA sequence transcribed from it as upstream or downstream of some reference point. **Upstream** is toward the 5′ end of the mRNA sequence or the 3′ end of the template DNA strand. **Downstream** is toward the 3′ end of the RNA or the 5′ end of the template DNA strand.



The synthesis of mRNA includes initiation, elongation, and termination

In both bacteria and eukaryotes, the nucleotide sequence in DNA to which RNA polymerase initially binds is called the **promoter.** Because the promoter is not transcribed, RNA polymerase moves past the promoter to begin transcription of the protein-coding sequence of DNA. Different genes may have slightly different promoter sequences, so the cell can direct which genes are transcribed at any one time. Bacterial promoters are usually about 40 bases long and lie in the DNA just upstream of the point at which transcription will begin. Once RNA polymerase has recognized the correct promoter, it unwinds the DNA double helix and *initiates* transcription. Unlike DNA synthesis, RNA synthesis does not require a primer. However, transcription requires several proteins in addition to RNA polymerase; we discuss these in Chapter 13.

As Figure 12-6 illustrates, the first nucleotide at the 5′ end of a new mRNA chain initially retains its triphosphate group. However, during the *elongation* stage of transcription, as each additional nucleotide is incorporated at the 3′ end of the growing RNA molecule, two of its phosphates are removed in an exergonic reaction that leaves the remaining phosphate to become part of the sugar-phosphate backbone (as in DNA replication). The last nucleotide to be incorporated has an exposed 3′-hydroxyl group.

Elongation of RNA continues until RNA polymerase recognizes a stop signal termination sequence consisting of a set of specific base sequences on the DNA template. This signal leads to a separation of the enzyme from both the template DNA and the newly synthesized RNA. Different mechanisms in bacteria and eukaryotes terminate transcription. In bacteria, transcription stops at the end of the stop signal. When RNA polymerase comes to the stop signal, it releases both the DNA template and the new RNA strand. In eukaryotic cells, RNA polymerase adds nucleotides to the mRNA molecule after it passes the stop signal. The 3′ end of the mRNA becomes separated from RNA polymerase about 10 to 35 nucleotides past the stop signal.

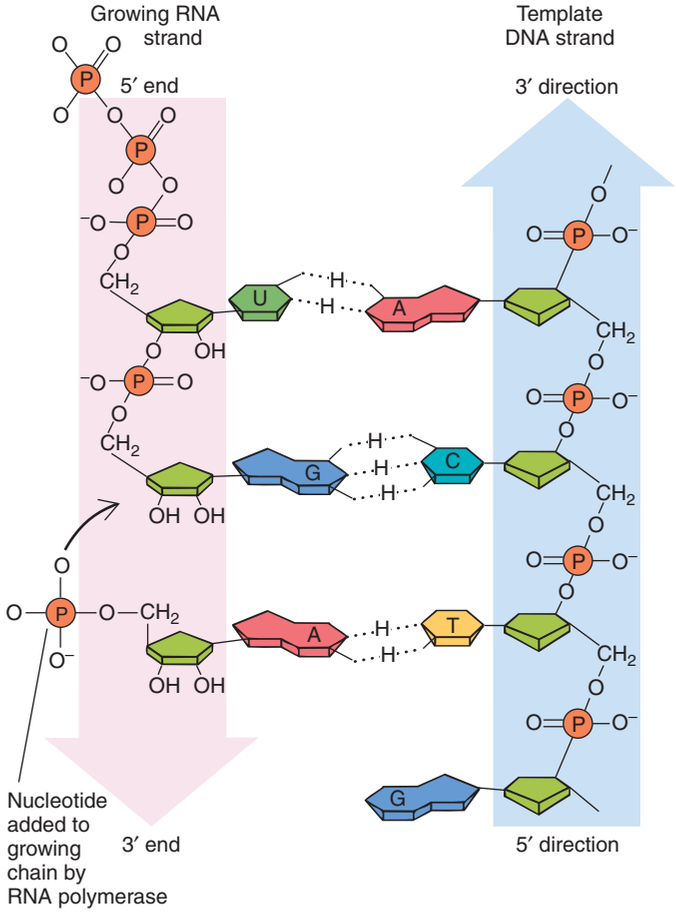


FIGURE **12-6** **Transcription.**
Incoming nucleotides with three phosphates pair with complementary bases on the template DNA strand *(right)*. RNA polymerase cleaves two phosphates *(not shown)* from each nucleotide and covalently links the remaining phosphate to the 3′ end of the growing RNA chain. Thus, RNA, like DNA, is synthesized in the 5′ ⟶ 3′ direction.

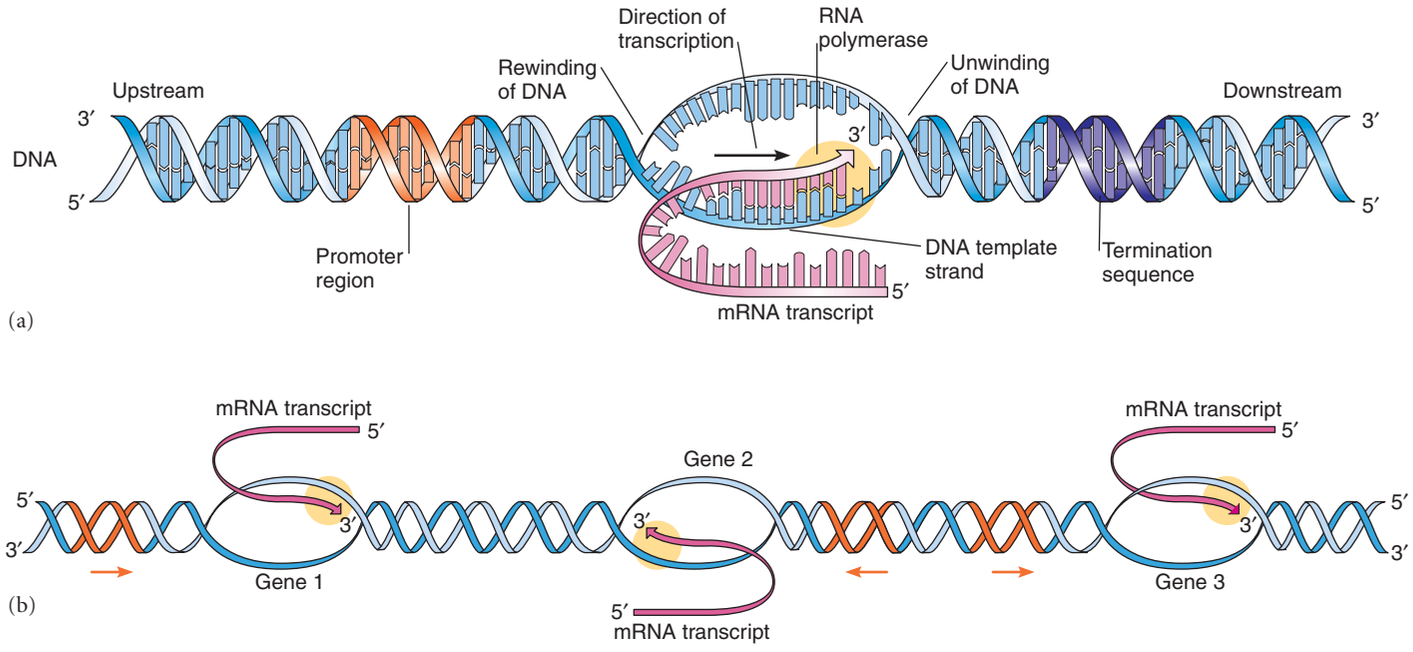
Usually only one strand in a protein-coding region of DNA is used as a template (Fig. 12-7a). For example, consider a segment of DNA that contains the following DNA base sequence in the template strand:

3′—TAACGGTCT—5′

If the complementary DNA strand

5′—ATTGCCAGA—3′

were used as a template, a message would be produced specifying an entirely different (and generally nonfunctional) protein. However, that only one strand is transcribed does not mean the same strand is always the template for all genes throughout the length of a chromosome-sized DNA molecule. Instead, a particular strand may serve as the template strand for some genes and the nontemplate strand for others (Fig. 12-7b).



ACTIVE FIGURE **12-7** **The synthesis of mRNA.**

(a) The mRNA is synthesized in the 5′ ⟶ 3′ direction from the template strand of the DNA molecule. Transcription starts downstream from a DNA promoter sequence, to which the RNA polymerase initially binds. Termination signals downstream from the protein-coding sequences, signal the RNA polymerase to stop transcription and be released from the DNA. **(b)** Usually only one of the two strands is transcribed for a given gene, but the opposite strand may be transcribed for a neighboring gene. Each transcript starts at its own promoter *(orange region).*

Biology Now™ Watch **transcription** unfold by clicking on this figure on your BiologyNow CD ROM.

Messenger RNA contains base sequences that do not directly code for protein

A completed mRNA contains more than the nucleotide sequence that codes for a protein. Figure 12-8 shows a typical bacterial mRNA. (The unique features of eukaryotic mRNA are discussed later in the chapter.) In both bacteria and eukaryotes, RNA polymerase starts transcription of a gene upstream of the protein-coding DNA sequence. As a result, the mRNA has a noncoding **leader sequence** at its 5′ end. The leader has recognition signals for ribosome binding, which properly position the ribosomes to translate the message. The **start codon** follows the leader sequence and signals the beginning of the **coding sequence** that contains the actual message for the polypeptide. Unlike eukaryotic cells, it is common for one or more polypeptides to be encoded by a single mRNA molecule in bacterial cells (see Chapter 13). At the end of each coding sequence, a **stop codon** signals the end of the protein. The stop codons—UAA, UGA, and UAG— end both bacterial and eukaryotic messages. They are followed by noncoding 3′ **trailing sequences,** which vary in length.

Review

- In what ways are DNA polymerase and RNA polymerase similar? How do they differ?
- A certain template DNA strand has the following nucleotide sequence:

  3′—TACTGCATAATGATT— 5′

  What would be the sequence of codons in the mRNA transcribed from this strand? What would be the nucleotide sequence of the complementary nontemplate DNA strand?

TRANSLATION

Learning Objectives

6 Identify the features of tRNA that are important in decoding genetic information and converting it into "protein language."
7 Explain how ribosomes function in protein synthesis.
8 Diagram the processes of initiation, elongation, and termination in protein synthesis.

In eukaryotes, mRNA must move from the nucleus (the site of transcription) to the cytosol (the site of translation or polypeptide synthesis). No such movement occurs in bacteria, which lack a nucleus. Translation adds another level of complexity to the process of information transfer because it involves conversion of the triplet nucleic acid code to the 20–amino-acid alphabet of proteins. The structural differences between a polynucleotide chain and a polypeptide chain prohibit amino acids from directly interacting with an mRNA molecule to make a protein. Translation requires the coordinated functioning of more than 100 kinds of macromolecules, including the protein and RNA components of the ribosomes, mRNA, and amino acids linked to tRNAs.

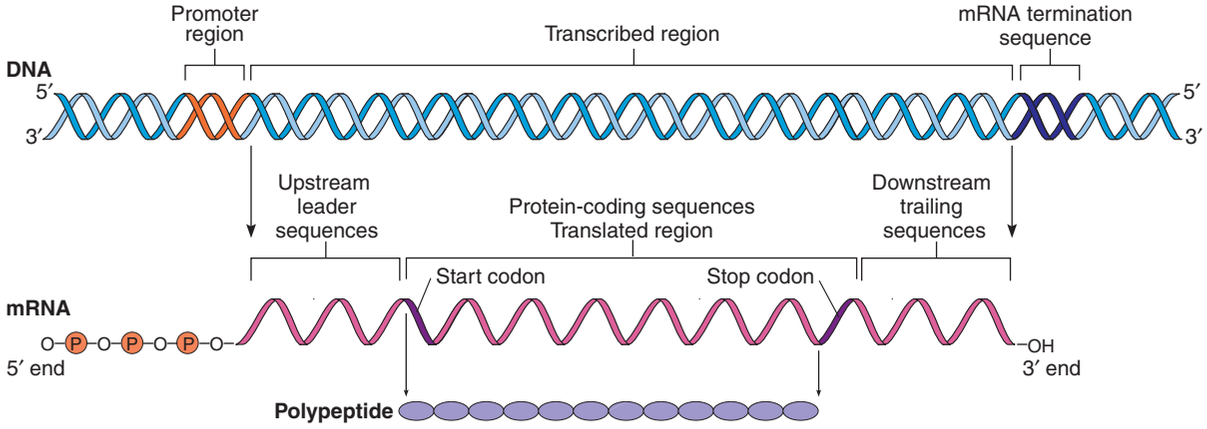

FIGURE **12-8** **Bacterial mRNA.**

This figure compares a bacterial mRNA with the region of DNA from which it was transcribed. RNA polymerase recognizes, but does not transcribe, promoter sequences in the DNA. Initiation of RNA synthesis occurs five to eight bases downstream from the promoter. Ribosome recognition sites are located in the 5′ mRNA upstream leader sequences. Protein-coding sequences begin at a start codon, which follows the leader sequences, and end at a downstream stop codon near the 3′ end of the molecule. Downstream trailing sequences, which vary in length, follow the protein-coding sequences.

Amino acids are joined by *peptide bonds* to form proteins (see Chapter 3). This joining links the amino and carboxyl groups of adjacent amino acids. The translation process ensures both that peptide bonds form and that the amino acids link in the correct sequence specified by the codons in the mRNA.

An amino acid is attached to tRNA before incorporation into a polypeptide

How do the amino acids align in the proper sequence so they can link together? Crick proposed that a molecule was needed to serve as an "adapter" in protein synthesis and bridge the gap between mRNA and proteins. Crick's adapters turned out to be tRNA molecules, as mentioned earlier. DNA contains tRNA genes that are transcribed to form the tRNAs. Each kind of tRNA molecule binds to a specific amino acid. Amino acids are covalently linked to their respective tRNA molecules by specific enzymes, **aminoacyl-tRNA synthetases,** which use ATP as an energy source. The resulting complexes, called **aminoacyl-tRNAs,** bind to the mRNA coding sequence to align the amino acids in the correct order to form the polypeptide chain.

The tRNAs are polynucleotide chains 70 to 80 nucleotides long, each with several unique base sequences, as well as some sequences that are common to all (Fig. 12-9). Although considerably smaller than mRNA or rRNA molecules, tRNA molecules have a complex structure. A tRNA molecule has several properties: (1) It has an anticodon, a specific complementary binding sequence for the correct mRNA codon; (2) it is recognized by a specific aminoacyl-tRNA synthetase that adds the correct amino acid; (3) it has an attachment site for the specific amino acid specified by the anticodon (the site lies about 180 degrees from the anticodon) and (4) it is recognized by ribosomes.

Complementary base-pairing within each tRNA molecule causes it to be doubled back and folded. Three or more loops of unpaired nucleotides are formed, one of which contains the anticodon. The amino acid–binding site is at the 3′ end of the molecule. The carboxyl group of the amino acid is bound to the exposed 3′ hydroxyl group of the terminal nucleotide, leaving the amino group of the amino acid free to participate in peptide bond formation. The pattern of folding in tRNAs keeps a constant distance between the anticodon and amino acid, allowing precise positioning of the amino acids during translation.

The components of the translational machinery come together at the ribosomes

The importance of ribosomes and of protein synthesis in cell metabolism is exemplified by a rapidly growing *E. coli* cell, which contains some 15,000 ribosomes—nearly one third of the total mass of the cell. Although bacterial and eukaryotic ribosomes are not identical, ribosomes from all organisms share many fundamental features and basically work in the same way. Ribosomes consist of two subunits, both made up of protein (about 40% by weight) and rRNA (about 60% by weight). Unlike mRNA and tRNA, rRNA does not transfer specific information but instead has catalytic functions. The ribosomal proteins do not appear to be catalytic but instead contribute to the overall structure of the ribosome.

Researchers have isolated each ribosomal subunit intact in the laboratory, then separated each into its RNA and protein constituents. In bacteria, the smaller of these subunits contains 21 proteins and one rRNA molecule, and the larger subunit contains 34 proteins and two rRNA molecules. Under certain conditions researchers can reassemble each subunit into a functional form by adding each component in its correct order. Using this approach, together with sophisticated electron microscopic studies, researchers have determined the 3-D structure of the ribo-

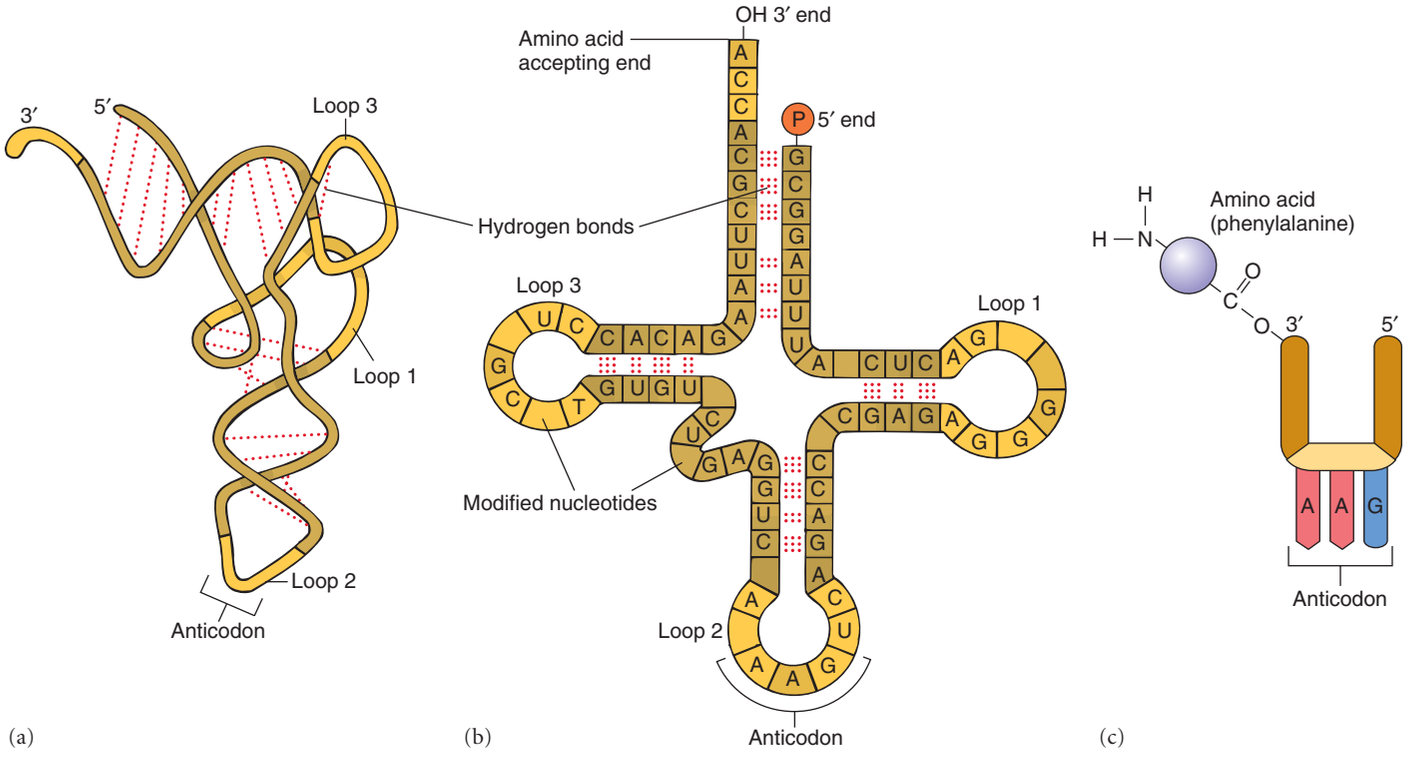

FIGURE **12-9** **Three representations of a tRNA molecule.**

(a) The 3-D shape of a tRNA molecule is determined by hydrogen bonds formed between complementary bases. **(b)** One loop contains the anticodon; these unpaired bases pair with a complementary mRNA codon. The amino acid attaches to the terminal nucleotide at the hydroxyl (OH) 3′ end. **(c)** This diagram of an aminoacyl-tRNA shows that the amino acid attaches to tRNA by its carboxyl group, leaving its amino group exposed for peptide bond formation.

some (Fig. 12-10a), as well as how it is assembled in the living cell. The large subunit contains a depression on one surface into which the small subunit fits. During translation, the mRNA fits in a groove between the contact surfaces of the two subunits.

The structure of the ribosome has four binding sites, one for mRNA and three for tRNAs. Thus the ribosome holds not only the mRNA template but also the aminoacyl-tRNA molecules and the growing polypeptide chain in the correct orientation so the genetic code can be read and the next peptide bond formed. Transfer RNA molecules attach to three depressions on the ribosome, the A, P, and E binding sites (Fig. 12-10b). The **P site,** or peptidyl site, is so named because the tRNA holding the growing polypeptide chain occupies the P site. The **A site** is named the aminoacyl site because the aminoacyl-tRNA delivering the next amino acid in the sequence binds at this location. The **E site** (for *exit*) is where tRNAs that have delivered their amino acids to the growing polypeptide chain exit the ribosome.

Translation begins with the formation of an initiation complex

The process of protein synthesis has three distinct stages: initiation, repeating cycles of elongation, and termination. Initiation

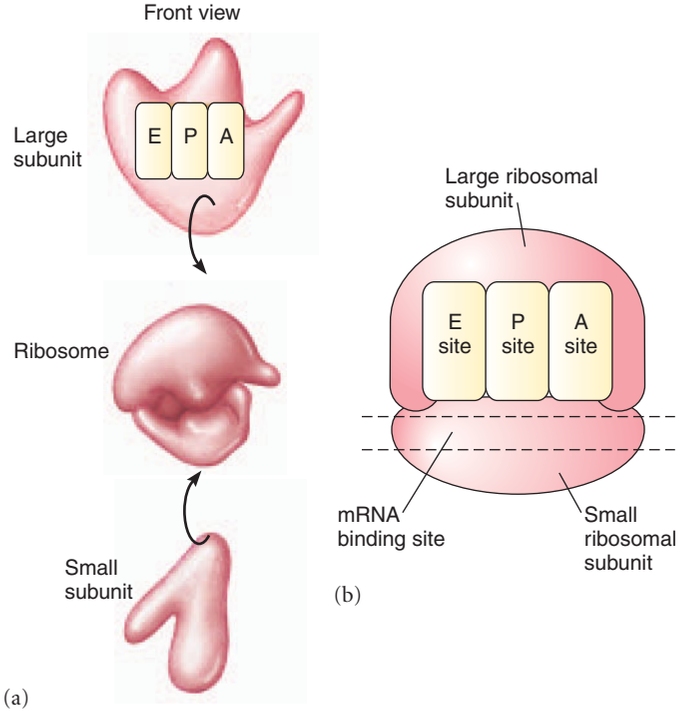

FIGURE **12-10** **Ribosome structure.**

(a) This model of a ribosome is based on a 3-D reconstruction of electron microscopic images. A ribosome consists of two subunits, one large and one small. **(b)** The mRNA passes through a groove between the two ribosomal subunits. Each ribosome contains three binding sites—the A, P, and E sites—that play an important role in protein synthesis.

of protein synthesis is essentially the same in all organisms. Here we describe initiation in bacteria and then briefly discuss some differences between bacterial and eukaryotic initiation.

The **initiation** of translation uses proteins called **initiation factors,** which become attached to the small ribosomal subunit. In bacteria, three different initiation factors attach to the small subunit, which then binds to the mRNA molecule in the region of the AUG start codon (Fig. 12-11, step ①). A leader sequence upstream (toward the 5′ end) of the AUG helps the ribosome identify the AUG sequence that signals the beginning of the mRNA code for a protein.

The tRNA that bears the first amino acid of the polypeptide is the **initiator tRNA.** The amino acid methionine is bound to the initiator tRNA, and as a result, the first amino acid on new polypeptides is methionine. (Quite often, the methionine is removed later). In bacteria, the initiator methionine is modified by the addition of a one-carbon group derived from formic acid, and is designated *fMet* for *N*-formylmethionine. The fMet-initiator tRNA, which has the anticodon 3′—UAC—5′, binds to the AUG start codon, releasing one of the initiation factors in the process (Fig. 12-11, step ②). The **initiation complex** is complete when the large ribosomal subunit binds to the small subunit, and the remaining initiation factors are released (Fig. 12-11, step ③).

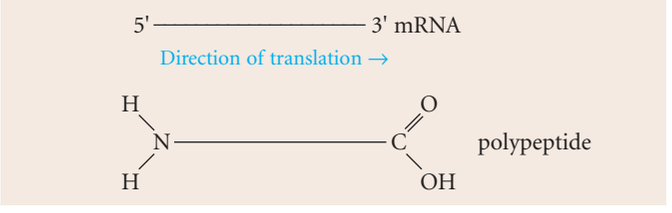
In eukaryotes, initiation of translation differs in three respects. One, the methionine of the initiator tRNA is unmodified. Two, instead of a leader sequence to help identify the start codon on mRNA, the start codon is *embedded* within a short sequence indicating the site of translation initiation. Three, the initiation complex in eukaryotes, which contains perhaps 10 protein factors, is more complex than in bacteria.

During elongation amino acids are added to the growing polypeptide chain

Figure 12-12 outlines the four steps in a cycle of **elongation,** the stage of translation in which other amino acids are added to the growing polypeptide. Elongation is essentially the same in bacteria and eukaryotes. In step ①, the appropriate aminoacyl-tRNA recognizes the codon in the A site and ② binds there by specific base-pairing of its anticodon with the complementary mRNA codon. This binding step requires several proteins called **elongation factors.** It also requires energy from **guanosine triphosphate (GTP),** an energy transfer molecule similar to ATP.

The amino group of the amino acid at the A site is now aligned with the carboxyl group of the preceding amino acid at the P site. In step ③ of elongation, a peptide bond forms between the amino group of the new amino acid and the carboxyl group of the preceding amino acid. In this way, the amino acid attached at the P site is released from its tRNA and attaches to the aminoacyl-tRNA at the A site. This reaction is spontaneous (it does not require additional energy), because ATP transferred energy during formation of the aminoacyl-tRNA. Peptide bond formation does, however, require the enzyme **peptidyl transferase.** Remarkably, this enzyme is not a protein but an rRNA component of the large ribosomal subunit. Such an RNA catalyst is known as a **ribozyme.**

Recall from Chapter 3 that polypeptide chains have direction, or polarity. The amino acid on one end of the polypeptide chain has a free amino group (the amino end), and the amino acid at the other end has a free carboxyl group (the carboxyl end). Protein synthesis always proceeds from the amino end to the carboxyl end of the growing polypeptide chain:



In step ④ of elongation, known as **translocation,** the ribosome moves down the mRNA by one codon. As a result, the

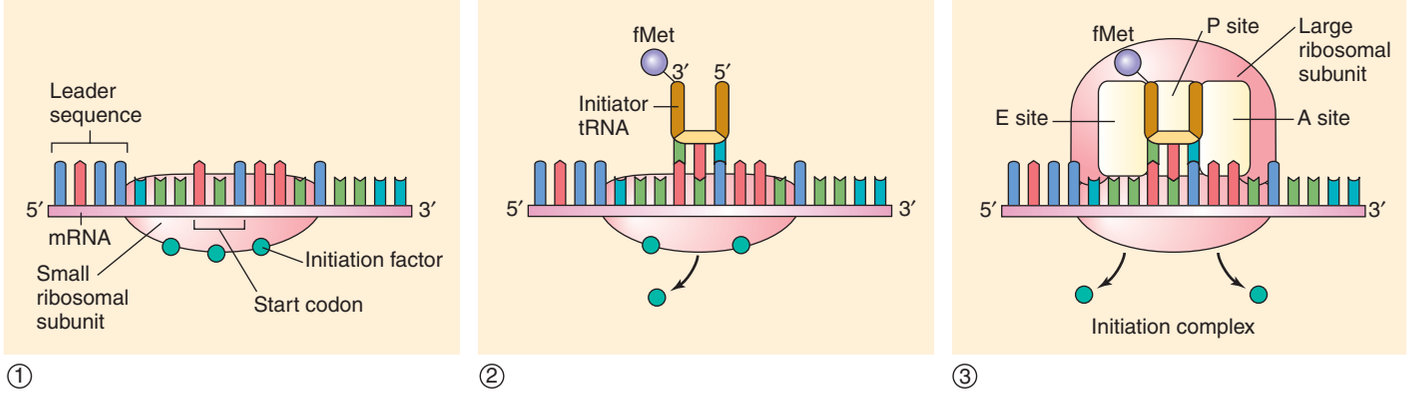


FIGURE **12-11** **The initiation of translation in bacteria.**

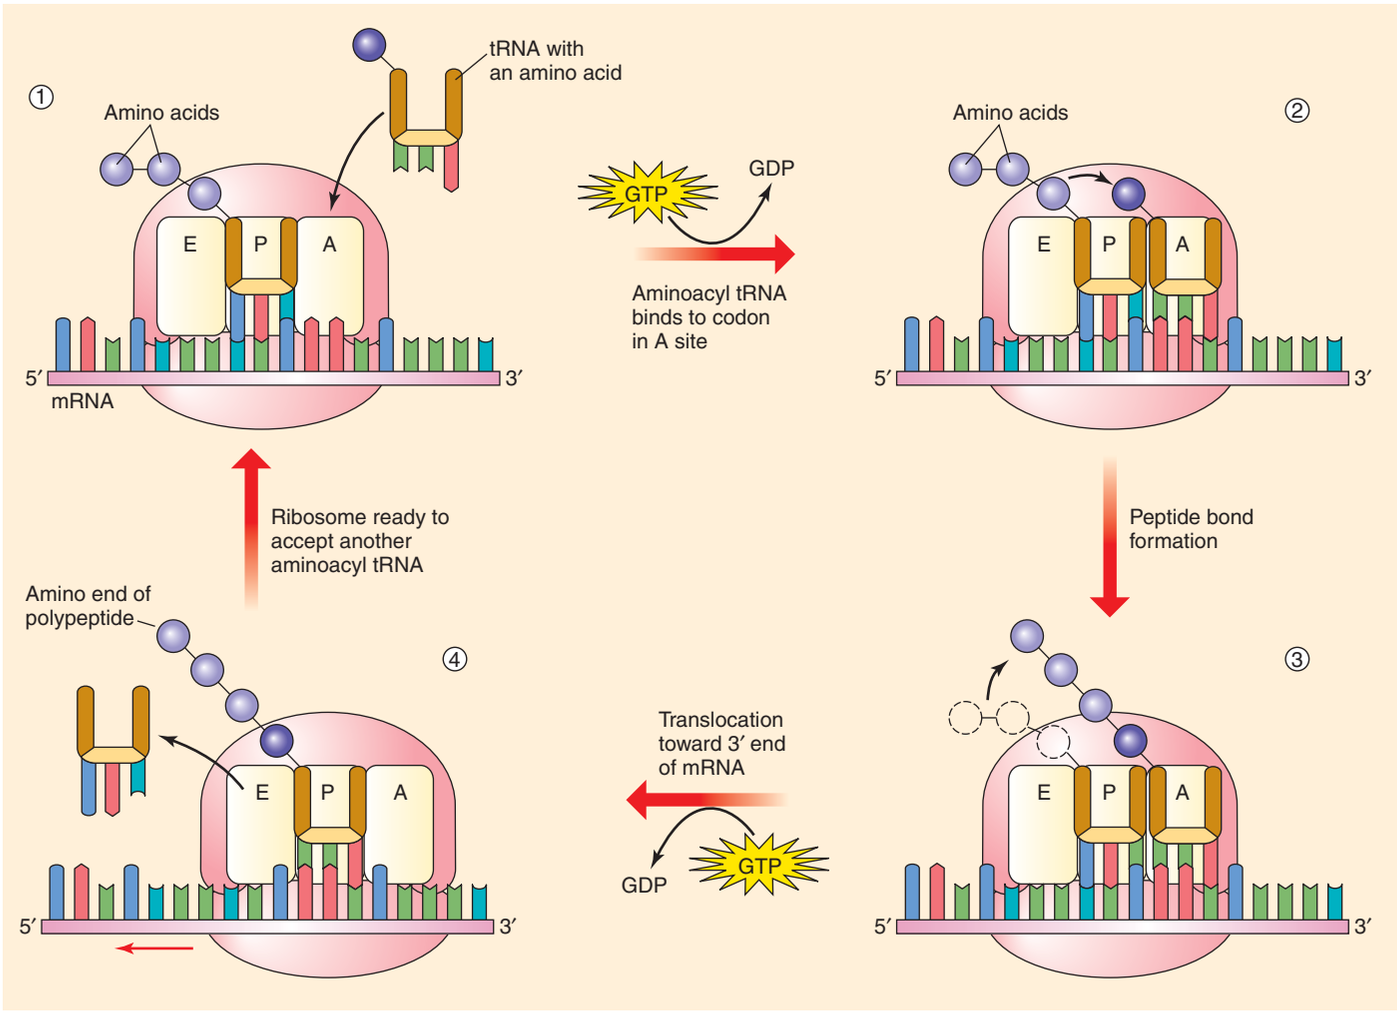
Initiation involves a ribosome, an mRNA, an initiator tRNA to which formylated methionine (fMet) is bound, and three different protein initiation factors. ① The small ribosomal subunit binds to the mRNA at the AUG start codon. The leader sequence upstream of the AUG sequence helps the ribosome identify the AUG sequence. ② The initiator tRNA binds to the start codon, and one of the initiation factors is released. ③ When the large ribosomal subunit binds to the small subunit and the remaining initiation factors are released, the initiation complex is complete.



ACTIVE FIGURE **12-12** **An elongation cycle in translation.**

Each repetition of the elongation process adds one amino acid to the growing polypeptide chain. This illustration begins after a short chain of amino acids has formed. ① The polypeptide chain is covalently bonded to the tRNA that carries the amino acid most recently added to the chain. This tRNA is in the P site of the ribosome. ② An aminoacyl-tRNA binds to the A site by complementary base-pairing between the tRNA's anticodon and the mRNA's codon. ③ The growing polypeptide chain detaches from the tRNA molecule in the P site and becomes attached by a peptide bond to the amino acid linked to the tRNA at the A site. ④ In the translocation step, the ribosome moves one codon toward the 3′ end of mRNA. As a result, the growing polypeptide chain is transferred to the P site. The uncharged tRNA in the E site exits the ribosome.

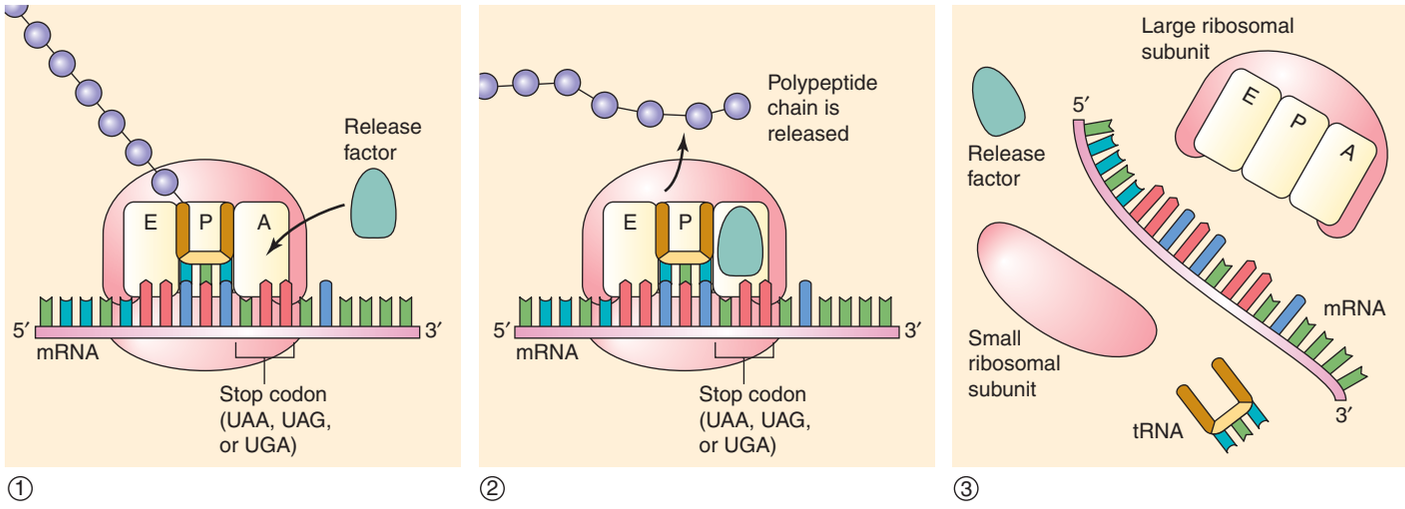
BiologyNow™ Learn more about **protein synthesis** by clicking on this figure on your BiologyNow CD ROM.

mRNA codon specifying the next amino acid in the polypeptide chain becomes positioned in the unoccupied A site. The translocation process requires energy, which again GTP supplies. The uncharged tRNA—that is, the tRNA without an attached amino acid—is moved from the P site to the E site. From there it exits the ribosome and joins the cytosolic pool of tRNAs.

Because translocation involves movement of the ribosome in the 3′ direction along the mRNA molecule, translation always proceeds in the 5′ to 3′ direction. Each peptide bond forms in a fraction of a second; by repeating the elongation cycle, an average-sized protein of about 360 amino acids is assembled by a bacterium in about 18 seconds, and by a eukaryotic cell in a little over 1 minute.

One of three stop codons signals the termination of translation

In **termination,** the final stage of translation, the synthesis of the polypeptide chain is terminated by a **release factor,** a protein that recognizes the stop codon at the end of the coding sequence. (No tRNA molecule binds to a stop codon, so the codon is available for binding by the release factor.) When the A site binds to the release factor, the bond between the tRNA in the P site and the last amino acid of the polypeptide chain breaks (Fig. 12-13). This hydrolysis reaction frees the newly synthesized polypeptide and also separates the translation complex into its parts: the mRNA molecule, the release factor, the tRNA molecule in the P site, and the large and small ribosomal



subunits. The two ribosomal subunits can be used to form a new initiation complex with another mRNA molecule.

FIGURE 12-13 The termination of translation.

No tRNA molecules exist with an anticodon complementary to a stop codon. ① When the ribosome reaches a stop codon, the A site binds to a protein release factor. ② The release factor hydrolyzes the bond between the polypeptide chain and the tRNA, causing the release of the polypeptide chain from the tRNA molecule in the P site. ③ The remaining parts of the translation complex dissociate.

A polyribosome is a complex of one mRNA and many ribosomes

In *E. coli* and other bacteria, transcription and translation are *coupled* (Fig. 12-14). The end of the mRNA molecule synthesized first during transcription is also the first translated to form a polypeptide. Ribosomes bind to the 5′ end of the growing mRNA and initiate translation long before the message is fully synthesized. As many as 15 ribosomes may bind to a single mRNA. Molecules of mRNA bound to clusters of ribosomes are called **polyribosomes,** or *polysomes.* Polyribosomes also occur in eukaryotic cells.

Although many polypeptide chains can be actively synthesized on a single mRNA at any one time, the half-life of mRNA molecules in bacterial cells is only about 2 minutes. (Half-life is the time it takes for half the molecules to be degraded.) Usually, degradation of the 5′ end of the mRNA begins even before the first polypeptide is complete. Once the ribosome recognition sequences at the 5′ end of the mRNA have been degraded, no more ribosomes attach and initiate protein synthesis.

VARIATIONS IN PROTEIN SYNTHESIS IN DIFFERENT ORGANISMS

Learning Objectives

9 Compare bacterial and eukaryotic mRNAs, and explain the functional significance of their structural differences.

10 Describe the differences in translation in bacterial and eukaryotic cells.

11 Describe retroviruses and the enzyme reverse transcriptase.

Although the basic mechanisms of transcription and translation are quite similar in all organisms, some significant differences separate bacteria and eukaryotes. Some result from differences in cell structure. Bacterial mRNA is translated as it is transcribed from DNA. This cannot occur in eukaryotes, because eukaryotic chromosomes are confined to the cell nucleus, and protein synthesis takes place in the cytosol. Before it is translated, eukaryotic mRNA is transported through the pores in the nuclear envelope and into the cytosol.

Many other differences separate bacterial and eukaryotic mRNA. Bacterial mRNAs are used immediately after transcription, without further processing. In eukaryotes, the original transcript, known as **precursor mRNA,** or **pre-mRNA,** is modified in several ways while it is still in the nucleus. These *post-transcriptional modification and processing* activities prepare mature mRNA for transport and translation (Fig. 12-15).

Modification of the eukaryotic message begins when the growing RNA transcript is about 20 to 30 nucleotides long. At that point, enzymes add a **5′ cap** to the 5′ end of the mRNA chain. The cap is in the form of an unusual nucleotide, 7-methylguanylate, which is guanosine monophosphate (GMP) with a methyl group added to one of the nitrogens in the base. Eukaryotic ribosomes cannot bind to an uncapped message.

Capping may also protect the RNA from certain types of degradation and may therefore partially explain why eukaryotic mRNAs are much more stable than bacterial mRNAs. Eukaryotic mRNAs have half-lives ranging from 30 minutes to as long as 24 hours. The average half-life of an mRNA molecule in a mammalian cell is about 10 hours, compared with 2 minutes in a bacterial cell.

A second modification of eukaryotic mRNA, known as **polyadenylation,** may occur at the 3′ end of the molecule. Near the 3′ end of a completed message usually lies a sequence of bases that serves as a signal for adding many adenine-containing nucleotides, known as a **poly-A tail** (for polyadenylated). Enzymes in the nucleus recognize the poly-A tail and cut the mRNA molecule at that site. This is followed by the enzymatic addition of a string of 100 to 250 adenine nucleotides to the 3′ end. Scientists do not completely understand the function of polyadenylation, although evidence indicates it helps export the mRNA from the nucleus, stabilizes some mRNAs against degradation in the cytosol, and facilitates initiation of translation.

Both noncoding and coding sequences are transcribed from eukaryotic genes

One of the greatest surprises in the history of molecular biology was the finding that most eukaryotic genes have **interrupted coding sequences;** that is, long sequences of bases within the protein-coding sequences of the gene do not code for amino acids in the final protein product. The noncoding regions within the gene are called **introns** (intervening sequences), as opposed to **exons** (expressed sequences), which are parts of the protein-coding sequence.

A typical eukaryotic gene may have multiple exons and introns, although the number varies. For example, the β-globin gene, which produces one component of hemoglobin, contains 2 introns; the ovalbumin gene of egg white contains 7; and the gene specifying another egg white protein, conalbumin, contains 16. In many cases, the combined lengths of the intron sequences are much greater than the combined lengths of the exons. For instance, the ovalbumin gene contains about 7700 base pairs, whereas the total of all the exon sequences is only 1859 base pairs.

When a gene that contains introns is transcribed, the entire gene is copied as a large RNA transcript, the pre-mRNA (see Fig. 12-15). A pre-mRNA molecule contains both exon and intron sequences. (Note that *intron* and *exon* refer to corresponding nucleotide sequences in both DNA and RNA.) For the pre-mRNA to be made into a functional message, it must be capped and have a poly-A tail added, and the introns must be removed and the exons spliced together to form a continuous protein-coding message.

Splicing itself occurs by several different mechanisms, depending on which type of RNA is involved. In many instances, splicing involves the association of **small nuclear ribonucleoprotein complexes (snRNPs),** which bind to the introns and catalyze the excision and splicing reactions. In some cases, the RNA within the intron acts as a ribozyme, splicing itself without the use of protein enzymes.

Posttranscriptional modification in eukaryotes is summarized as follows:

Pre-mRNA containing introns and exons ⟶ 5′ end of pre-mRNA capped with modified nucleotide ⟶ poly-A tail added to 3′ end ⟶ introns removed and exons spliced together ⟶ mature mRNA transported into cytosol ⟶ translation at ribosome

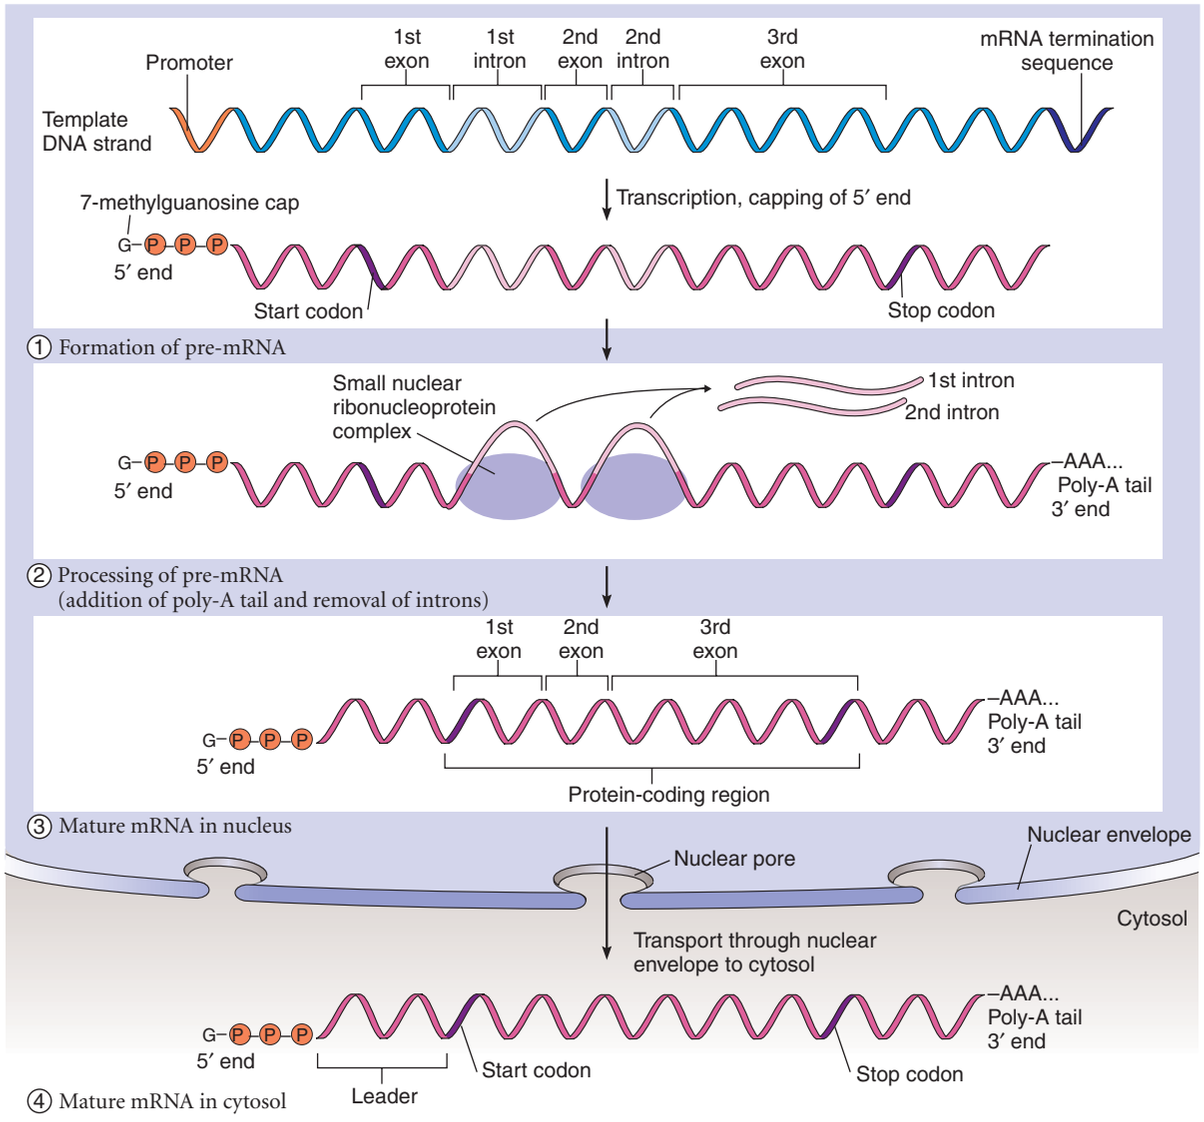

FIGURE **12-15** **Posttranscriptional modification of eukaryotic RNA.**

① A DNA sequence containing both exons and introns is transcribed by RNA polymerase to make the primary transcript, or pre-mRNA. As it is synthesized, the pre-mRNA is capped by the addition of a modified base attached "backward" (by a 5′—5′ linkage) to its 5′ end. ② A poly-A tail (100 to 250 nucleotides long) is added to the 3′ end; introns are removed, and the exons are spliced together. ③ The mature mRNA is transported through the nuclear envelope and ④ into the cytosol to be translated by a ribosome.

The evolution of eukaryotic gene structure is not completely understood

The reason for the complex structure of eukaryotic genes is a matter of ongoing debate among molecular biologists. Why do introns occur in most eukaryotic nuclear genes but not in the genes of most bacteria (or of mitochondria and chloroplasts)? How did this remarkable genetic system with interrupted coding sequences ("split genes") evolve, and why has it survived? It seems incredible that as much as 75% of the original transcript of a eukaryotic nuclear gene must be *removed* to make a working message.

In the early 1980s, Walter Gilbert of Harvard University proposed that exons are nucleotide sequences that code for **protein domains,** regions of protein tertiary structure that may have specific functions. For example, the active site of an enzyme may comprise one domain. A different domain may enable that enzyme to bind to a particular cell structure, and yet another may be a site involved in allosteric regulation (see Chapter 6). Analyses of the DNA and amino acid sequences of many eukaryotic genes have shown that most exons are too small to code for an entire protein domain, although a block of several exons can code for a domain.

Gilbert further postulated that new proteins with new functions emerge rapidly when genetic recombination produces novel combinations of exons that code for different proteins. This hypothesis has become known as *evolution by exon shuf-*

fling. It has been supported by examples such as the low-density lipoprotein (LDL) receptor protein, a protein found on the surface of human cells that binds to cholesterol transport molecules (see Chapter 5). The LDL receptor protein has domains that are related to parts of other proteins with totally different functions. However, many other genes and their corresponding proteins show no evidence of exon shuffling.

Some scientists hypothesize that introns first evolved in the nucleus of an early eukaryote and were propagated as movable genetic elements, known as *transposons* (to be discussed shortly). Regardless of how split genes originated, intron excision provides one of many ways in which present-day eukaryotes regulate expression of their genes (see Chapter 13). This opportunity for control, together with the fact that eukaryotic RNAs are far more stable than those of bacteria, may balance the energy cost of maintaining a large load of noncoding DNA.

The usual direction of information flow has exceptions

PROCESS OF SCIENCE

For several decades, a central premise of molecular biology was that genetic information always flows from DNA to RNA to protein. Through his studies of viruses, U.S. biologist Howard Temin discovered an important exception to this rule in 1964. Although viruses are not cellular organisms, they contain a single type of nucleic acid and reproduce in a host cell. Temin was studying unusual, cancer-causing tumor viruses that have RNA, rather than DNA, as their genetic material. He found that infection of a host cell by one of these viruses is blocked by inhibitors of DNA synthesis and also by inhibitors of transcription. These findings suggested that DNA synthesis and transcription are required for RNA tumor viruses to multiply and that there must be a way for information to flow in the "reverse" direction—from RNA to DNA.

Temin proposed that a **DNA provirus** forms as an intermediary in the replication of RNA tumor viruses. This hypothesis required a new kind of enzyme that would synthesize DNA using RNA as a template. In 1970, Temin and U.S. biologist David Baltimore discovered just such an enzyme, and they shared the Nobel Prize in Medicine in 1975 for their discovery. This RNA-directed DNA polymerase, also known as **reverse transcriptase,** is found in all RNA tumor viruses. (Some RNA viruses that do not produce tumors, however, replicate directly without using a DNA intermediate.) Figure 12-16 shows the steps of RNA tumor virus reproduction. Because they reverse the usual direction of information flow, viruses that require reverse transcriptase are called **retroviruses.** HIV-1, the virus that causes AIDS, is the most widely known retrovirus. As you will see in Chapter 14, the reverse transcriptase enzyme has become an extremely important research tool for molecular biologists.

Review

- What features do mature eukaryotic mRNA molecules have that bacterial mRNAs lack?
- How do retroviruses use the enzyme reverse transcriptase?

BiologyNow™ Assess your understanding of **variations in protein synthesis in different organisms** by taking the pretest on your BiologyNow CD-ROM.

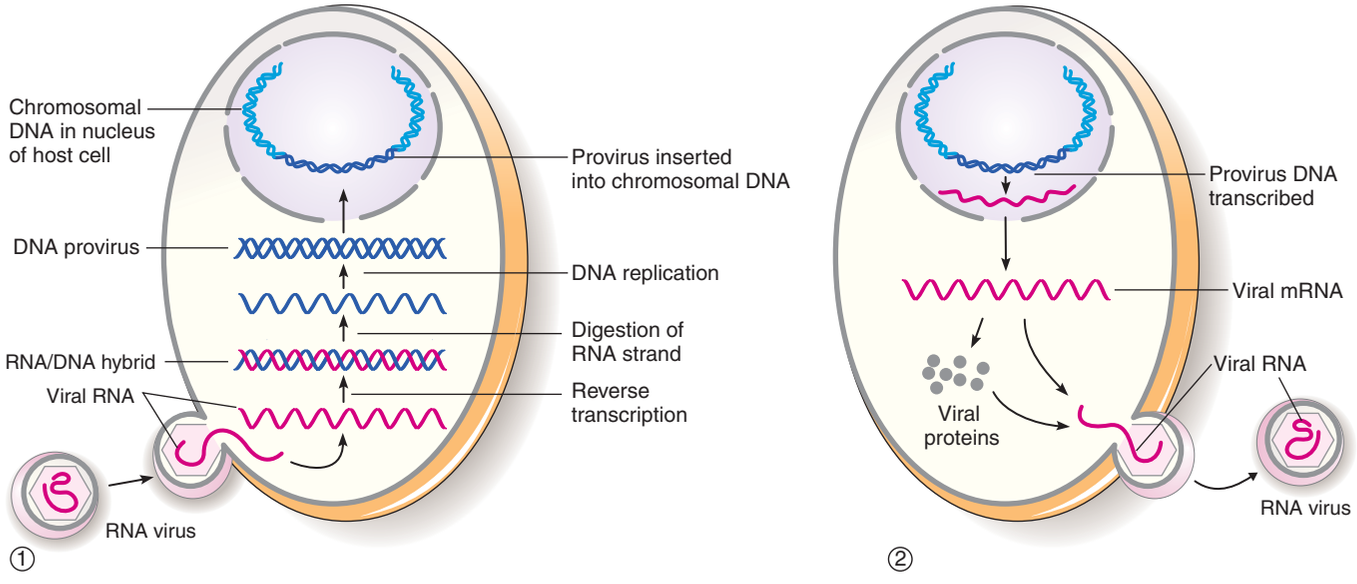

FIGURE **12-16** **The infection cycle of an RNA tumor virus.**

① After an RNA tumor virus enters the host cell, the viral enzyme reverse transcriptase synthesizes a DNA strand that is complementary to the viral RNA. Next, the RNA strand is degraded and a complementary DNA strand is synthesized, thus completing the double-stranded DNA provirus, which is then integrated into the host cell's DNA. ② The provirus DNA is transcribed, and the resulting viral mRNA is translated to form viral proteins. Additional viral RNA molecules are produced and then incorporated into mature viral particles enclosed by protein coats.

MUTATIONS AND GENES

Learning Objective

12 Give examples of the different classes of mutations that affect the base sequence of DNA, and explain the effects that each has on the protein produced.

One of the first major discoveries about genes was that they undergo **mutations,** changes in the nucleotide sequence of the DNA. However, the overall observed mutation rate is much lower than the frequency of damage to DNA, because all organisms have systems of enzymes that repair certain kinds of DNA damage.

As explained in Chapter 11, once the DNA sequence has been changed, DNA replication copies the altered sequence just as it would copy a normal sequence, making the mutation stable over an indefinite number of generations. In most cases, the mutant allele has no greater tendency than the original allele to mutate again. Mutations provide the diversity of genetic material that enables researchers to study inheritance and the molecular nature of genes. As you will see in later chapters, mutations also provide the variation necessary for evolution within a given species.

Mutation alters genes in several ways. Scientists now determine where a specific mutation occurs in a gene by using recombinant DNA methods to isolate the gene and determine its sequence of bases (see Chapter 14).

Base substitution mutations result from the exchange of one base pair for another

The simplest type of mutation, called a **base substitution,** involves a change in only one pair of nucleotides (Fig. 12-17a). Often these mutations result from errors in base pairing during the replication process. For example, a GC, CG, or TA pair might replace an AT base pair. Such a mutation may cause the altered DNA to be transcribed as an altered mRNA. The altered mRNA may then be translated into a polypeptide chain with only one amino acid different from the normal sequence.

Base substitutions that result in replacement of one amino acid by another are sometimes called **missense mutations.** Missense mutations have a wide range of effects. If the amino acid substitution occurs at or near the active site of an enzyme, the activity of the altered protein may decrease or even be destroyed. Some missense mutations involve a change in an amino acid that is not part of the active site. Others may result in the substitution of a closely related amino acid (one with very similar chemical characteristics). Such silent mutations may be undetectable if one simply examines their effect on the whole organism. Because silent mutations occur relatively frequently, the true number of mutations in an organism or a species is much greater than is actually observed.

Nonsense mutations are base substitutions that convert an amino acid–specifying codon to a stop codon. A nonsense mutation usually destroys the function of the gene product; in the case of a protein-specifying gene, the part of the polypeptide chain that follows the mutant stop codon is missing.

Frameshift mutations result from the insertion or deletion of base pairs

In **frameshift mutations,** one or two nucleotide pairs are inserted into or deleted from the molecule, altering the reading frame (Fig. 12-17b). As a result, codons downstream of the insertion or deletion site specify an entirely new sequence of amino acids. Depending on where the insertion or deletion occurs in the gene, different effects are generated. In addition to producing an entirely new polypeptide sequence immediately after the change, frameshift mutations may produce a stop codon within a short distance of the mutation. This codon terminates the already altered polypeptide chain. A frame shift in a gene specifying an enzyme usually results in a complete loss of enzyme activity.

Some mutations involve larger DNA segments

Some types of mutations are due to a change in chromosome structure. These changes usually have a wide range of effects because they involve many genes.

PROCESS OF SCIENCE

One type of mutation is caused by DNA sequences that "jump" into the middle of a gene. These movable sequences of DNA are known as **transposons,** or **transposable genetic elements.** They not only disrupt the functions of some genes but also inactivate some previously active genes. Transposons were discovered in maize (corn) by the U.S. geneticist Barbara McClintock in the 1950s. She observed that certain genes appeared to be "turned off" and "turned on" spontaneously. She deduced that the mechanism involved a segment of DNA that moved from one region of a chromosome to another, where it would inactivate a gene. However, biologists did not understand this phenomenon until the development of recombinant DNA methods and the discovery of transposons in a wide variety of organisms. We now know that transposons are segments of DNA that range from a few hundred to several thousand bases. For incorporation into a new location within the chromosome, transposons require the enzyme **transposase.** In recognition of her insightful findings, McClintock was awarded the Nobel Prize in Physiology or Medicine in 1983.

Most transposons are **retrotransposons,** which replicate by forming an RNA intermediate. Reverse transcriptase converts them to their original DNA sequence before jumping into a gene. Many retrotransposons enlist the host cell's gene expression machinery to produce reverse transcriptase. Because retrotransposons use reverse transcriptase, some biologists hypothesize that certain retrotransposons evolved from retroviruses, and vice versa. Scientists estimate that human cells have fewer than 100 retrotransposons actively jumping around. Nevertheless, retrotransposons are extremely important agents of mutation.

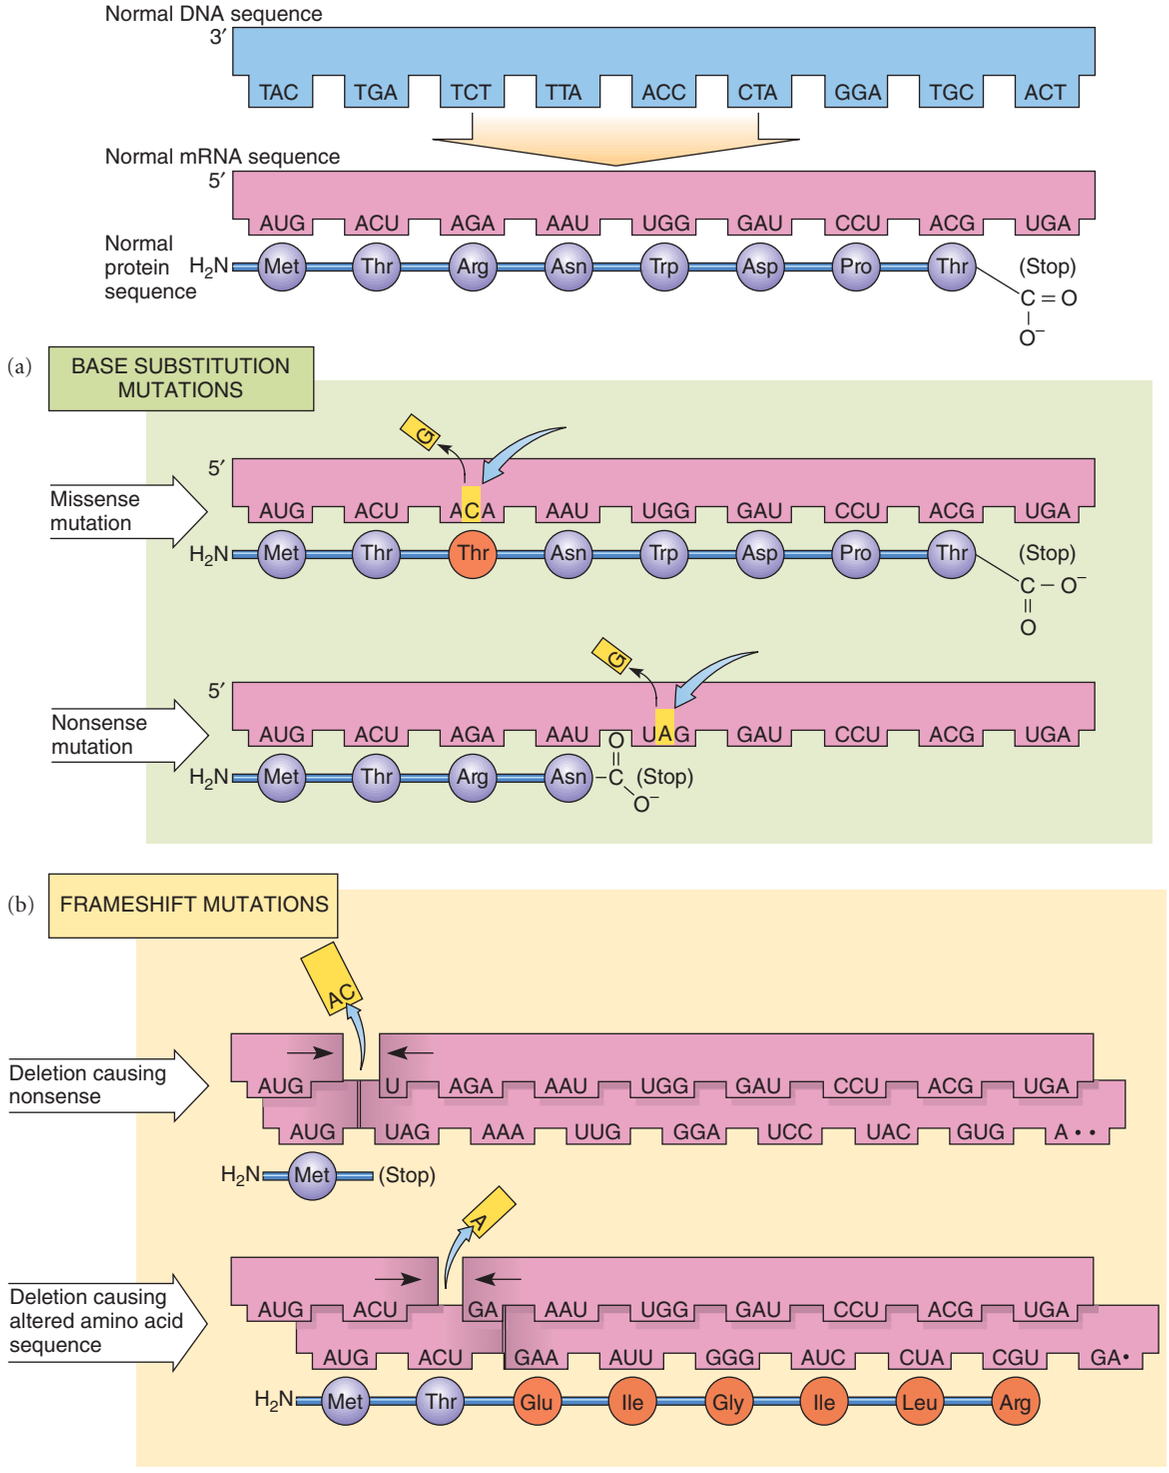

FIGURE **12-17** **Mutations.**

(a) Missense and nonsense mutations are types of base substitution mutations. A missense mutation results in a protein of normal length, but with an amino acid substitution. A nonsense mutation, caused by conversion of an amino acid–specifying codon to a stop codon, results in the production of a truncated (shortened) protein, which is usually not functional. **(b)** A frameshift mutation results from the deletion or insertion (not shown) of one or two bases, causing the base sequence following the mutation to shift to a new reading frame. A frame shift may produce a stop codon downstream of the mutation (which would have the same effect as a nonsense mutation caused by base substitution), or it may produce an entirely new amino acid sequence.

By one estimate, retrotransposons cause about 10% of naturally occurring mutations that cause noticeable phenotypic changes.

Mutations have various causes

Most types of mutations occur infrequently but spontaneously from mistakes in DNA replication or defects in the mitotic or meiotic separation of chromosomes. Some regions of DNA, known as mutational *hot spots,* are much more likely than others to undergo mutation. An example is a short stretch of repeated nucleotides, which can cause DNA polymerase to "slip" while reading the template during replication.

Mutations in certain genes increase the overall mutation rate. For example, a mutation in a gene coding for DNA polymerase may make DNA replication less precise, or a mutation in a gene coding for a repair enzyme may allow more mutations to arise as a result of unrepaired DNA damage.

Not all mutations occur spontaneously. **Mutagens,** which cause many of the types of mutations discussed previously, include various types of radiation, such as x-rays, gamma rays, cosmic rays, and ultraviolet rays. Some chemical mutagens react with and modify specific bases in the DNA, leading to mistakes in complementary base pairing when the DNA molecule is replicated. Other mutagens cause nucleotide pairs to be inserted into or deleted from the DNA molecule, changing the normal reading frame during replication.

Despite the presence of enzymes that repair damage to DNA, some new mutations do arise. In fact, each of us has some mutant alleles that either of our parents didn't have. Although some of these mutations alter the phenotype, most are not noticeable, because they are recessive.

Mutations that occur in the cells of the body (somatic cells) are not passed on to offspring. However, these mutations are of concern because somatic mutations and cancer are closely related. Many mutagens are also **carcinogens,** agents that cause cancer.

A gene is a functional unit

At the beginning of this chapter, we traced the development of ideas regarding the nature of the gene. For a time scientists found it useful to define a gene as a sequence of nucleotides that codes for one polypeptide chain. As biologists have learned more about how genes work, they have revised the definition. They now know some genes are transcribed to produce RNA molecules such as rRNA and tRNA, whereas others specify the RNA component of the snRNPs used to modify mRNA molecules. Studies have also shown that in eukaryotic cells, a single gene may produce more than one polypeptide chain by modifications in the way the mRNA is processed.

As we end this chapter, it is perhaps most useful to define a gene in terms of its product. A **gene** is a DNA nucleotide sequence that carries the information needed to produce a specific RNA or protein product. As you will see in Chapter 13, a gene includes noncoding regulatory sequences, as well as coding sequences.

Review

- What are the main types of mutations?
- What effects does each type of mutation have on the protein product produced?

BiologyNow™ Assess your understanding of **mutations and genes** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Summarize the early evidence indicating that most genes specify the structure of proteins.

- Garrod's early work on inborn errors of metabolism and that of Beadle and Tatum in the 1940s with *Neurospora* mutants provided strong evidence that genes specify proteins.

2 Outline the flow of genetic information in cells, from DNA to protein.

- The process by which information encoded in DNA specifies the sequences of amino acids in proteins involves two steps: transcription and translation.
- During **transcription,** an RNA molecule complementary to the template DNA strand is synthesized. **Messenger RNA (mRNA)** molecules contain information that specifies the amino acid sequences of polypeptide chains.
- During **translation,** a polypeptide chain specified by the mRNA is synthesized. Each sequence of three nucleotide bases in the mRNA constitutes a **codon,** which specifies one amino acid in the polypeptide chain, or a start or stop signal. Translation requires tRNAs and cell machinery, including ribosomes.

3 Compare the structures of DNA and RNA.

- RNA is formed from nucleotide subunits, each of which contains the sugar ribose, a base (uracil, adenine, guanine, or cytosine), and three phosphates. Like DNA, RNA subunits are covalently joined by a 5′—3′ linkage to form an alternating sugar-phosphate backbone.

4 Explain why the genetic code is said to be redundant and virtually universal, and discuss how these features may reflect its evolutionary history.

- The **genetic code** is read from mRNA as a series of nonoverlapping codons that specify a single sequence of amino acids. Of the 64 codons, 61 code for amino acids, and 3 codons serve as stop signals.
- The genetic code is redundant because some amino acids are specified by more than one codon. The genetic code is virtually universal, strongly suggesting that all organisms are descended from a common ancestor. Only a few minor variations are exceptions to the standard code.

5 Compare the processes of transcription and DNA replication, identifying both similarities and differences.

- **DNA-dependent RNA polymerases,** involved in RNA synthesis, have many similarities to DNA polymerases involved in DNA replication. Both enzymes carry out synthesis in the 5′ ⟶ 3′ direction. Both use nucleotides with three phosphate groups as substrates, removing two of the phosphates as the nucleotides are covalently linked to the 3′ end of the newly synthesized strand.

SUMMARY WITH KEY TERMS *(continued)*

- Just as the paired strands of DNA are **antiparallel,** the template strand of the DNA and its complementary RNA strand are also antiparallel. As a result, the DNA template strand is read in its 3′⟶ 5′ direction as RNA is synthesized in its 5′ ⟶ 3′ direction.
- The same base-pairing rules are followed as in DNA replication, except that uracil is substituted for thymine.

6 Identify the features of tRNA that are important in decoding genetic information and converting it into "protein language."

- **Transfer RNAs (tRNAs)** are the "decoding" molecules in the translation process.
- Each tRNA molecule is specific for only one amino acid. One part of the molecule contains an **anticodon,** which is complementary to a codon of mRNA. Attached to one end of the tRNA molecule is the amino acid specified by the complementary mRNA codon.
- Amino acids are covalently bound to tRNA by **aminoacyl-tRNA synthetase** enzymes.

7 Explain how ribosomes function in protein synthesis.

- **Ribosomes** bring together all the mechanical machinery necessary for translation. They couple the tRNAs to their proper codons on the mRNA, catalyze the formation of peptide bonds between amino acids, and translocate the mRNA so the next codon can be read.
- Each ribosome is made of a large and a small subunit; each subunit contains **ribosomal RNA (rRNA)** and many proteins.

8 Diagram the processes of initiation, elongation, and termination in protein synthesis.

- **Initiation** is the first stage of translation. **Initiation factors** bind to the small ribosomal subunit, which then binds to mRNA in the region of AUG, the **start codon.** The **initiator tRNA** binds to the start codon, followed by binding of the large ribosomal subunit.
- **Elongation** is a cyclic process in which amino acids are added one by one to the growing polypeptide chain. Elongation proceeds in the 5′ ⟶ 3′ direction along the mRNA. The polypeptide chain grows from its amino end to its carboxyl end.
- **Termination,** the final stage of translation, occurs when the ribosome reaches one of three **stop codons.** The A site binds to a **release factor,** which triggers the release of the completed polypeptide chain and dissociation of the translation complex.

9 Compare bacterial and eukaryotic mRNAs, and explain the functional significance of their structural differences.

- Eukaryotic genes and their mRNA molecules are more complex than those of bacteria.
- After transcription, a **5′ cap** (a modified guanosine triphosphate) is added to the 5′ end of a eukaryotic mRNA molecule. Many also have a **poly-A tail** of adenine-containing nucleotides added at the 3′ end. These modifications seem to protect eukaryotic mRNA molecules from degradation, giving them a longer life span than bacterial mRNA.
- In many eukaryotic genes the coding regions, called **exons,** are interrupted by noncoding regions, called **introns.** Both introns and exons are transcribed, but the introns are later removed from the original transcript, or **pre-mRNA,** and the exons are spliced together to produce a continuous protein-coding sequence.

10 Describe the differences in translation in bacterial and eukaryotic cells.

- Unlike eukaryotic cells, in bacterial cells transcription and translation are coupled. Translation of the bacterial mRNA molecule usually begins before the 3′ end of the transcript is completed.

11 Describe retroviruses and the enzyme reverse transcriptase.

- The flow of genetic information is reversed by **reverse transcriptase,** an enzyme associated with **retroviruses,** which synthesize DNA from an RNA template. HIV-1, the virus that causes AIDS, is a retrovirus.

12 Give examples of the different classes of mutations that affect the base sequence of DNA, and explain the effects that each has on the protein produced.

- Types of **mutations** range from disruption of a chromosome's structure to a change in only a single pair of nucleotide bases. A **base substitution** destroys the function of a protein if a codon changes so that it specifies a different amino acid (a **missense mutation,**) or becomes a stop codon (a **nonsense mutation**). A base substitution has minimal effects if the amino acid is not altered or if the codon is changed to specify a chemically similar amino acid.
- The insertion or deletion of one or two base pairs in a gene invariably destroys the function of that protein because it results in a **frameshift mutation,** which changes the codon sequences downstream from the mutation.
- One type of mutation is caused by movable DNA sequences, known as **transposons,** that "jump" into the middle of a gene. Most transposons are **retrotransposons,** which replicate by forming an RNA intermediate; reverse transcriptase converts them to their original sequence before they jump into a gene.

POST-TEST

1. Beadle and Tatum (a) predicted that tRNA molecules would have anticodons (b) discovered the genetic disease alkaptonuria (c) showed that the genetic disease sickle cell anemia is caused by a change in a single amino acid in a hemoglobin polypeptide chain (d) worked out the genetic code (e) studied the relationship between genes and enzymes in *Neurospora*
2. What is the correct order of information flow in bacterial and eukaryotic cells? (a) DNA ⟶ mRNA ⟶ protein (b) protein ⟶ mRNA ⟶ DNA (c) DNA ⟶ protein ⟶ mRNA (d) protein ⟶ DNA ⟶ mRNA (e) mRNA ⟶ protein ⟶ DNA
3. During transcription, how many RNA nucleotide bases would usually be encoded by a sequence of 99 DNA nucleotide bases? (a) 297 (b) 99 (c) 33 (d) 11 (e) answer is impossible to determine with the information given
4. The genetic code is defined as a series of _____ in _____. (a) anticodons; tRNA (b) codons; DNA (c) anticodons; mRNA (d) codons; mRNA (e) codons and anticodons; rRNA

POST-TEST *(continued)*

5. Transcription is the process by which _____ is/are synthesized. (a) mRNA only (b) mRNA and tRNA (c) mRNA, tRNA, and rRNA (d) protein (e) mRNA, tRNA, rRNA, and protein
6. RNA differs from DNA in that the base _____ is substituted for _____. (a) adenine; uracil (b) uracil; thymine (c) guanine; uracil (d) cytosine; guanine (e) guanine; adenine
7. RNA grows in the _____ direction, as DNA-dependent RNA polymerase moves along the template DNA strand in the _____ direction. (a) 5′ ⟶ 3′; 3′ ⟶ 5′ (b) 3′ ⟶ 5′; 3′ ⟶ 5′ (c) 5′ ⟶ 3′; 5′ ⟶ 3′ (d) 3′ ⟶ 3′; 5′ ⟶ 5′ (e) 5′ ⟶ 5′; 3′ ⟶ 3′
8. Which of the following is/are *not* found in a bacterial mRNA molecule? (a) stop codon (b) upstream leader sequences (c) downstream trailing sequences (d) start codon (e) promoter sequences
9. Which of the following is/are typically removed from pre-mRNA during nuclear processing in eukaryotes? (a) upstream leader sequences (b) poly-A tail (c) introns (d) exons (e) all the preceding are removed
10. Which of the following is a spontaneous process, with no direct requirement for ATP or GTP? (a) formation of a peptide bond (b) translocation of the ribosome (c) formation of aminoacyl-tRNA (d) a and b (e) all the preceding
11. The role of tRNA is to transport (a) amino acids to the ribosome (b) amino acids to the nucleus (c) initiation factors to the ribosome (d) mRNA to the ribosome (e) release factors to the ribosome
12. Select the steps of an elongation cycle during protein synthesis from the following list and place them in the proper sequence:
    1. Peptide bond formation
    2. Binding of the small ribosomal subunit to the 5′ end of the mRNA
    3. Binding of aminoacyl-tRNA to the A site
    4. Translocation of the ribosome
    (a) 1 ⟶ 3 ⟶ 2 ⟶ 4 (b) 3 ⟶ 1 ⟶ 4 (c) 3 ⟶ 1 ⟶ 3 ⟶ 2 (d) 1 ⟶ 3 ⟶ 4 (e) 4 ⟶ 2 ⟶ 1 ⟶ 3
13. Suppose you mix the following components of protein synthesis in a test tube: amino acids from a rabbit; ribosomes from a dog; tRNAs from a mouse; mRNA from a chimpanzee; and necessary enzymes plus an energy source from a giraffe. If protein synthesis occurs, which animal's protein will be made? (a) rabbit (b) dog (c) mouse (d) chimpanzee (e) giraffe
14. During elongation in translation, the growing polypeptide chain attaches to a tRNA in the _____ site, and an incoming aminoacyl-tRNA attaches to the _____ site. (a) E; P (b) P; E (c) E; A (d) A; E (e) P; A
15. What is the minimum number of tRNA molecules needed to produce a polypeptide chain 50 amino acids long but that has only 16 different kinds of amino acids? (a) 50 (b) 25 (c) 20 (d) 16 (e) 8
16. The statement "the genetic code is redundant" means that (a) some codons specify punctuation (stop and start signals) rather than amino acids (b) some codons specify more than one amino acid (c) certain amino acids are specified by more than one codon (d) the genetic code is read one triplet at a time (e) all organisms have essentially the same genetic code
17. A nonsense mutation (a) causes one amino acid to be substituted for another in a polypeptide chain (b) results from the deletion of one or two bases, leading to a shift in the reading frame (c) results from the insertion of one or two bases, leading to a shift in the reading frame (d) results from the insertion of a transposon (e) usually results in the formation of an abnormally short polypeptide chain

CRITICAL THINKING

1. Compare and contrast the formation of mRNA in bacterial and eukaryotic cells. How do the differences affect the way in which each type of mRNA is translated? Does one system have any obvious advantage in terms of energy cost? Which system offers greater opportunities for control of gene expression?
2. Biologists hypothesize that transposons eventually lose the ability to replicate themselves and therefore remain embedded in DNA without moving around. Based on what you have learned in this chapter, suggest a possible reason for this loss.

Gene Regulation

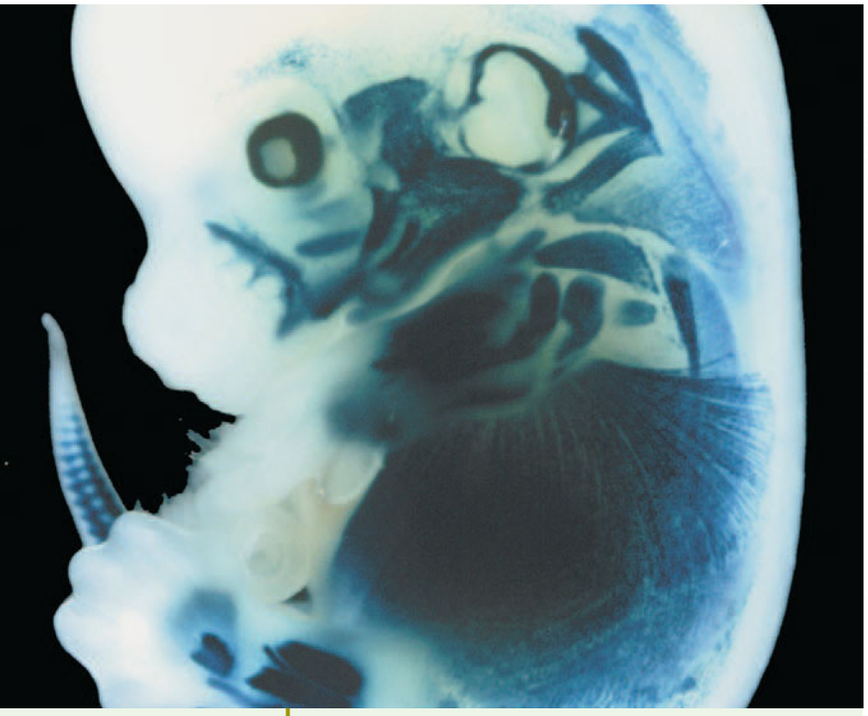

Photo Courtesy of David J. Goldhamer, from Chen et al. (2001), *Developmental Dynamics*, 221, 274–288

Specific gene expression in a mouse embryo. This 13.5-day-old mouse embryo has been genetically engineered so that cells that transcribe and express the myogenin gene stain blue. The myogenin gene is expressed only in those cells of the embryo that will give rise to muscle tissue.

CHAPTER OUTLINE

- **Gene Regulation in Bacteria and Eukaryotes: An Overview**
- **Gene Regulation in Bacteria**
- **Gene Regulation in Eukaryotic Cells**

Each type of cell in a multicellular organism has a characteristic shape, carries out very specific activities, and makes a distinct set of proteins. Yet with few exceptions, all an organism's cells contain the same genetic information. Why, then, aren't they identical in structure and molecular composition? Cells differ because gene expression is regulated, and only certain subsets of the total genetic information are expressed in any given cell (see photograph).

What mechanisms control gene expression? Let's consider a gene coding for a protein that is an enzyme. Expressing that gene involves three steps: transcribing the gene to form messenger RNA (mRNA), translating the mRNA into protein, and activating the protein so it carries out its role to catalyze a specific reaction in the cell. Thus gene expression results from a series of processes, each of which is regulated in many different ways. The control mechanisms use information in the form of various signals, some originating within the cell and others coming from other cells or from the environment, that interact with DNA, RNA, or protein.

Some of the main mechanisms of regulating gene expression are controls on the amount of mRNA transcribed from a gene, on the rate of translation of the mRNA, and on the activity of the protein product. These controls are accomplished in a variety of ways. For example, the rate of transcription and the rate of mRNA degradation both control the amount of available mRNA.

Although bacteria are not multicellular, regulation of gene expression is essential for their survival. Energy efficiency and the economical use of resources, for example, are crucial to bacterial functions. Therefore, gene regulation in bacteria often involves controlling the transcription of genes whose products are involved in resource use. In eukaryotes, by contrast, fine-tuning the control systems occurs at *all* levels of gene regulation. Involving all levels of gene regulation is consistent with the greater complexity of eukaryotic cells and the need for developmental controls in multicellular organisms (see Chapter 16). ■

GENE REGULATION IN BACTERIA AND EUKARYOTES: AN OVERVIEW

Learning Objective

1 Explain why bacterial and eukaryotic cells have different mechanisms of gene regulation.

Bacterial and eukaryotic cells use distinctly different mechanisms of gene regulation, based on the specific requirements of the organism. Bacterial cells exist independently, and each cell performs all its own essential functions. Because they grow rapidly and have relatively short times between cell division events, bacteria carry fewer chemical components.

The primary requirement of bacterial gene regulation is *economy,* and **transcriptional-level control** is the most efficient mechanism. The organization of related genes into groups that are rapidly turned on and off as units allows the synthesis of only the gene products needed at any particular time. This type of regulation requires rapid turnover of mRNA molecules, to prevent messages from accumulating and continuing to be translated when they are not needed. Bacteria rarely regulate enzyme levels by degrading proteins. Once the synthesis of a protein ends, the previously synthesized protein molecules are diluted so rapidly in subsequent cell divisions that breaking them down is usually not necessary. Only when cells are starved or deprived of essential amino acids do protein-digesting enzymes recycle amino acids by breaking down proteins no longer needed for survival.

Eukaryotic cells have different regulatory requirements. Although transcriptional-level control predominates, control at other levels of gene expression is also very important, especially in multicellular organisms, in which groups of cells cooperate with each other in a division of labor. Because a single gene is regulated in different ways in different types of cells, eukaryotic gene regulation is complex.

Eukaryotic cells usually have a long life span during which they may need to respond repeatedly to many different stimuli. New enzymes are not synthesized each time the cells respond to a stimulus; instead, preformed enzymes and other proteins are rapidly converted from an inactive to an active state. Some cells have a large store of inactive messenger RNA; for example, the mRNA of an egg cell becomes activated when it is fertilized.

Much gene regulation in multicellular organisms is focused on *specificity* in the form and function of the cells in each tissue. Each type of cell has certain genes that are active and other genes that may never be used (see Chapter 16). For example, developing red blood cells produce the oxygen transport protein hemoglobin, whereas muscle cells never produce hemoglobin but instead produce myoglobin, a related protein that stores oxygen in muscle tissues. Apparently the selective advantages of cell cooperation in eukaryotes far outweigh the detrimental effects of carrying a load of inactive genes through many cell divisions.

Review

- What is the overall mechanism of gene regulation in bacteria? In eukaryotes?

BiologyNow™ Assess your understanding of **gene regulation in bacteria and eukaryotes** by taking the pretest on your BiologyNow CD-ROM.

GENE REGULATION IN BACTERIA

Learning Objectives

2 Define *operon;* sketch the main elements of the *lac* operon, and explain the functions of the operator and promoter regions.

3 Distinguish among inducible, repressible, and constitutive genes.

4 Differentiate between positive and negative control, and show how both types of control operate in regulating the *lac* operon.

5 Describe the types of posttranscriptional control in bacteria.

The *E. coli* bacterium is common in the intestines of humans and other mammals. It has 4288 genes that code for proteins, approximately 60% of which have known functions. Some of these genes encode proteins that are always needed (such as enzymes involved in glycolysis). These genes, which are constantly transcribed, are **constitutive genes;** biologists say they are *constitutively expressed.* Other proteins are needed only when the bacterium is growing under certain conditions.

For instance, bacteria living in the colon of an adult cow are not normally exposed to the milk sugar lactose, a disaccharide. If those cells ended up in the colon of a calf, however, they would have lactose available as a source of energy. This situation presents a dilemma. Should a bacterial cell invest energy and materials to produce lactose-metabolizing enzymes just in case it ends up in the digestive system of a calf? Given that the average life span of an actively growing *E. coli* cell is about 30 minutes, such an evolutionary strategy appears wasteful. Yet if *E. coli* cells couldn't produce those enzymes, they might starve in the middle of an abundant food supply. Thus *E. coli* functions by regulating many enzymes to efficiently use available organic molecules.

Cell metabolic activity is controlled in two ways, by regulating the *activity* of certain enzymes (how effectively an enzyme molecule works), and/or by regulating the *number* of enzyme molecules present in each cell. Some enzymes are regulated in both ways in the same type of cell.

An *E. coli* cell growing on glucose needs about 800 different enzymes. Some are present in large numbers, whereas only a few molecules of others are required. For the cell to function properly, the quantity of each enzyme must be efficiently controlled.

Bacteria respond to changing environmental conditions. If lactose is added to a culture of *E. coli* cells, they rapidly synthesize the three enzymes needed to metabolize lactose. Bacteria respond so efficiently because functionally related genes—such as the three genes involved in lactose metabolism—are regulated together in gene complexes called *operons.*

Operons in bacteria facilitate the coordinated control of functionally related genes

The French researchers François Jacob and Jacques Monod are credited with the first demonstration, in 1961, of gene regula-

tion at the biochemical level, through their studies on the genes that code for the enzymes that metabolize lactose. In 1965, they received the Nobel Prize in Medicine for their discoveries relating to genetic control of enzymes.

To use lactose as an energy source, *E coli* cells first cleave the sugar into the monosaccharides glucose and galactose, using the enzyme β-galactosidase. Another enzyme converts galactose to glucose, and enzymes in the glycolysis pathway further break down the resulting two glucose molecules (see Chapter 7).

E. coli cells growing on glucose produce very little β-galactosidase enzyme. However, each cell grown on lactose as the sole carbon source has several thousand β-galactosidase molecules, accounting for about 3% of the cell's total protein. Amounts of two other enzymes, galactose permease and galactoside transacetylase, also increase when the cells are grown on lactose. The cell needs permease to transport lactose efficiently across the bacterial plasma membrane; without it, only small amounts of lactose enter the cell. The transacetylase may function in a minor aspect of lactose metabolism, although its role is not clear.

Jacob and Monod identified mutant strains of *E. coli* in which a single genetic defect wiped out all three enzymes. This finding, along with other information, led the researchers to conclude that the DNA coding sequences for all three enzymes are linked together as a unit on the bacterial DNA and are controlled by a common mechanism. Each protein-coding sequence is a **structural gene.** Jacob and Monod coined the term **operon** for a gene complex consisting of a group of structural genes with related functions, plus the closely linked DNA sequences responsible for controlling them. The structural genes of the *lac* operon (lactose operon)—*lac Z, lac Y,* and *lac A*—code for β-galactosidase, galactose permease, and galactoside transacetylase, respectively.

Transcription of the *lac* operon begins as RNA polymerase binds to a single **promoter** region upstream from the coding sequences. It then proceeds to transcribe the DNA, forming a single mRNA molecule that contains the coding information for all three enzymes. Each enzyme-coding sequence on this mRNA contains its own start and stop codons; thus the mRNA is translated to form three separate protein molecules. Because all three enzymes are translated from the same mRNA molecule, their synthesis is coordinated by turning a single molecular "switch" on or off.

The switch that controls mRNA synthesis is the **operator,** which is a sequence of bases upstream from the first structural gene in the operon. In the absence of lactose, a **repressor protein** called the **lactose repressor** binds tightly to the operator. RNA polymerase binds to the promoter but is blocked from transcribing the protein-coding genes of the *lac* operon (Fig. 13-1a).

The lactose repressor protein is encoded by a **repressor gene,** which in this case is an adjacent structural gene located upstream from the promoter site. Unlike the *lac* operon genes, the repressor gene is constitutively expressed and is therefore constantly transcribed; the cell continually produces small amounts of the repressor protein.

The repressor protein binds specifically to the *lac* operator sequence. When cells grow in the absence of lactose, a repressor molecule nearly always occupies the operator site. When the operator site is briefly free of the repressor, the cell synthesizes a small amount of mRNA. However, the cell synthesizes very few enzyme molecules, because *E. coli* mRNA is degraded rapidly (it has a half-life of about 2 to 4 minutes).

Lactose "turns on," or *induces,* the transcription of the *lac* operon because the lactose repressor protein contains a second functional region separate from its DNA binding site. This second region is an allosteric binding site for allolactose, a structural isomer made from lactose (Fig. 13-1b). Recall from Chapter 6 that an **allosteric regulator,** such as allolactose, binds to a region in a protein other than its active site, changing its shape and thereby altering its function. If lactose is in the growth medium, a few molecules enter the cell and are converted to allolactose by the few β-galactosidase molecules present. When a molecule of allolactose binds to the repressor at the allosteric site, it alters the shape of the protein so that its DNA-binding site no longer recognizes the operator. When all the repressor molecules have allolactose bound to them and are therefore inactivated, RNA polymerase actively transcribes the structural genes of the operon.

The *E. coli* cell continues to produce β-galactosidase and the other *lac* operon enzymes until it uses up virtually all the lactose. When intracellular levels of lactose drop, allolactose dissociates from the repressor protein, which then takes a shape that lets it bind to the operator region and shut down transcription of the operon.

Jacob and Monod isolated genetic mutants to study the lac *operon*

PROCESS OF SCIENCE

How did Jacob and Monod elucidate the functioning of the *lac* operon? Their approach involved the use of mutant strains, which even today play an essential role in enabling researchers to unravel the components of a regulatory system. Mutant strains allow investigators to carry out genetic crosses to determine the map positions (linear order) of the genes on the DNA and to infer normal gene functions by studying what happens when they are missing or altered. Researchers usually combine this information with the results of direct biochemical studies.

To understand Jacob and Monod's reasoning, follow the branching steps in Figure 13-2 as you read. They divided their mutant strains into two groups, based on whether a particular mutation affected only one enzyme or all three. In one group, only one enzyme of the three—β-galactosidase, galactose permease, or galactoside transacetylase—was affected. Subsequent gene mapping studies showed these were mutations in structural genes located next to each other in a linear sequence (*left side,* Fig. 13-2).

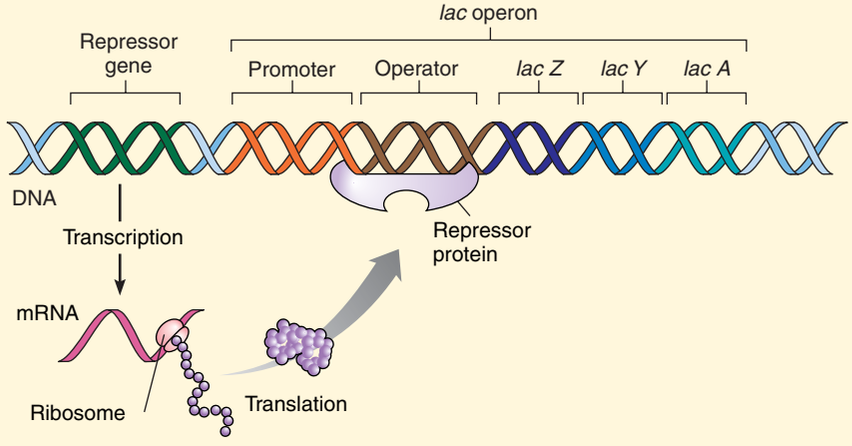
Jacob and Monod also studied strains they classified as regulatory mutants because a single mutation affected the expression of all three enzymes (*right side,* Fig. 13-2). Some of these regulatory mutants were constitutive; in these the structural genes of the *lac* operon were always transcribed at a significant rate, even in the absence of lactose, causing the cell to waste energy in producing unneeded enzymes. One group of constitutive gene mutations had map positions just outside the *lac* operon

itself. Using certain genetic strains, it was possible to show that these particular mutations always caused constitutive expression, regardless of their location in the genome. On the basis of these findings, Jacob and Monod hypothesized the existence of a repressor gene that codes for a repressor molecule (later found to be a protein). Although the specific defect may vary, the members of this group of constitutive mutants do not produce active repressor proteins; hence, no binding to the *lac* operator and promoter takes place, and the *lac* operon is constitutively expressed.

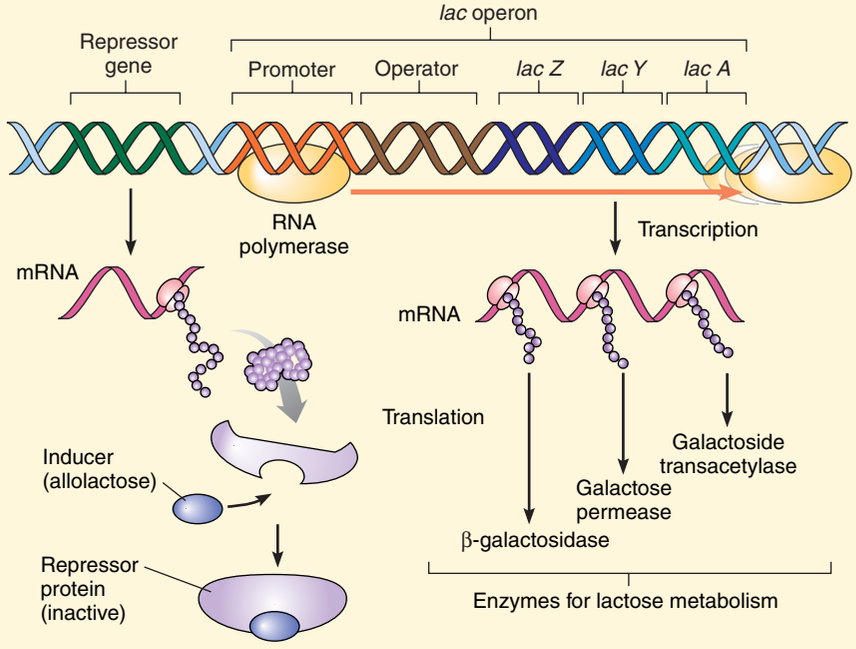
The genes responsible for the behavior of a second group of constitutive mutants had map positions within the *lac* operon but did not directly involve any of the three structural genes. Jacob and Monad hypothesized that the members of this group produced normal repressor molecules but had abnormal operator sequences incapable of binding to the repressor.

In contrast to the constitutive mutants, other mutants failed to transcribe the *lac* operon even when lactose was present. Some of these abnormal genes had the same map position as the hypothesized regulatory gene. Researchers eventually found these abnormal genes had an altered binding site on the repressor protein that prevented allolactose from binding, although the repressor could still bind to the operator. Once bound to the operator, such a mutant repressor remains bound, keeping the operon "turned off."

KEY CONCEPT: The order of elements in the *lac* operon is promoter-operator-*lac*Z-*lac*Y-*lac*A



(a) In the absence of lactose, a repressor protein, encoded by an adjacent gene, binds a region known as the operator, thereby blocking transcription of the structural genes.



(b) When lactose is present, it is converted to allolactose, which binds to the repressor at an allosteric site, altering the structure of the protein so it no longer binds to the operator. This allows RNA polymerase to transcribe the structural genes.

An inducible gene is not transcribed unless a specific inducer inactivates its repressor

Geneticists call the *lac* operon an **inducible operon.** A repressor usually controls an inducible gene or operon by keeping it turned "off." The presence of an **inducer** (in this case, allolactose) inactivates the repressor, permitting the gene or operon to be transcribed. Inducible genes or operons usually code for enzymes that are part of catabolic pathways, which break down molecules to provide both energy and components for anabolic reactions. This type of regulatory system lets the cell save the energy cost of making enzymes when no substrates are available on which they can act.

ACTIVE FIGURE **13-1** **The *lac* operon.**

The structural genes coding for the three enzymes used by *E. coli* to metabolize the disaccharide lactose are transcribed as part of a single mRNA molecule.

Jacob and Monod analyzed the properties of various mutant strains of *E. coli* to deduce the structure and function of the *lac* operon.

A repressible gene is transcribed unless a specific repressor-corepressor complex is bound to the DNA

Another type of gene regulation system in bacteria is associated mainly with anabolic pathways such as those in which cells synthesize amino acids, nucleotides, and other essential biological molecules from simpler materials. Enzymes coded by repressible genes normally regulate these pathways.

Repressible operons and genes are usually turned "on"; they are turned off only under certain conditions. In most cases the molecular signal for regulating these genes is the end product of the anabolic pathway. When the supply of the end product (such as an amino acid) becomes low, all enzymes in the pathway are actively synthesized. When intracellular levels of the end product rise, enzyme synthesis is repressed. Because the growing cell continuously needs compounds such as amino acids, the most effective mechanism for the cell is to keep the genes that control their production turned on, except when a large supply of the amino acid is available. The ability to turn the genes off prevents cells from overproducing amino acids and other molecules that are essential but expensive to make, in terms of energy.

The *trp* operon (tryptophan operon) is an example of a repressible system. In both *E. coli* and a related bacterium, *Salmonella,* the *trp* operon consists of five structural genes that code for the enzymes the cell needs to synthesize the amino acid tryptophan; these are clustered together as a transcriptional unit with a single promoter and a single operator (Fig. 13-3a). A distant repressor gene codes for a diffusible repressor protein, which differs from the lactose repressor in that the cell synthesizes it in an inactive form that cannot bind to the operator region of the *trp* operon.

The DNA-binding site of the repressor becomes effective only when tryptophan, its **corepressor,** binds to an allosteric site on the repressor (Fig. 13-3b). When intracellular tryptophan levels are low, the repressor protein is inactive and cannot bind to the operator region of the DNA. The enzymes required for tryptophan synthesis are produced, and the intracellular concentration of tryptophan increases. Some of it binds to the allosteric site of the repressor, altering the repressor's shape so it binds tightly to the operator. This switches the operon off, thereby blocking transcription.

Negative regulators inhibit transcription; positive regulators stimulate transcription

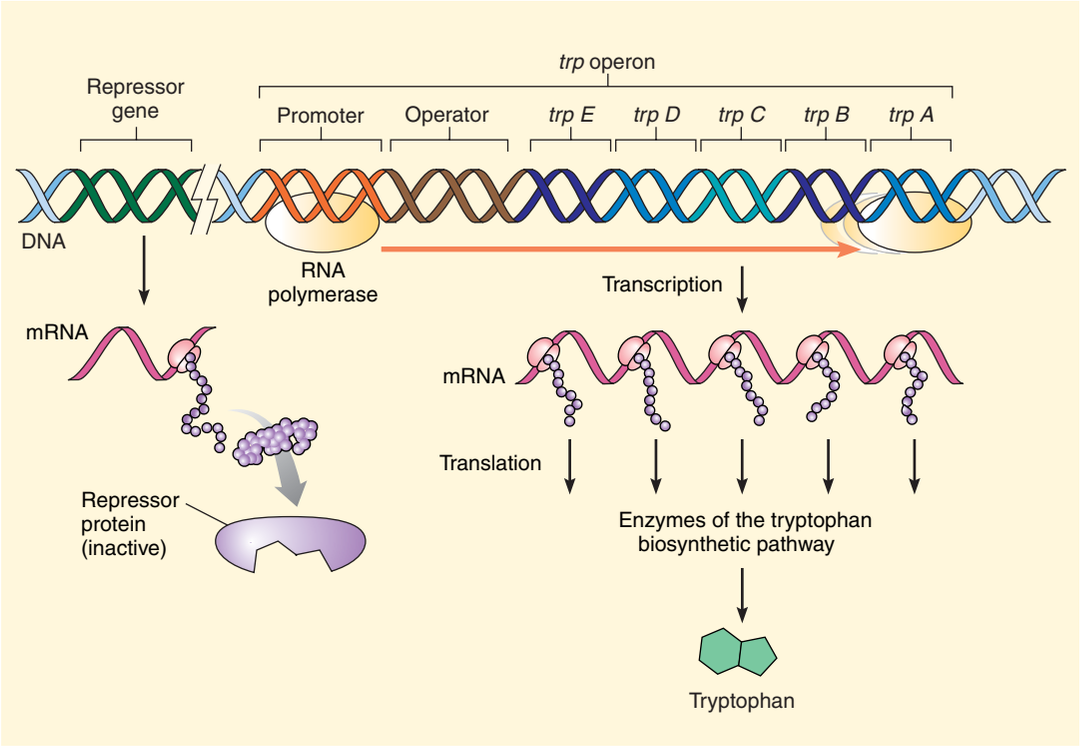
The features of the *lac* and *trp* operons we have described so far are examples of **negative control,** a regulatory mechanism in which the DNA binding regulatory protein is a repressor that turns off transcription of the gene. **Positive control** is regulation by **activator proteins** that bind to DNA and thereby stimulate the transcription of a gene. The *lac* operon is controlled by both a negative regulator (the lactose repressor) and a positively acting activator protein.

Positive control of the *lac* operon requires the cell to recognize the absence of the sugar glucose, which is the initial substrate in the glycolysis pathway. Lactose, like glucose, undergoes stepwise breakdown to yield energy. However, because glucose is a product of the catabolic hydrolysis of lactose, it is most effi-

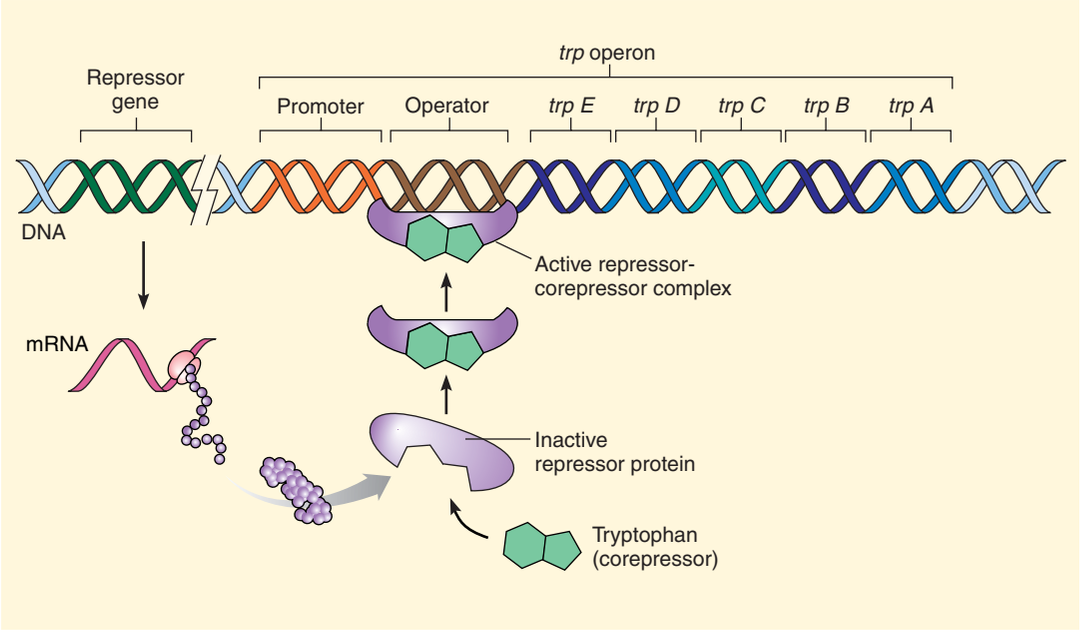
FIGURE **13-3**

The *trp* operon.

Genes coding for enzymes that synthesize the amino acid tryptophan are organized in a repressible operon.



(a) Intracellular tryptophan levels low. Repressor protein is unable to prevent transcription because it cannot bind to the operator.

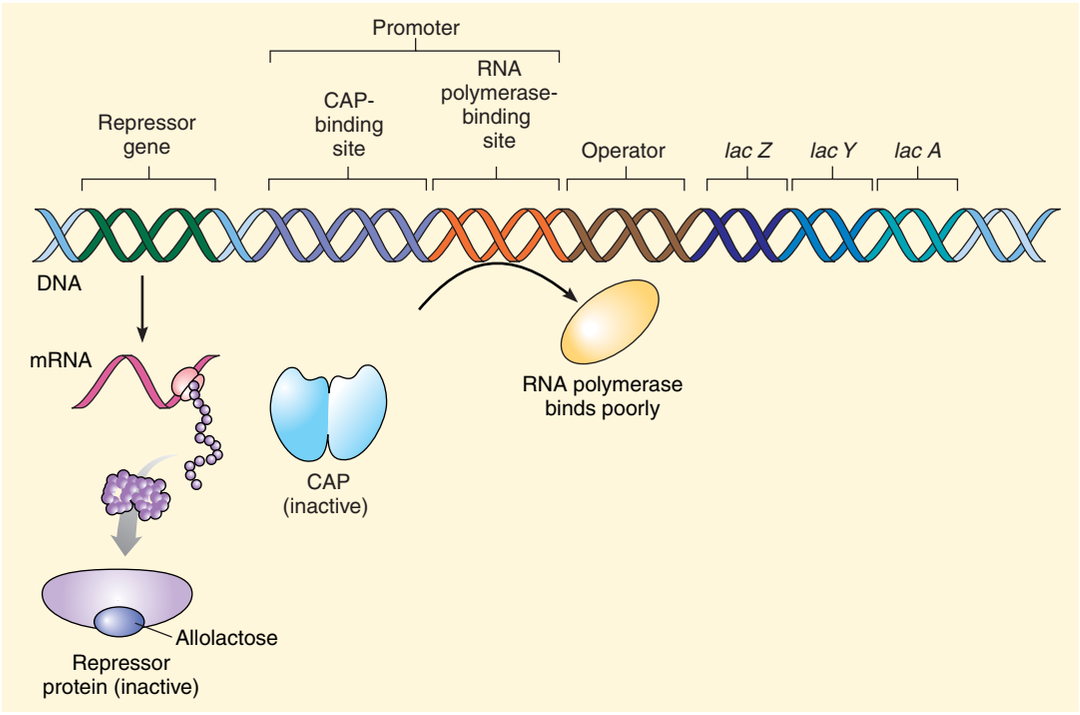


(b) Intracellular tryptophan levels high. The amino acid tryptophan binds to an allosteric site on the repressor protein, changing its conformation. The resulting active form of the repressor binds to the operator region, blocking transcription of the operon until tryptophan is again required by the cell.

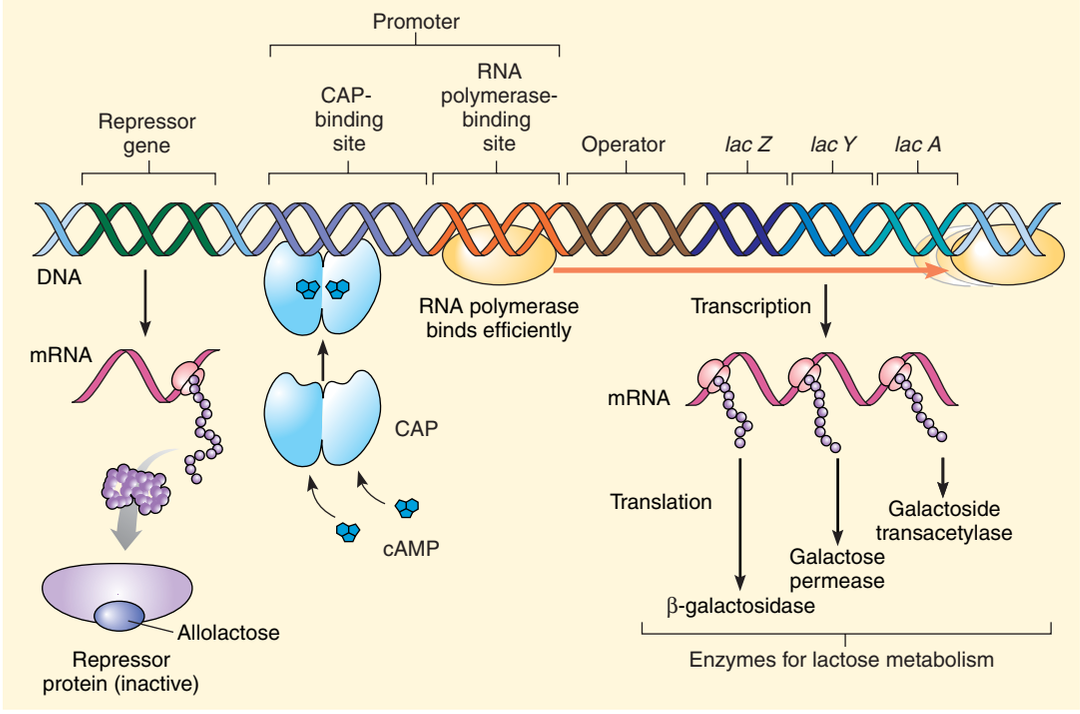
cient for *E. coli* cells to use the available supply of glucose first, sparing the cell the considerable energy cost of making additional enzymes such as β-galactosidase (Fig. 13-4a).

The *lac* operon has a very inefficient promoter element—that is, it has a low affinity for RNA polymerase, even when the repressor protein is inactivated. However, a DNA sequence adjacent to the promoter site is a binding site for another regulatory protein, the **catabolite activator protein (CAP).**

In its active form, CAP has **cyclic AMP,** or **cAMP,** an alternative form of adenosine monophosphate (see Fig. 3-25), bound



(a) Lactose high, glucose high, cAMP low. When glucose levels are high, cAMP is low. CAP is in an inactive form and cannot stimulate transcription. Transcription occurs at a low level or not at all.



(b) Lactose high, glucose low, cAMP high. When glucose concentrations are low, each CAP polypeptide has cAMP bound to its allosteric site. The active form of CAP binds to the DNA sequence, and transcription becomes activated.

FIGURE **13-4**

Positive control of the *lac* operon.

The lactose promoter by itself is weak and binds RNA polymerase inefficiently even when the lactose repressor is inactive. CAP is an allosteric regulator whose active form binds to a sequence of bases in the promoter, allowing RNA polymerase to bind efficiently, thereby stimulating transcription of the operon. The CAP molecule contains two polypeptides, both of which bind to cAMP at allosteric sites. The cell's cAMP concentration is inversely proportional to the glucose concentration.

to an allosteric site. As the cells become depleted of glucose, cAMP levels increase (Fig. 13-4b). The cAMP molecules bind to CAP, and the resulting active complex then binds to the CAP-binding site near the *lac* operon promoter. This binding of active CAP bends DNA's double helix (Fig. 13-5), strengthening the affinity of the promoter region for RNA polymerase so that the rate of transcriptional initiation accelerates in the presence of lactose. Thus the *lac* operon is fully active only if lactose is

FIGURE **13-5** **The binding of CAP to DNA.**

This computer-generated image shows the bend formed in the DNA double helix when it binds to CAP. CAP is a dimer consisting of two identical polypeptide chains, each of which binds one molecule of cAMP.

available and intracellular glucose levels are low. Table 13-1 summarizes negative and positive controls in bacteria.

A regulon is a group of functionally related operons controlled by a common regulator

CAP differs from the lactose and tryptophan repressors in that it controls the transcription of operons involved in the metabolism of several catabolites, such as the sugars galactose, arabinose, and maltose, as well as of lactose. A group of operons controlled by a single regulator is called a **regulon** (Fig. 13-6).

Other multigene systems in bacteria are also controlled this way. For example, genes involved in nitrogen and phosphate metabolism are organized into regulons that consist of multiple sets of operons controlled by one or more combinations of regulatory genes. Other multigene systems respond to changes in environmental conditions, such as rapid shifts in temperature, exposure to radiation, changes in osmotic pressure, and changes in oxygen levels. Specific mutants often provide clues to the existence of a regulon system. A single mutation that destroys CAP activity, for example, prevents the cell from efficiently metabolizing not only lactose but also many other sugars that CAP regulates.

Constitutive genes are transcribed at different rates

Many gene products encoded by *E. coli* DNA are needed only under certain environmental or nutritional conditions. As you have seen, these genes are generally regulated at the level of transcription. They are turned on and off as metabolic and environmental conditions change. By contrast, constitutive genes are continuously transcribed, but they are not necessarily transcribed (or their mRNAs translated) at the same rate. Some enzymes work more effectively or are more stable than others and thus are present in smaller amounts. Constitutive genes that encode proteins required in large amounts generally have greater expression—that is, are transcribed more rapidly—than genes coding for proteins required in smaller amounts. The promoter elements of these genes control their transcriptional rate. Constitutive genes with efficient ("strong") promoters bind RNA polymerase more frequently and consequently transcribe more mRNA molecules than those with inefficient ("weak") promoters.

Genes coding for repressor or activator proteins that regulate metabolic enzymes are usually constitutive and produce their protein products constantly. Because each cell usually needs relatively few molecules of any specific repressor or activator protein, promoters for those genes tend to be relatively weak.

TABLE **13-1** **Transcriptional Control in Bacteria***

Negative Control	Result
Inducible genes	
Repressor protein alone	**Active repressor turns off regulated gene(s)**
Lactose repressor alone	*lac* operon not transcribed
Repressor protein + inducer	**Inactive repressor-inducer complex fails to turn off regulated gene(s)**
Lactose repressor + allolactose	*lac* operon transcribed
Repressible genes	
Repressor protein alone	**Inactive repressor fails to turn off regulated gene(s)**
Tryptophan repressor alone	*trp* operon transcribed
Repressor protein + corepressor	**Active repressor-corepressor complex turns off regulated gene(s)**
Tryptophan repressor + tryptophan	*trp* operon not transcribed
Positive Control	**Result**
Activator protein alone	**Activator alone cannot stimulate transcription of regulated gene(s)**
CAP alone	Transcription of *lac* operon not stimulated
Activator protein + coactivator	**Functional activator-coactivator complex stimulates transcription of regulated gene(s)**
CAP + cAMP	Transcription of *lac* operon stimulated

*A general description of each type is followed by a specific example. A negative regulator is a repressor that turns off transcription of the regulated gene(s). Conversely, a positive regulator is an activator that stimulates transcription.

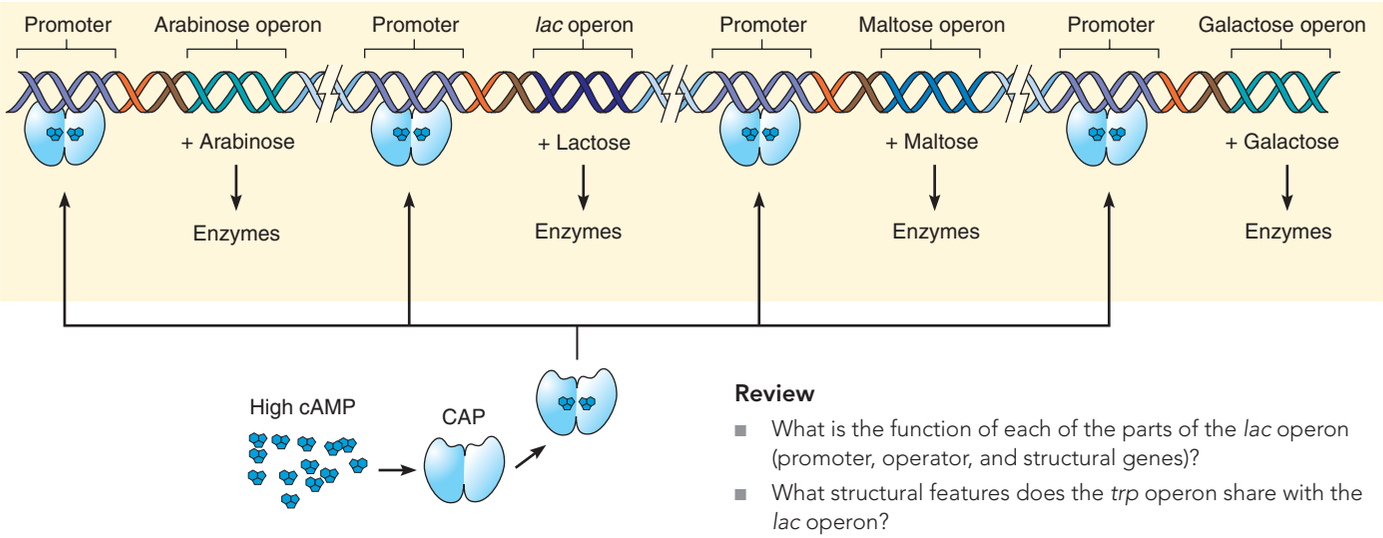

FIGURE **13-6** **A regulon.**

Operons that convert several different sugars to glucose in *E. coli* make up a regulon under positive control by CAP. When glucose levels are low, cAMP levels rise, activating CAPs, which bind to their recognition sites in the promoter regions of all operons in the regulon. If the inducer for an operon is available, its repressor is inactivated, and transcription of the message occurs at a rapid rate.

Some posttranscriptional regulation occurs in bacteria

As you have seen, much of the variability in protein levels in *E. coli* is determined by transcriptional-level control. However, regulatory mechanisms after transcription, known as **posttranscriptional controls,** also occur at various levels of gene expression.

Translational controls are posttranscriptional controls that regulate the rate at which an mRNA molecule is translated. Because the life span of an mRNA molecule in a bacterial cell is very short, one that is translated rapidly produces more proteins than one that is translated slowly. Some mRNA molecules in *E. coli* are translated as much as 1000 times faster than other mRNAs. Most of the differences appear to be due to the rate at which ribosomes attach to the mRNA and begin translation.

Posttranslational controls act as switches that activate or inactivate one or more existing enzymes, thereby letting the cell respond to changes in the intracellular concentrations of essential molecules, such as amino acids. A common posttranslational control adjusts the rate of synthesis in a metabolic pathway through **feedback inhibition** (see Fig. 6-15). The end product of a metabolic pathway binds to the first enzyme in the pathway at an allosteric site, temporarily inactivating the enzyme. When the first enzyme in the pathway does not function, all the succeeding enzymes are deprived of substrates. Notice that feedback inhibition differs from the repression caused by tryptophan discussed previously. In that case, the end product of the pathway (tryptophan) prevented the formation of *new* enzymes. Feedback inhibition acts as a fine-tuning mechanism that regulates the activity of the *existing* enzymes in a metabolic pathway.

Review

- What is the function of each of the parts of the *lac* operon (promoter, operator, and structural genes)?
- What structural features does the *trp* operon share with the *lac* operon?
- Why do scientists define the *trp* operon as repressible and the *lac* operon as inducible?
- How is glucose involved in positive control of the *lac* operon?

GENE REGULATION IN EUKARYOTIC CELLS

Learning Objectives

6 Discuss the structure of a typical eukaryotic gene and the DNA sequences involved in regulating that gene.
7 Give examples of some of the ways eukaryotic DNA-binding proteins bind to DNA.
8 Illustrate how a change in chromosome structure may affect the activity of a gene.
9 Explain how a gene in a multicellular organism may produce different products in different types of cells.
10 Identify some of the types of regulatory controls that operate in eukaryotes after mature mRNA is formed.

Like bacteria, eukaryotic cells respond to changes in their environment. In addition, multicellular eukaryotes require regulation modes that let individual cells commit to specialized roles and groups of cells organize into tissues and organs. This is mainly done by regulating transcription, but posttranscriptional (translational and posttranslational) controls are also important. In Chapters 11 and 12, we observed that in eukaryotes all aspects of information transfer—including replication, transcription, and translation—are far more complicated. Not surprisingly, this complexity offers more ways to control gene expression.

Unlike many bacterial genes, eukaryotic genes do not normally form operon-like clusters. (A notable exception is the nematodes, or roundworms, in which some genes are organized into operons.) However, each eukaryotic gene has specific regulatory sequences that are essential in controlling transcription.

Many "housekeeping" enzymes (those needed by virtually all cells) are encoded by constitutive genes and are expressed at

all times. Some inducible genes also respond to environmental threats or stimuli, such as heavy metal ingestion, viral infection, and heat shock. For example, when a cell is exposed to high temperature, many proteins fail to fold properly. These unfolded proteins elicit a survival response in which *heat-shock genes* are transcribed, and heat-shock proteins are formed. Although the functions of most heat-shock proteins are unknown, some are **molecular chaperones,** which help newly synthesized proteins fold into their proper shape (see Chapter 3).

Some genes are inducible only during certain periods in the life of the organism; they are controlled by **temporal regulation** mechanisms. Finally, some genes are under **tissue-specific regulation.** For example, a gene involved in production of a particular enzyme may be regulated by one stimulus (such as a hormone) in muscle tissue, by an entirely different stimulus in pancreatic cells, and by a third stimulus in liver cells. We explore these types of regulation in more detail in Chapters 16 and 47.

Table 13-2 summarizes the regulation of gene expression in eukaryotes. You may want to refer to it as you read the following discussion.

Eukaryotic transcription is controlled at many sites and by many different regulatory molecules

Most genes of multicellular eukaryotes are controlled at the transcriptional level. As you will see, various base sequences in the DNA are important in transcriptional control. In addition, regulatory proteins and the way the DNA is organized in the chromosome affect the rate of transcription.

TABLE **13-2** Gene Regulation In Eukaryotes

Level of Regulation	Description
Transcriptional control (main level of gene regulation in eukaryotes)	Selective transcription: promoter and enhancer elements in DNA interact with protein transcription factors to activate or repress transcription
	Chromatin structure regulates transcription; heterochromatin cannot be transcribed
	DNA methylation regulates transcription; methylated DNA is inaccessible to transcription machinery
Posttranscriptional control: mRNA processing and transport	Control mechanisms, such as rate of intron/exon splicing, regulate mRNA processing
	Differential mRNA processing (alternate splicing of exons) produces different proteins from same mRNA
	Controlling access to, or efficiency of, transport through nuclear pores regulates mRNA transport from nucleus to cytosol
Translational control	Translational controls determine how often and how long specific mRNA is translated
	Translational controls determine degree to which mRNA is protected from destruction; proteins that bind to mRNA in cytosol affect stability
Posttranslational control of protein product	Chemical modifications, such as phosphorylation, affect activity of protein after it is produced
	Selective degradation targets specific proteins for destruction

Eukaryotic promoters vary in efficiency, depending on their upstream promoter elements

In eukaryotic as well as bacterial cells, the transcription of any gene requires a base pair where transcription begins, known as **transcription initiation site,** plus a sequence of bases, the promoter, to which RNA polymerase binds. In multicellular eukaryotes, RNA polymerase binds to a promoter called a **TATA box,** located about 25 to 35 base pairs upstream from the transcription initiation site (Fig. 13-7a). The TATA box is required for transcription to begin.

Other eukaryotic promoter elements have a regulatory function and control the expression of the gene. Many eukaryotic promoters contain one or more sequences of 8 to 12 bases within a short distance upstream of the RNA polymerase-binding site. These promoters are called **upstream promoter elements (UPEs).** Specific regulatory proteins bind to the UPEs to regulate expression of the gene. The efficient initiation of transcription seems related to the number and type of UPEs. A constitutive gene containing only one UPE is generally weakly expressed, whereas one with five or six UPEs is transcribed much more actively (Fig. 13-7b and c). Thus a given gene may have one, a few, or many promoter elements.

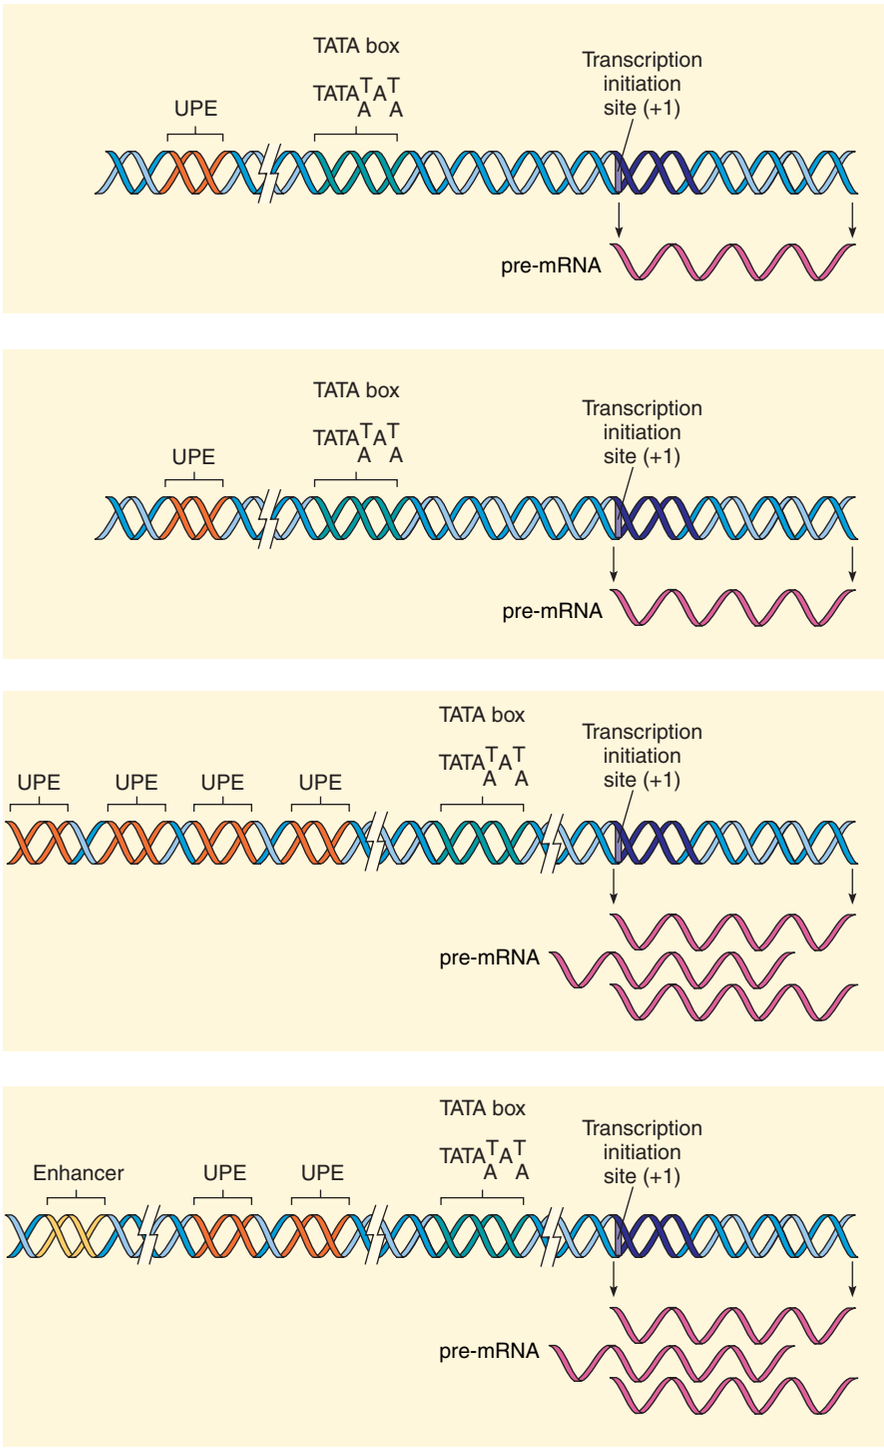
Enhancers are DNA sequences that increase the transcription rate

Regulated eukaryotic genes commonly need not only UPEs but also DNA sequences called **enhancers.** Whereas the promoter elements are required for accurate and efficient initiation of mRNA synthesis, enhancers increase the *rate* of RNA synthesis after initiation, often by several orders of magnitude (Fig. 13-7d). Specific regulatory proteins bind to enhancer elements and activate transcription by interacting with the proteins bound to the promoters.

Enhancer elements are remarkable in many ways. Although present in all cells, a particular enhancer is functional only in certain types of cells. An enhancer regulates a gene on the same DNA molecule from very long distances—up to thousands of base pairs away from the promoter—and is either upstream or downstream of the promoter it controls. Furthermore, if an enhancer element is experimentally cut out of the DNA and inverted, it still regulates the gene it normally controls. As you will see, evidence suggests that at least some enhancers work by interacting with proteins that regulate transcription.

Transcription factors are regulatory proteins with several functional domains

We previously discussed some DNA-binding proteins that regulate transcription in bacteria. These include the lactose repressor, the tryptophan repressor, and the catabolite activator protein (CAP). Researchers have identified many more DNA-binding



(a) Eukaryotic promoter elements. A eukaryotic promoter usually contains a TATA box located 25 to 35 base pairs upstream from the transcription initiation site. The most commonly found base sequence is shown (either T or A can be present at the positions where they appear together). One or more upstream promoter elements (UPEs) are usually present.

(b) A weak eukaryotic promoter. A weakly expressed gene contains only one UPE.

(c) A strong eukaryotic promoter. A strongly expressed gene is likely to contain several UPEs.

(d) A strong eukaryotic promoter plus an enhancer. Transcription of this eukaryotic gene is stimulated by an enhancer, located several thousand bases from the promoter.

FIGURE **13-7**

The regulation of transcription in eukaryotes.

The DNA double helix and other elements are not drawn to scale.

proteins that regulate transcription in eukaryotes than in bacteria; these eukaryotic proteins are known as **transcription factors.** In humans, for example, researchers have identified more than 2000 transcription factors

It is useful to compare regulatory proteins in bacteria and eukaryotes. Many regulatory proteins are modular molecules; that is, they have more than one **domain,** a region with its own tertiary structure, and each domain has a different function. Each eukaryotic transcription factor, like the regulatory proteins of bacteria, has a DNA-binding domain, plus at least one other domain that is either an activator or a repressor of transcription for a given gene.

Many transcription factors in eukaryotes (and regulatory proteins in bacteria) have similar DNA-binding domains. One example is the *helix-turn-helix* arrangement, consisting of two α-helical segments. One of these, the recognition helix, inserts into a groove of the DNA without unwinding the double helix. The other helps hold the first one in place (Fig. 13-8a). The "turn" is a sequence of amino acids that forms a sharp bend in the molecule.

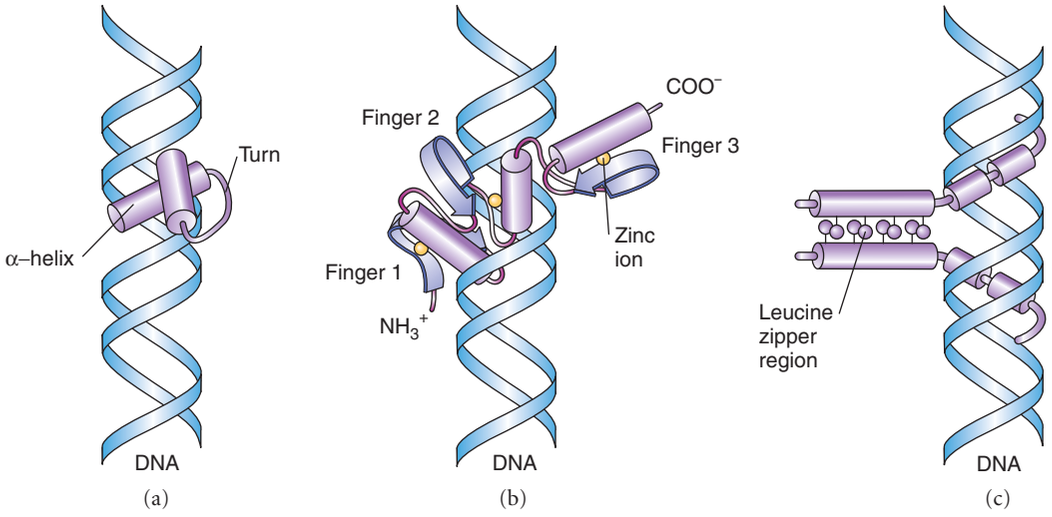


FIGURE **13-8** **Regulatory proteins.**

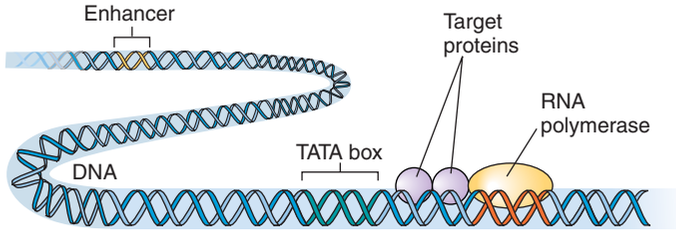
In these illustrations, cylinders represent α-helical regions of regulatory proteins and ribbons represent β-pleated sheets. **(a)** This portion of a regulatory protein *(purple)* contains the helix-turn-helix arrangement. The recognition helix is inserted into the groove of the DNA and is connected to a second helix that helps hold it in place by a sequence of amino acids that form a sharp bend. **(b)** Regions of certain transcription factors form projections known as "zinc fingers," which insert into the grooves of the DNA and bind to specific base sequences. **(c)** This leucine zipper protein is a dimer, held together by hydrophobic interactions involving side chains of leucine and other amino acids.

Other regulatory proteins have DNA binding domains with multiple "zinc fingers," loops of amino acids held together by zinc ions. Each loop includes an α-helix that fits into a groove of the DNA (Fig. 13-8b). Certain amino acid functional groups exposed in each finger have been shown to recognize specific DNA sequences.

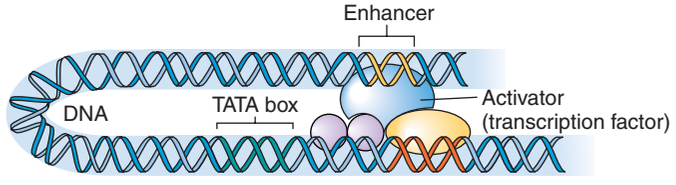
Many regulatory proteins have DNA-binding domains that function only as pairs, or *dimers*. Many of these transcription factors are known as **leucine zipper proteins** because they are held together by the side chains of leucine and other hydrophobic amino acids (Fig. 13-8c). In some cases the two polypeptides that make up the dimer are identical and form a *homodimer*. In other instances they are different, and the resulting *heterodimer* may have very different regulatory properties from a homodimer. For a simple and speculative example, let's assume that three regulatory proteins—A, B, and C—are involved in controlling a particular set of genes. These three proteins might associate as dimers in six different ways: three kinds of homodimers (AA, BB, and CC) and three kinds of heterodimers (AB, AC, and BC). Such multiple combinations of regulatory proteins greatly increase the number of possible ways that transcription is controlled.

Transcription in eukaryotes requires multiple regulatory proteins that are bound to different parts of the promoter. The general transcriptional machinery is a protein complex that binds to the TATA box of the promoter near the transcription initiation site. That complex is required for RNA polymerase to bind, thereby initiating transcription.

Both enhancers and UPEs apparently become functional when specific transcription factors bind to them. Figure 13-9



(a) Little or no transcription



(b) High rate of transcription

FIGURE **13-9** **The stimulation of transcription by an enhancer.**

(a) This gene is transcribed at a very low rate or not at all, even though the general transcriptional machinery, including RNA polymerase, is bound to the promoter. **(b)** A transcription factor that functions as an activator binds to an enhancer. The intervening DNA forms a loop, allowing the transcription factor to contact one or more target proteins in the general transcriptional machinery, thereby increasing the rate of transcription. This diagram is highly simplified, and many more target proteins than the two shown are involved.

shows interactions involving an enhancer and a transcription factor that acts as an activator. Each activator has at least two functional domains: a DNA recognition site that usually binds to an enhancer or UPE, and a gene activation site that contacts the target in the general transcriptional machinery. The DNA between the enhancer and promoter elements forms a loop that lets an activator bound to an enhancer come in contact with the target proteins associated with the general transcriptional machinery. When this occurs, the rate of transcription increases.

Chromosome organization may affect the expression of some genes

A chromosome is not only a bearer of genes. Various arrangements of a chromosome's ordered components (see Fig. 9-4) increase or decrease expression of the genes it contains. In multicellular eukaryotes, only a subset of the genes in a cell are active at any one time. The inactivated genes differ among cell types and in many cases are irreversibly dormant. Recent evidence suggests that certain small RNA molecules, 21 to 28 nucleotides long, affect chromatin structure and can permanently shut down sections of chromosomes. This inhibition of gene expression is known as *RNA interference.*

Some of the inactive genes lie in highly compacted chromatin, visible microscopically as densely staining regions of chromosomes during cell division. These regions of chromatin remain tightly coiled and bound to chromosome proteins throughout the cell cycle; even during interphase, they are visible as darkly staining fibers called **heterochromatin** (Fig. 13-10a). Evidence suggests that most of the heterochromatin DNA is not transcribed. When researchers inactivate one of the two X chromosomes in female mammals, most of the inactive X chromosome becomes heterochromatic and is seen as a *Barr body* (see Fig. 10-17).

Active genes are associated with a more loosely packed chromatin structure called **euchromatin** (Fig. 13-10b). The exposure of the DNA in euchromatin lets it interact with transcription factors and other regulatory proteins.

Gene inactivation by DNA methylation Inactive genes of vertebrates and some other organisms typically show a pattern of **DNA methylation** in which the DNA has been chemically altered by enzymes that add methyl groups to certain cytosine nucleotides in DNA. (The resulting 5-methylcytosine still pairs with guanine in the usual way.) Evidence indicates that certain regulatory proteins selectively bind to methylated DNA and make it inaccessible to the general transcriptional machinery.

DNA methylation probably reinforces gene inactivation rather than serving as the initial mechanism to silence genes. Apparently once a gene has been turned off by some other means, DNA methylation ensures it will remain inactive. For example, the DNA of the inactive X chromosome of a female mammal becomes methylated after the chromosome has become a condensed Barr body. Each time the DNA replicates, methylation enzymes perpetuate the pre-existing methylation pattern; hence, the DNA continues to be transcriptionally inactive in both daughter cells.

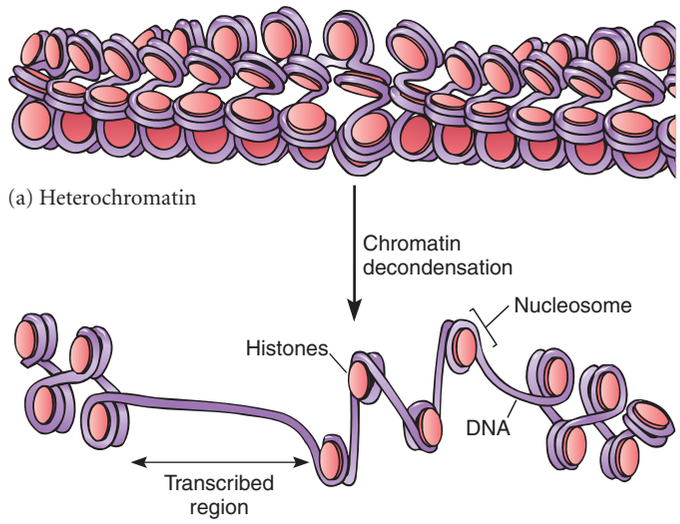


FIGURE **13-10** **The effect of chromatin structure on transcription.**

(a) An inactive region of DNA, heterochromatin is organized into tightly associated nucleosomes. **(b)** Active genes are found in decondensed chromatin called euchromatin. Chromatin decondensation is often a response to specific inducing signals. Loosely packed chromatin increases the accessibility to RNA polymerase required for transcription of the region. The histones are physically removed from the DNA in the region where transcription occurs.

Multiple copies of genes A single gene cannot always provide enough copies of its mRNA to meet the cell's needs. The requirement for high levels of certain products is met if multiple copies of the genes that encode them are present in the chromosome. Genes of this type, whose products are essential for all cells, may occur as multiple copies arranged one after another along the chromosome, in *tandemly repeated gene sequences.* Other genes, which are required only by a small group of cells, are selectively replicated in those cells in a process called **gene amplification** (see Fig. 16-5).

Within an array of repeated genes, all the copies are almost identical. Histone genes, which code for the proteins that associate with DNA to form nucleosomes (see Chapter 9), are usually multiple copies of 50 to 500 genes in cells of multicellular organisms. Similarly, multiple copies (150 to 450) of genes for rRNA and tRNA are present in cells.

The mRNAs of eukaryotes have many types of posttranscriptional control

The half-life of bacterial mRNA is usually minutes long; eukaryotic mRNA, even when it turns over rapidly, is far more stable. Bacterial mRNA is transcribed in a form that is translated immediately. In contrast, eukaryotic mRNA molecules undergo further modification and processing before use in protein synthesis. The message is capped, polyadenylated, spliced, and then transported from the nucleus to the cytoplasm to initi-

ate translation (see Chapter 12). These events represent potential control points for translation of the message and the production of its encoded protein.

The addition of a **poly-A tail** to eukaryotic mRNA, for example, appears necessary to initiate translation. Researchers have shown that mRNAs with long poly-A tails are efficiently translated, whereas mRNAs with short poly-A tails are essentially dormant. *Polyadenylation,* which commonly occurs in the nucleus, can also take place in the cytosol. When the short poly-A tail of an mRNA is elongated, the mRNA becomes activated and is then translated.

Some pre-mRNAs are processed in more than one way

Investigators have discovered several forms of regulation involving mRNA processing. In some instances, the same gene produces one type of protein in one tissue and a related but somewhat different type of protein in another tissue. This is possible because some genes produce pre-mRNA molecules that have alternative splicing patterns; that is, they are spliced in different ways depending on the tissue. Typically, such a gene includes at least one segment that can be either an intron or an exon. As an intron, the sequence is removed, but as an exon, it is retained. Through **differential mRNA processing,** the cells in each tissue produce their own version of mRNA corresponding to the particular gene (Fig. 13-11). For example, this mechanism produces different forms of troponin, a protein that regulates muscle contraction, in different muscle tissues.

The stability of mRNA molecules varies

Controlling the life span of a particular kind of mRNA molecule permits control over the number of protein molecules translated from it. In some cases, mRNA stability is under hormonal control. This is true for mRNA that codes for vitellogenin, a protein synthesized in the liver of certain female animals, such as frogs and chickens. Vitellogenin is transported to the oviduct, where it is used in forming egg yolk proteins.

The hormone estradiol regulates vitellogenin synthesis. When estradiol levels are high, the half-life of vitellogenin mRNA in frog liver is about 500 hours. When researchers deprive cells of estradiol, the half-life of the mRNA drops rapidly, to less than 165 hours. This rapidly lowers cell vitellogenin mRNA levels and decreases synthesis of the vitellogenin protein. In addition to affecting mRNA stability, the hormone seems to control the rate at which the mRNA is synthesized.

Posttranslational chemical modifications may alter the activity of eukaryotic proteins

Another way to control the ultimate phenotypic expression of a gene is by regulating the activity of the gene product. As in bacteria, many metabolic pathways in eukaryotes contain allosteric enzymes regulated through feedback inhibition. In addition, after they are synthesized many eukaryotic proteins are extensively modified.

In *proteolytic processing,* proteins are synthesized as inactive precursors, which are converted to an active form by the removal of a portion of the polypeptide chain. For example, proinsulin contains 86 amino acids. Removing 35 amino acids yields the hormone insulin, which consists of two polypeptide chains containing 30 and 21 amino acids, respectively, linked by disulfide bridges. Other proteins are regulated in part by *selective degradation,* which keeps their numbers constant within the cell.

Chemical modification, by adding or removing functional groups, reversibly alters the activity of an enzyme. One common way to modify the activity of an enzyme or other protein is to add or remove phosphate groups. Enzymes that add phosphate groups are called **kinases;** those that remove them are **phosphatases.** For example, the cyclin-dependent kinases discussed in Chapter 9 help control the cell cycle by adding phosphate groups to certain key proteins, causing them to become activated or inactivated. Chemical modifications such as protein phosphorylation also let the cell respond rapidly to certain hormones (see Chapter 47), or to fast-changing environmental or nutritional conditions.

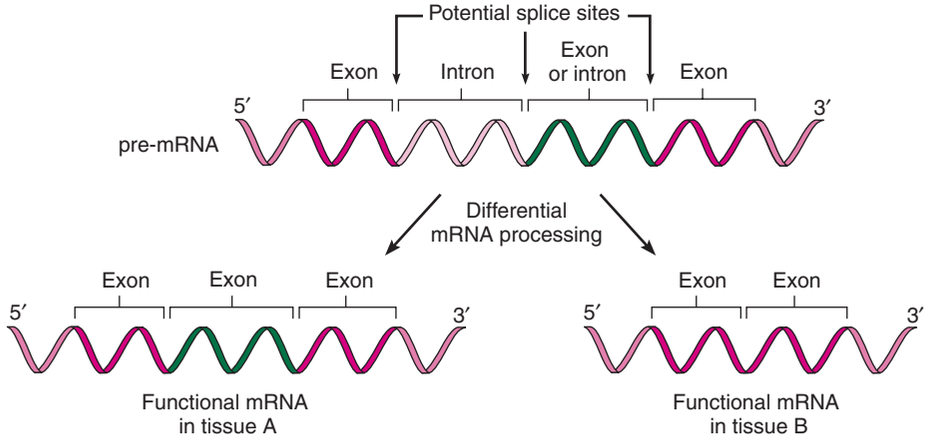

FIGURE **13-11**

Differential mRNA processing.

In some cases, a pre-mRNA molecule is processed in more than one way to yield two or more mature mRNAs, each of which encodes a related, but different, protein. In this generalized example, the gene contains a segment that can be an exon in tissue A *(left),* but an intron in tissue B *(right).*

Review

- How does regulation of eukaryotic genes differ from regulation of bacterial genes?
- Why must certain genes in eukaryotic cells be present in multiple copies?
- How does chromosome structure affect the activity of some eukaryotic genes?
- How does differential mRNA processing give rise to different proteins?

BiologyNow™ Assess your understanding of **gene regulation in eukaryotic cells** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Explain why bacterial and eukaryotic cells have different mechanisms of gene regulation.

- Bacterial cells grow rapidly and have a relatively short life span. Controlling transcription is the most economical way for the cell to regulate gene expression.
- Eukaryotic cells have different regulatory requirements, in part because eukaryotes usually have a long life span, during which they respond to many different stimuli. Also, a single gene is regulated in different ways in different types of cells. Although transcriptional-level control predominates, control at other levels of gene expression is also important.

2 Define *operon;* sketch the main elements of the *lac* operon, and explain the functions of the operator and promoter regions.

- Most regulated genes in bacteria are organized into operons. Each **operon** is a gene complex consisting of a group of structural genes with related functions, plus the closely linked DNA sequences responsible for controlling them.
- Each operon has a single **promoter** region upstream from the protein-coding regions.
- The **operator** serves as the regulatory switch for **transcriptional-level control** of the operon. When a **repressor protein** binds to the operator sequence, it prevents transcription; although RNA polymerase binds to the promoter, it is blocked from transcribing the structural genes. When the repressor is not bound to the operator, transcription proceeds.

3 Distinguish among inducible, repressible, and constitutive genes.

- An **inducible operon,** such as the *lac* operon, is normally turned off. The repressor protein is synthesized in an active form that binds to the operator. If lactose is present, it is converted to allolactose, the **inducer,** which binds an allosteric site on the repressor protein, changing its shape. The altered repressor cannot bind to the operator, and the operon is transcribed.
- A **repressible operon,** such as the *trp* operon, is normally turned on. The repressor protein is synthesized in an inactive form that cannot bind to the operator. A metabolite (usually the end product of a metabolic pathway) acts as a **corepressor.** When intracellular corepressor levels are high, a corepressor molecule binds to an allosteric site on the repressor, changing its shape so that it binds to the operator and thereby turns off transcription of the operon.
- **Constitutive genes** are neither inducible nor repressible; they are active at all times. Regulatory proteins such as **catabolite activator protein** (**CAP**) and the repressor proteins are produced constitutively. These proteins work by recognizing and binding to specific base sequences in the DNA. The activity of constitutive genes is controlled by how efficiently RNA polymerase binds to their promoter regions.

4 Differentiate between positive and negative control, and show how both types of control operate in regulating the *lac* operon.

- Repressible and inducible operons are under **negative control.** When the repressor protein binds to the operator, transcription of the operon is turned off.
- Some inducible operons are also under **positive control.** A separate protein binds to the DNA and stimulates transcription of the gene. CAP activates the lactose operon; CAP binds to the promoter region, stimulating transcription by binding RNA polymerase tightly. To bind to the *lac* operon, CAP requires **cyclic AMP** (**cAMP**). Levels of cAMP increase as levels of glucose decrease.

5 Describe the types of posttranscriptional control in bacteria.

- Some **posttranscriptional controls** operate in bacteria. A **translational control** is a posttranscriptional control that regulates the rate of translation of a particular mRNA. **Posttranslational controls** include **feedback inhibition** of key enzymes in some metabolic pathways.

6 Discuss the structure of a typical eukaryotic gene and the DNA sequences involved in regulating that gene.

- Eukaryotic genes are not normally organized into operons. Regulation of eukaryotic genes occurs at the levels of transcription, mRNA processing, translation, and the protein product.
- The promoter of a regulated eukaryotic gene consists of an RNA polymerase-binding site and short DNA sequences known as **upstream promoter elements** (**UPEs**). The number and types of UPEs within the promoter region determine the efficiency of the promoter.
- Inducible eukaryotic genes are controlled by **enhancers,** which are located thousands of bases away from the promoter. Proteins that bind to enhancers seem to facilitate the binding of RNA polymerase to the promoter.

7 Give examples of some of the ways eukaryotic DNA-binding proteins bind to DNA.

- Eukaryotic genes are controlled by DNA-binding protein regulators called **transcription factors.** Many are transcriptional activators; others are transcriptional repressors.
- Each transcription factor has a DNA-binding **domain**. Some transcription factors have a helix-turn-helix arrangement and insert one of the helices into the DNA. Other transcription

SUMMARY WITH KEY TERMS *(continued)*

factors have loops of amino acids held together by zinc ions; each loop includes an α-helix that fits into the DNA. Some transcription factors are **leucine zipper proteins** that have dimers that insert into the DNA.

8 Illustrate how a change in chromosome structure may affect the activity of a gene.

- Genes are inactivated by changes in chromosome structure. Densely packed regions of chromosomes called **heterochromatin** contain inactive genes. Active genes are associated with a loosely packed chromatin structure called **euchromatin.**
- **DNA methylation** is a mechanism that perpetuates gene inactivation.
- Some genes whose products are required in large amounts exist as multiple copies in the chromosome. In the process of **gene amplification,** some cells selectively amplify genes by DNA replication.

9 Explain how a gene in a multicellular organism may produce different products in different types of cells.

- As a result of **differential mRNA processing,** a single gene produces different forms of a protein in different tissues, depending on how the pre-mRNA is spliced. Typically, such a gene contains a segment that can be either an intron or an exon. As an intron, the sequence is removed, and as an exon, the sequence is retained.

10 Identify some of the types of regulatory controls that operate in eukaryotes after mature mRNA is formed.

- Certain regulatory mechanisms increase the stability of mRNA, allowing more protein molecules to be synthesized before mRNA degradation. In certain cases mRNA stability is under hormonal control.
- Posttranslational control of eukaryotic genes occurs by feedback inhibition or by modification of the protein structure. The function of a protein is changed by **kinases** adding phosphate groups or by **phosphatases** removing phosphates.

POST-TEST

1. The regulation of most bacterial genes occurs at the level of (a) transcription (b) translation (c) replication (d) posttranslation (e) postreplication
2. The operator of an operon (a) encodes information for the repressor protein (b) is the binding site for the inducer (c) is the binding site for the repressor protein (d) is the binding site for RNA polymerase (e) encodes the information for the CAP
3. A mutation that inactivates the repressor gene of the *lac* operon results in (a) the continuous transcription of the structural genes (b) no transcription of the structural genes (c) the binding of the repressor to the operator (d) no production of RNA polymerase (e) no difference in the rate of transcription
4. At a time when the *lac* operon is actively transcribed, (a) the operator is bound to the inducer (b) the lactose repressor is bound to the promoter (c) the operator is not bound to the promoter (d) the gene coding for the repressor is not expressed constitutively (e) the lactose repressor is bound to the inducer
5. A repressible operon codes for the enzymes of the following pathway. Which component of the pathway is most likely to be the corepressor for that operon?

(a) substance A (b) substance B or C (c) substance D (d) enzyme 1 (e) enzyme 3

6. An mRNA molecule transcribed from the *lac* operon contains nucleotide sequences complementary to (a) structural genes coding for enzymes (b) the operator region (c) the promoter region (d) the repressor gene (e) introns
7. Feedback inhibition is an example of control at the level of _____. (a) transcription (b) translation (c) posttranslation (d) replication (e) all of the preceding
8. Which of the following control mechanisms is generally the most economical in terms of conserving energy and resources? (a) control by means of operons and regulons (b) feedback inhibition (c) selective degradation of mRNA (d) selective degradation of enzymes (e) gene amplification
9. A repressible operon, such as the *trp* operon, is "off" when (a) the gene that codes for the repressor is expressed constitutively (b) the repressor-corepressor complex binds to the operator (c) the repressor binds to the structural genes (d) the corepressor binds to RNA polymerase (e) CAP binds to the promoter
10. Which of the following is an example of positive control? (a) transcription occurs when a repressor binds to an inducer (b) transcription cannot occur when a repressor binds to a corepressor (c) transcription is stimulated when an activator protein binds to DNA (d) a and b (e) a and c
11. Which of the following are typically absent in bacteria? (a) enhancers (b) proteins that regulate transcription (c) repressors (d) promoters (e) operators
12. The "zipper" of a leucine zipper protein attaches (a) specific amino acids to specific DNA base pairs (b) two polypeptide chains to each other (c) one DNA region to another DNA region (d) amino acids to zinc atoms (e) RNA polymerase to the operator
13. Inactive genes tend to be found in (a) highly condensed chromatin, known as euchromatin (b) decondensed chromatin, known as euchromatin (c) highly condensed chromatin, known as heterochromatin (d) decondensed chromatin, known as heterochromatin (e) chromatin that is not organized as nucleosomes
14. Which of the following is characteristic of genes and gene regulation in bacteria, but *not* eukaryotes? (a) presence of enhancers (b) capping of mRNAs (c) many chromosomes per cell (d) extensive binding of DNA to many kinds of regulatory proteins (e) exon splicing not required
15. Which of the following is characteristic of genes and gene regulation in *both* bacteria and eukaryotes? (a) promoter (b) noncoding

POST-TEST *(continued)*

DNA within coding sequences (c) enhancer (d) operons (e) DNA located in a nucleus

16. Which of the following is characteristic of genes and gene regulation in eukaryotes, but *not* bacteria? (a) enhancers (b) transcription factors (c) promoters (d) a and b only (e) a, b, and c are found in eukaryotes but not bacteria
17. Through differential mRNA processing, eukaryotes (a) reinforce gene inactivation (b) prevent transcription of heterochromatin (c) produce related but different proteins in different tissues (d) amplify genes to meet the requirement of high levels of a gene product (e) bind transcription factors to enhancers to activate transcription

CRITICAL THINKING

1. Develop a simple hypothesis that would explain the behavior of each of the following types of mutants in *E. coli:*
   Mutant a: The map position of this mutation is in the *trp* operon. The mutant cells are constitutive; that is, they produce all the enzymes coded for by the *trp* operon, even if large amounts of tryptophan are present in the growth medium.
   Mutant b: The map position of this mutation is in the *trp* operon. The mutant cells do not produce any enzymes coded for by the *trp* operon under any conditions.
   Mutant c: The map position of this mutation is some distance from the *trp* operon. The mutant cells are constitutive; that is, they produce all the enzymes coded for by the *trp* operon, even if the growth medium contains large amounts of tryptophan.
   Mutant d: The map position of this mutation is some distance from the *trp* operon. The mutant cells do not produce any enzymes coded for by the *trp* operon under any conditions.
2. Compare the types of bacterial genes associated with inducible operons, those associated with repressible operons, and those that are constitutive. Predict the category into which each of the following would most likely fit: (a) a gene that codes for RNA polymerase, (b) a gene that codes for an enzyme required to break down maltose, (c) a gene that codes for an enzyme used in the synthesis of adenine.
3. The regulatory gene that codes for the tryptophan repressor is not tightly linked to the *trp* operon. Would it be advantageous if it were? Explain your answer.

CHAPTER OUTLINE

- Recombinant DNA Methods
- Applications of DNA Technologies
- Safety Guidelines for DNA Technology

During the mid-1970s, as the development of new ways of studying DNA led to radically new research approaches, a revolution in the field of biology began. These techniques have had a major impact, and not just in genetic studies. DNA technologies affect a wide range of areas from cell biology and evolution to ethical and societal issues.

This chapter begins with a consideration of **recombinant DNA technology,** in which researchers splice together DNA from different organisms in the laboratory. The primary goal of this technology is to enable scientists to obtain many copies of any specific DNA segment for the purpose of studying it biochemically. Using recombinant DNA technology, scientists introduce foreign DNA into the cells of microorganisms. Under the right conditions, when a cell divides this DNA is replicated and transmitted to the daughter cells. In this way, a particular DNA sequence is amplified, or **cloned,** to provide millions of identical copies that are isolated in pure form. Today these methods have been supplemented by extremely valuable techniques for the cloning of DNA in vitro, outside a living organism. Because new recombinant DNA methods are continually emerging, we do not attempt to explore them all here. Instead, we discuss some of the major approaches that have provided a foundation for the technology.

We also consider the ways in which studies of **cloned DNA sequences** have been of immense value in helping scientists understand the organization of genes and the relationship between genes and their products. In fact, most current knowledge of the structure and control of eukaryotic genes, and of the roles of genes in development, comes from applying these methods.

This chapter also explores some of the many practical applications of DNA technologies. One of the rapidly advancing areas of study is **genetic engineering**—modifying the DNA of an organism to produce new genes with new traits. Genetic engineering can take many forms, ranging from basic research (see photograph) to the production of strains of bacteria that manufacture useful protein products, to the development of plants and animals that express foreign genes.

This wide range of applications of ongoing discoveries in molecular genetics is transforming people's view of **biotechnology,** the use of organisms to benefit humanity. Traditional forms of biotechnology include such familiar examples as the selective breeding of plants and the use of yeast to make alcoholic beverages or cause bread to rise. However, the examples of biotechnology most frequently cited today are applications of genetic engineering in such diverse areas as medicine and the pharmaceutical industry, foods and agriculture, and forensic science. Biotechnology does not stand alone; its advances are greatly facilitated by other kinds of technology, including powerful computer programs and automated systems. ■

RECOMBINANT DNA METHODS

Learning Objectives

1. Explain how a typical restriction enzyme cuts DNA molecules, and give examples of the ways in which these enzymes are used in recombinant DNA technology.
2. Distinguish among a genomic library, a chromosome library, and a complementary DNA (cDNA) library; explain why one would clone the same eukaryotic gene from both a genomic library and a cDNA library.
3. Identify some uses of DNA hybridization probes.
4. Describe how the polymerase chain reaction amplifies DNA in vitro.
5. Describe the chain termination method of DNA sequencing.

Recombinant DNA technology was not developed quickly. It actually had its roots in the 1940s with genetic studies of bacteria and **bacteriophages** ("bacteria eaters"), the viruses that infect them (see Chapters 11 and 23). After decades of basic research and the accumulation of extensive knowledge, the technology became feasible and available to the many scientists who now use these methods.

In recombinant DNA technology, enzymes from bacteria, known as **restriction enzymes,** are used to cut DNA molecules only in specific places. Restriction enzymes enable researchers to cut DNA into manageable segments. Each fragment is then incorporated into a suitable **vector** molecule, a carrier capable of transporting the DNA fragment into a cell. Bacteriophages and DNA molecules called plasmids are two examples of vectors. Bacterial DNA is circular; a **plasmid** is a separate, much smaller, circular DNA molecule that may be present and replicate inside a bacterial cell, such as *E. coli.* Researchers introduce plasmids into bacterial cells by a method called **transformation,** the uptake of foreign DNA by cells (see Chapter 11). For transformation to be efficient, the researcher alters the bacterial cell walls to make them permeable to the plasmid DNA molecules. Once a plasmid enters a cell, it is replicated and distributed to its daughter cells during cell division. When a *recombinant plasmid* (one that has foreign DNA spliced into it) replicates in this way, many copies of the foreign DNA are made—that is, the foreign DNA is cloned.

Restriction enzymes are "molecular scissors"

Discovering restriction enzymes was a major breakthrough in developing recombinant DNA technology. Today large numbers of different types of restriction enzymes, each with its own characteristics, are readily available to researchers. For example, a restriction enzyme known as *Hin*dIII recognizes and cuts a DNA molecule at the restriction site 5′—AAGCTT—3′, whereas the sequence 5′—GAATTC—3′ is cut by another, known as *Eco*RI. (The names of restriction enzymes are generally derived from the names of the bacteria from which they were originally isolated. Thus, *Hin*dIII and *Eco*RI are derived from *Hemophilus influenzae* and *E. coli,* respectively.)

Why do bacteria produce such enzymes? During infection, a bacteriophage injects its DNA into a bacterial cell. The bacterium can defend itself if it has restriction enzymes that can attack the bacteriophage DNA. The cell protects its own DNA from breakdown by modifying it after replication. An enzyme adds a methyl group to one or more bases in each restriction site so that the restriction enzyme does not recognize and cut the bacterial DNA.

Restriction enzymes enable scientists to cut DNA from chromosomes into shorter fragments in a controlled way. Many of the restriction enzymes used for recombinant DNA studies cut **palindromic sequences,** which means the base sequence of one strand reads the same as its complement when both are read in the 5′ to 3′ direction. Thus, in our *Hin*dIII example, both strands read 5′—AAGCTT—3′, which as a double-stranded molecule is diagrammed as

```
5′—AAGCTT—3′
3′—TTCGAA—5′
```

By cutting both strands of the DNA, but in a staggered fashion, these enzymes produce fragments with identical, complementary, single-stranded ends:

```
5′—A AGCTT—3′
3′—TTCGA A—5′
```

These ends are called *sticky ends* because they pair (by hydrogen bonding) with the complementary, single-stranded ends of other DNA molecules that have been cut with the same enzyme (Fig. 14-1). Once the sticky ends of two molecules have been joined together in this way, they are treated with **DNA ligase,** an enzyme that covalently links the two DNA fragments to form a stable recombinant DNA molecule.

Recombinant DNA forms when DNA is spliced into a vector

In recombinant DNA technology, geneticists cut both foreign DNA and plasmid DNA with the same restriction enzyme. The two types of DNA are then mixed together under conditions that facilitate hydrogen bonding between the complementary

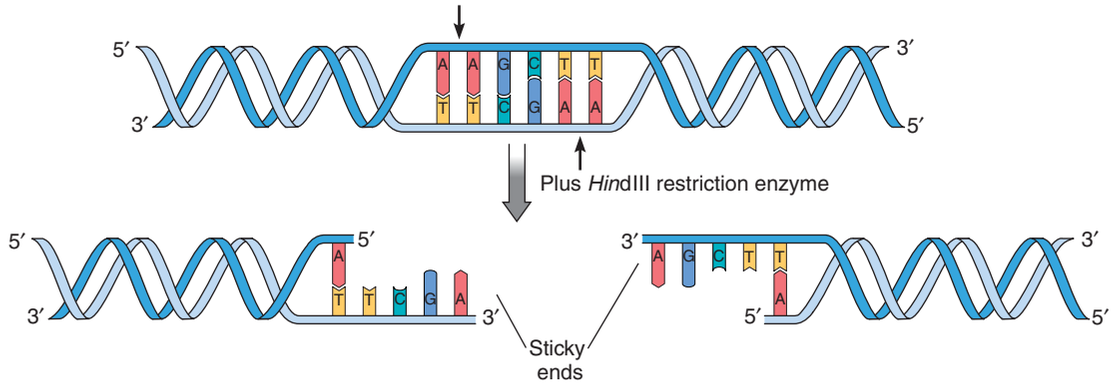

FIGURE **14-1** **Cutting DNA with a restriction enzyme.**

Many restriction enzymes, like *Hin*dIII, cut DNA at sequences that are palindromic, producing complementary sticky ends. The small black arrows designate the enzyme's cleavage sites.

bases of the sticky ends, and the nicks in the resulting recombinant DNA are sealed by DNA ligase (Fig. 14-2).

The plasmids now used in recombinant DNA work have been extensively manipulated in the laboratory to include features helpful in isolating and analyzing cloned DNA (Fig. 14-3). Among these are an origin of replication (see Chapter 11), one or more restriction sites, and genes that let researchers select cells transformed by recombinant plasmids. These genes cause transformed cells to grow under specified conditions that do not allow untransformed cells to grow. In this way, the researchers use features that are also common in naturally occurring plasmids. Typically, plasmids do not contain genes essential to the bacterial cells under normal conditions. However, they often carry genes useful under specific environmental conditions, such as genes that confer resistance to particular antibiotics or let the cells use a specific nutrient. For example, cells transformed with a plasmid that includes a gene for resistance to the antibiotic tetracycline can grow in a medium that contains tetracycline, whereas untransformed cells cannot.

A limiting property of any vector, however, is the size of the DNA fragment it can effectively carry. The size of a DNA segment is often given in kilobases, with 1 kilobase (kb) being

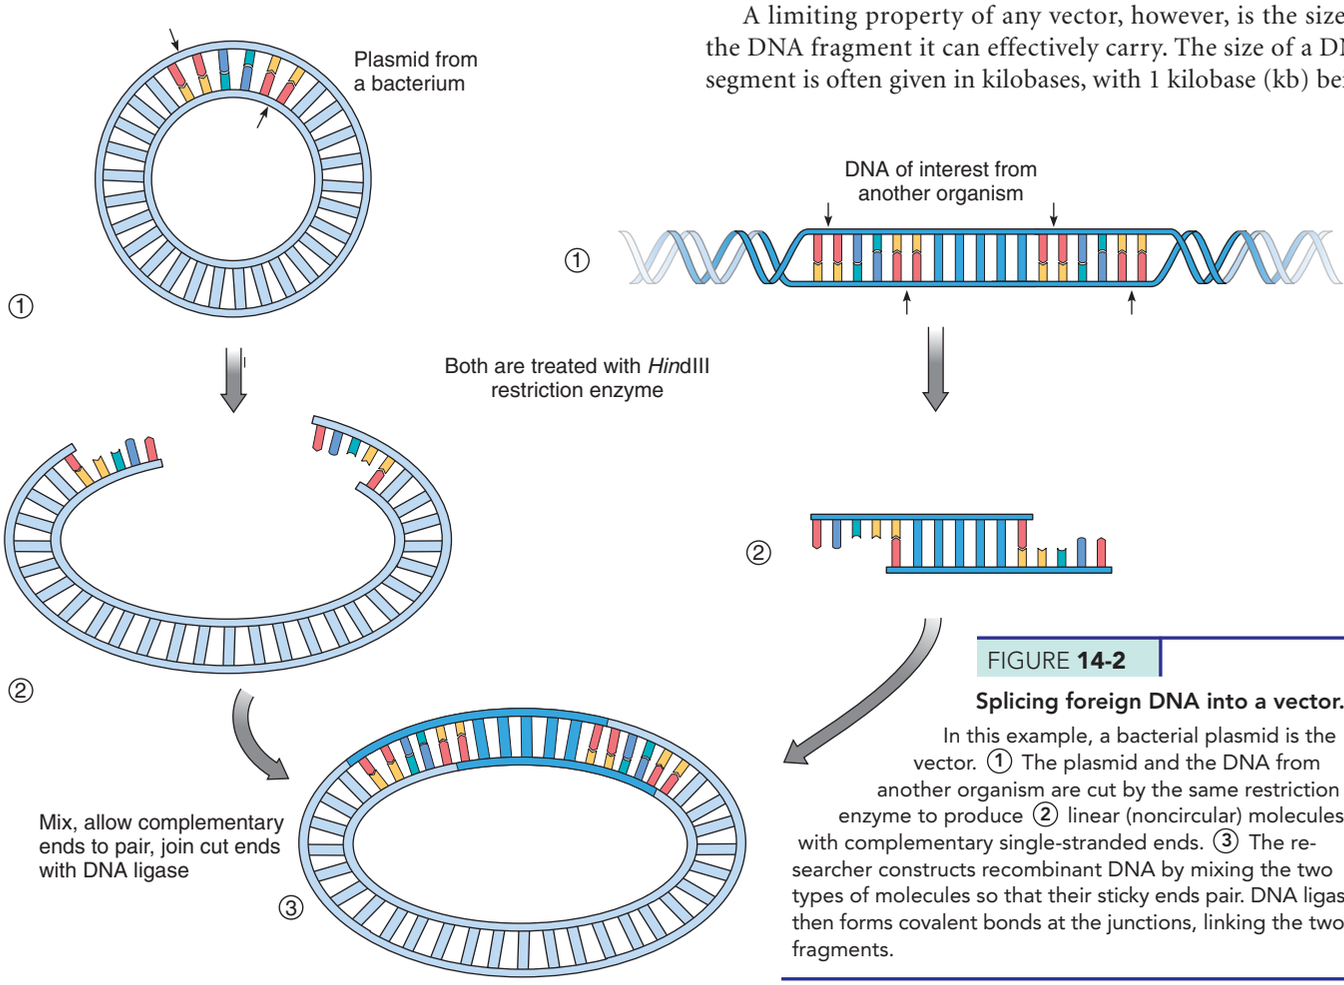

FIGURE **14-2**

Splicing foreign DNA into a vector.

In this example, a bacterial plasmid is the vector. ① The plasmid and the DNA from another organism are cut by the same restriction enzyme to produce ② linear (noncircular) molecules with complementary single-stranded ends. ③ The researcher constructs recombinant DNA by mixing the two types of molecules so that their sticky ends pair. DNA ligase then forms covalent bonds at the junctions, linking the two fragments.

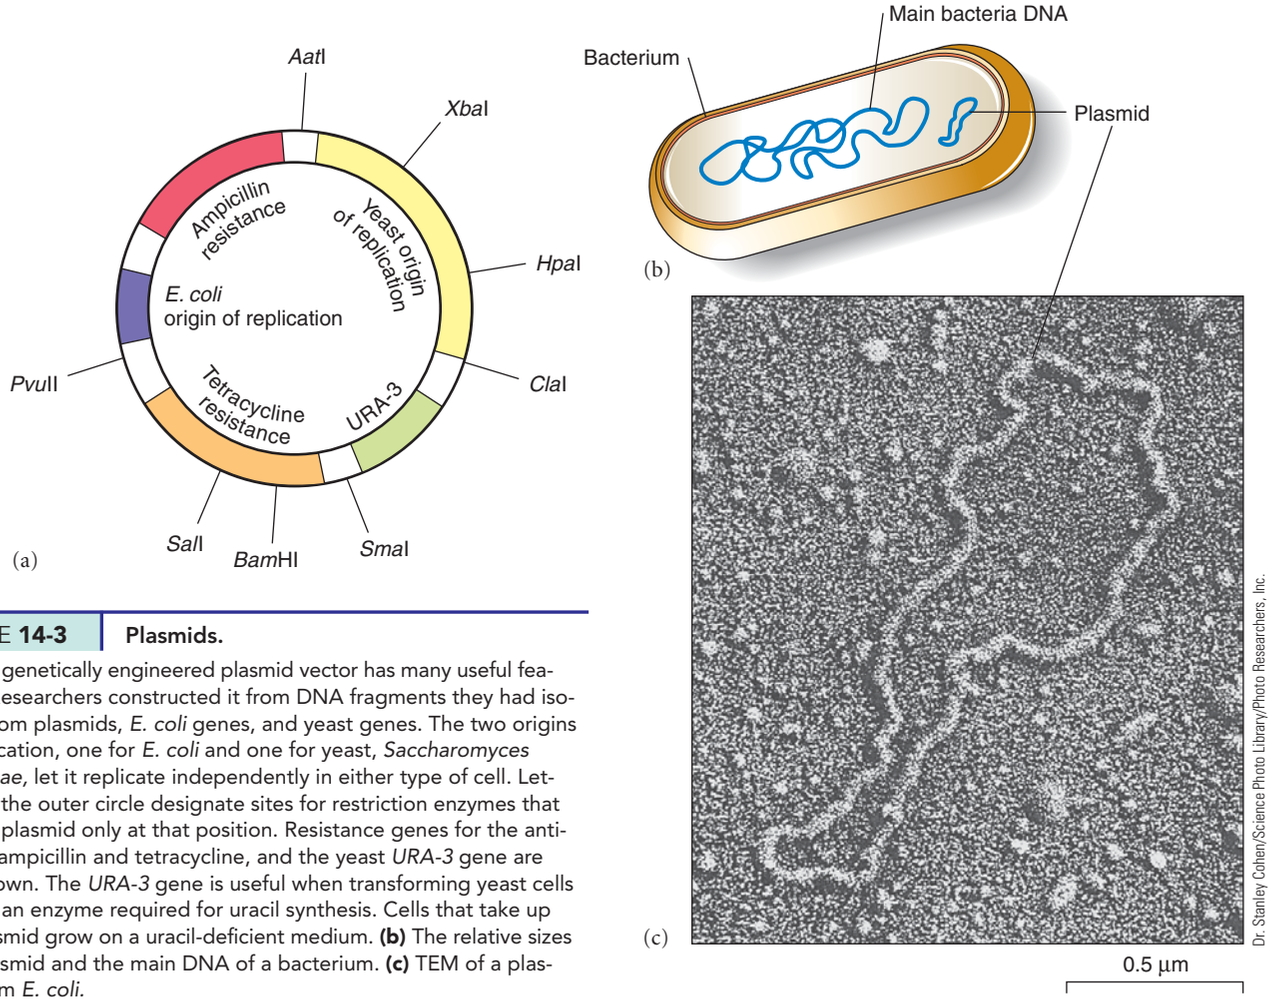

FIGURE **14-3** **Plasmids.**

(a) This genetically engineered plasmid vector has many useful features. Researchers constructed it from DNA fragments they had isolated from plasmids, *E. coli* genes, and yeast genes. The two origins of replication, one for *E. coli* and one for yeast, *Saccharomyces cerevisiae,* let it replicate independently in either type of cell. Letters on the outer circle designate sites for restriction enzymes that cut the plasmid only at that position. Resistance genes for the antibiotics ampicillin and tetracycline, and the yeast *URA-3* gene are also shown. The *URA-3* gene is useful when transforming yeast cells lacking an enzyme required for uracil synthesis. Cells that take up the plasmid grow on a uracil-deficient medium. **(b)** The relative sizes of a plasmid and the main DNA of a bacterium. **(c)** TEM of a plasmid from *E. coli.*

equal to 1000 base pairs. Fragments smaller than 10 kb can usually be inserted into plasmids for use in *E. coli.* However, larger fragments require the use of bacteriophage vectors, which can handle up to 23 kb of DNA. Other vectors are **cosmid cloning vectors,** which are combination vectors with features from both bacteriophages and plasmids, and **bacterial artificial chromosomes (BACs),** which accommodate much larger fragments of DNA. For example, a BAC can include up to about 200 kb of extra DNA, a feature that made BACs especially useful in the Human Genome Project (see Chapter 15).

Recombinant DNA can also be introduced into cells of eukaryotic organisms. For example, geneticists use engineered viruses as vectors in mammal cells. These viruses are disabled so they do not kill the cells they infect. Instead, the viral DNA, as well as any foreign DNA they carry, becomes incorporated into the cell's chromosomes after infection. As discussed later, other methods do not require a biological vector.

DNA can be cloned inside cells

Because a single gene is only a small part of the total DNA in an organism, isolating the piece of DNA containing that particular gene is like finding a needle in a haystack: A powerful detector is needed. Today many methods enable biologists to isolate a specific nucleotide sequence from an organism. We start by discussing methods in which DNA is cloned inside bacterial cells. We use the cloning of human DNA as an example, although the procedure is applicable for any organism.

A genomic library contains fragments of all DNA in the genome

The total DNA in a cell is called the **genome.** For example, if DNA is extracted from human cells, we refer to it as human genomic DNA. A **genomic library** is a collection of thousands of DNA fragments that represent all the DNA in the genome. Each fragment is inserted into a plasmid, which is usually incorporated into a bacterial cell. Thus the human genomic library is stored in a collection of recombinant bacteria, each with a different fragment of human DNA. Genomic libraries are used to isolate and study specific genes.

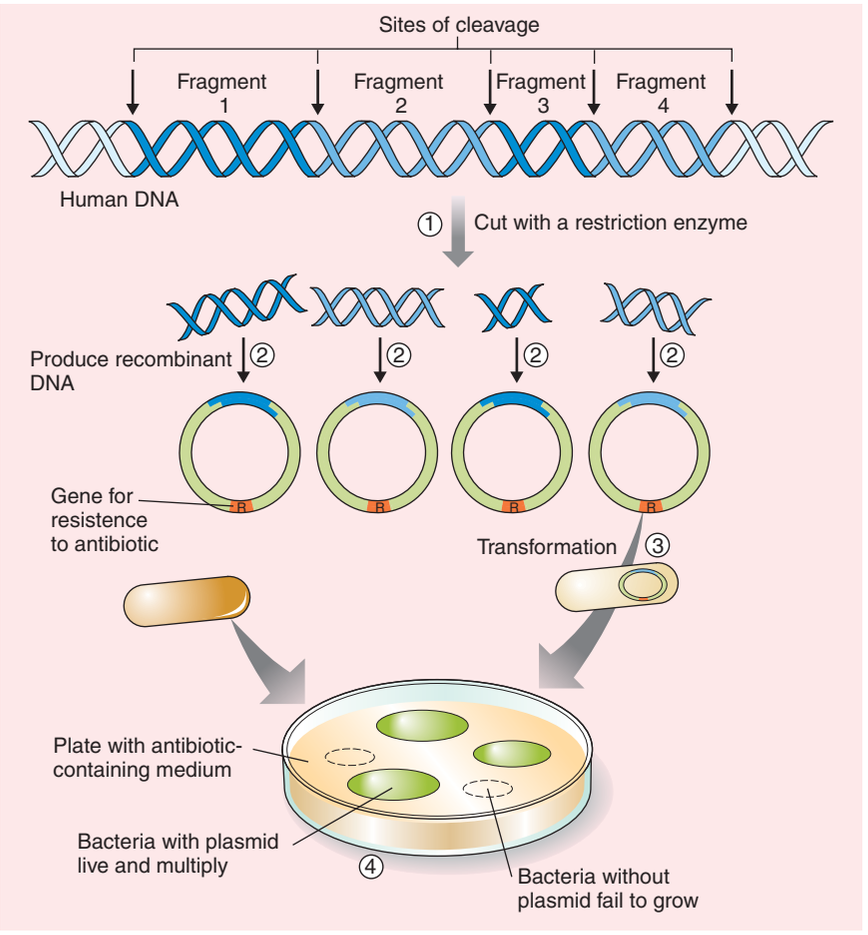
Individual chromosomes can also be isolated to make a **chromosome library** containing all the DNA fragments in that specific chromosome. If a gene of interest is known to be associated with a particular chromosome, it is easier to isolate that gene from a chromosome library than from a genomic library.

The first step in producing a genomic or chromosome library is to cut the DNA with a restriction enzyme, generating

FIGURE **14-4**

Producing a genomic or chromosome library.

Only a small part of one chromosome is shown. A great many more DNA fragments would be produced from an entire chromosome or genome. The numbered steps in the figure are explained in the text.



a population of DNA fragments (Fig. 14-4, step ①). These fragments vary in size and in the genetic information they carry, but they all have identical sticky ends. Geneticists treat plasmid DNA that will be used as a vector with the same restriction enzyme, which converts the circular plasmids into linear molecules with sticky ends complementary to those of the human DNA fragments. Recombinant plasmids are produced by mixing the two kinds of DNA (human and plasmid) together under conditions that promote hydrogen bonding of complementary bases. Then DNA ligase is used to covalently bond the paired ends of the plasmid and human DNA, forming recombinant DNA (Fig. 14-4, step ②). Unavoidably, nonrecombinant plasmids also form, because some plasmids revert to their original circular shape without incorporating foreign DNA.

The geneticists insert plasmids into antibiotic-sensitive bacterial cells by transformation (Fig. 14-4, step ③). Because the ratio of plasmids to cells is kept very low, it is rare for a cell to receive more than one plasmid molecule, and not all cells receive a plasmid. The researchers incubate normally antibiotic-sensitive cells on a nutrient medium that includes antibiotics, so only those cells grow that have incorporated a plasmid (which contains a gene for antibiotic resistance) (Fig. 14-4, step ④). In addition, the plasmid has usually been engineered in ways that enable researchers to identify those cells containing recombinant plasmids.

Genomic and chromosome libraries contain redundancies; that is, certain human DNA sequences have been inserted into plasmids more than once, purely by chance. However, each individual recombinant plasmid (analogous to a book in the library) contains only a single fragment of the total human genome.

To identify a plasmid containing a sequence of interest, the researcher clones each plasmid until there are millions of copies to work with. This process occurs as the bacterial cells grow and divide. A dilute sample of the bacterial culture is spread on solid growth medium, so the cells are widely separated. Each cell divides many times, yielding a visible **colony,** which is a clone of genetically identical cells originating from a single cell. All the cells of a particular colony contain the same recombinant plasmid, so during this process a specific sequence of human DNA is also cloned. The major task is to determine which colony (out of thousands) contains a cloned fragment of interest. Specific DNA sequences are identified in various ways.

A complementary genetic probe detects a specific DNA sequence

Suppose a researcher wishes to screen the thousands of recombinant DNA molecules in bacterial cells to find the one that contains a gene coding for a specific protein. A common approach to detecting the DNA of interest involves using a **genetic probe,** which is usually a radioactively labeled segment of single-stranded DNA that can **hybridize**—become attached by base pairing—to complementary base sequences in the target gene. If at least part of the amino acid sequence of that protein is known, it is possible to synthesize a radioactive, single-stranded DNA fragment to code for that sequence. However, because of the existence of synonymous codons, a specific amino acid sequence could potentially be coded for by many different base sequences (see Fig. 12-5). One approach to solving this problem has been to synthesize a complete mixture of all possible probes that could code for the desired amino acid sequence.

Biologists use genetic probes in a variety of ways. For example, they transfer cells from bacterial colonies containing recombinant plasmids to a nitrocellulose or nylon membrane, which then becomes a *replica* of the colonies (Fig. 14-5). They treat the cells on the membrane chemically to lyse them, making the DNA single-stranded. Then they incubate the membrane with the radioactive probe mixture to let the probes hybridize with any complementary strands of DNA that may be

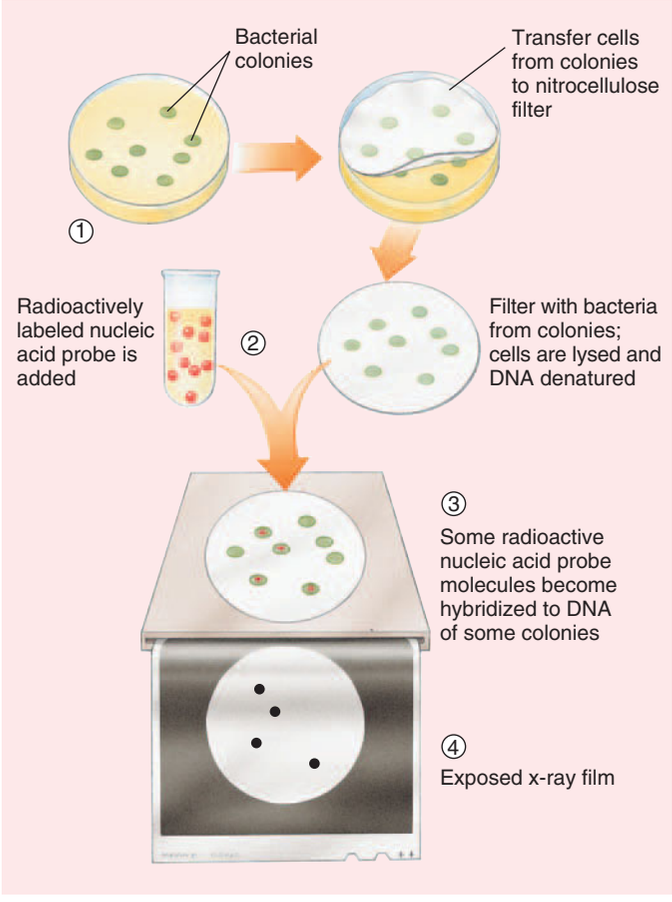


FIGURE **14-5** **Using a genetic probe to find bacterial cells with a specific recombinant DNA molecule.**

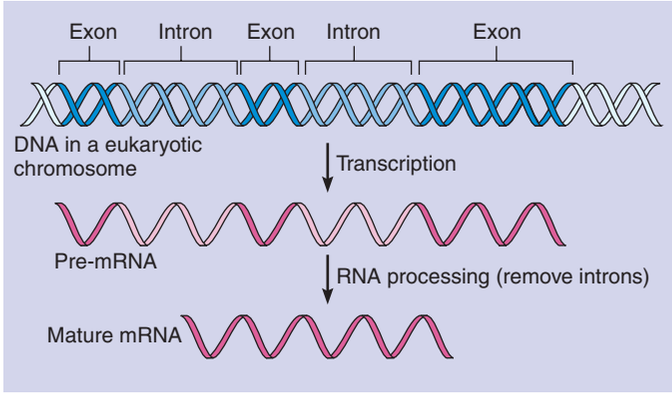
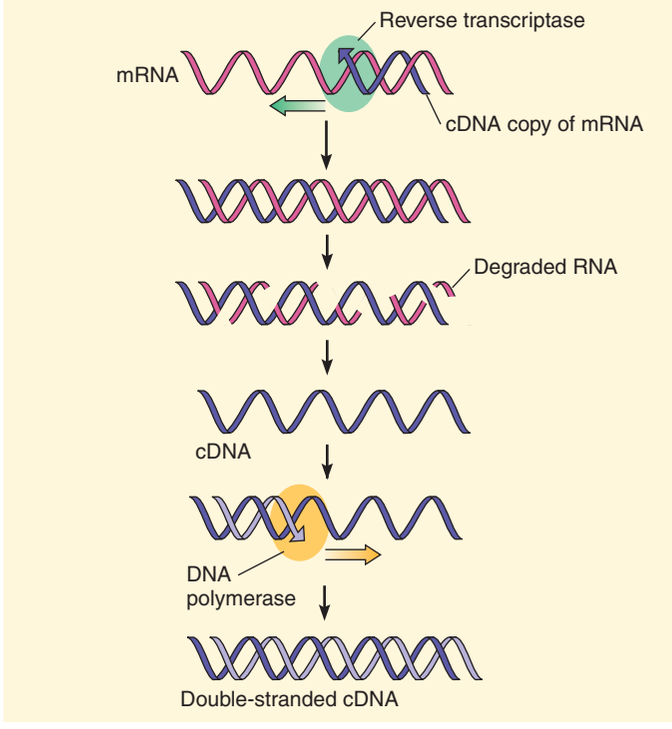
A radioactive nucleic acid probe, which is usually single-stranded DNA, reveals the presence of complementary sequences of DNA.



(a)



(b)

FIGURE **14-6** **The formation of cDNA.**

(a) The formation of cDNA relies on RNA processing that occurs in the nucleus to yield mature mRNA. **(b)** The mature mRNA is extracted and purified. To make a DNA copy of the mature mRNA, researchers use reverse transcriptase to produce a single-stranded cDNA complementary to the mRNA. Specific enzymes then degrade the mRNA, and DNA polymerase is used to synthesize a second strand of DNA. The end result is a double-stranded cDNA molecule.

present. Each spot on the membrane containing DNA complementary to that particular probe becomes radioactive and is detected by autoradiography (see Chapter 2), using x-ray film. Each spot on the film therefore identifies a colony containing a plasmid that includes the DNA of interest. Cells from the desired colonies are then cultured to produce millions of new bacteria, all containing the recombinant DNA of interest.

A cDNA library is complementary to mRNA and does not contain introns

Researchers frequently wish to clone intact genes while avoiding **introns,** which are regions of eukaryotic genes that do not code for proteins. Scientists also may wish to clone only genes that are expressed in a particular cell type. In such cases, they construct libraries of DNA copies of mature mRNA from which introns have been removed. The copies, known as **complementary DNA (cDNA)** because they are complementary to mRNA, also lack introns. The researchers use the enzyme **reverse transcriptase** (see Chapter 12) to synthesize single-stranded cDNA, which they separate from the mRNA and make double-stranded with DNA polymerase (Fig. 14-6). A **cDNA library** is formed using mRNA from a single cell type as the starting material. The double-stranded cDNA molecules are inserted into plasmid or virus vectors, which then multiply in bacterial cells.

Analyzing cDNA clones lets investigators determine certain characteristics of the protein encoded by the gene, including its amino acid sequence. They can also study the structure of the mature mRNA. Because the cDNA copy of the mRNA does

not contain intron sequences, comparing the DNA base sequences in cDNA and the DNA in genomic or chromosome libraries reveals the locations of intron and exon coding sequences in the gene.

Cloned cDNA sequences are also useful when geneticists want to produce a eukaryotic protein in bacteria. When they introduce an intron-containing human gene, such as the gene for human growth hormone, into a bacterium, it can't remove the introns from the transcribed RNA to make a functional mRNA for producing its protein product. If they insert a cDNA clone of the gene into the bacterium, however, its transcript contains an uninterrupted coding region. A functional protein is synthesized if the geneticist inserts the gene downstream of an appropriate bacterial promoter and if he or she places the appropriate bacterial translation initiation sequences in it.

The polymerase chain reaction is a technique for amplifying DNA in vitro

The methods for amplifying a specific DNA sequence just described all involve cloning DNA in cells, usually those of bacteria. These processes are time consuming and require an adequate DNA sample as starting material. The **polymerase chain reaction** (**PCR**) technique, which U.S. biochemist Kary Mullis developed in 1985, lets researchers amplify a tiny sample of DNA millions of times in a few hours. In 1993, Mullis received the Nobel Prize in Chemistry for his work.

In PCR, DNA polymerase uses nucleotides and primers to replicate a DNA sequence in vitro, thereby producing two DNA molecules (Fig. 14-7). Then the researchers denature (separate by heating) the two strands of each molecule and replicate them again, yielding four double-stranded molecules. After the next cycle of heating and replication, there are eight molecules, and so on, with the number of DNA molecules doubling in each cycle. After only 20 heating and cooling cycles (done using automated equipment), this exponential process yields 2^{20}, or more than 1 million, copies of the target sequence!

Because the reaction can be carried out efficiently only if the DNA polymerase can remain stable through many heating cycles, researchers use a heat-resistant DNA polymerase, known as *Taq* polymerase. The name of this enzyme reflects its source, *Thermus aquaticus,* a bacterium that lives in hot springs in Yellowstone National Park. Because the water in this environment is close to the boiling point, all enzymes in *T. aquaticus* have evolved to be stable at high temperatures. Bacteria living in deep-sea thermal vents have similar enzymes (see *Focus On: Life without the Sun,* Chapter 53).

The PCR technique has virtually limitless applications. It enables researchers to amplify and analyze tiny DNA samples from a variety of sources, ranging from crime scenes to archaeological remains. For example, in 1997 investigators reported the first analysis of mitochondrial DNA obtained from the bones of Neandertals (see Chapter 21).

A limitation of the PCR technique is that it is almost too sensitive. Even a tiny amount of contaminant DNA in a sample

KEY CONCEPT: PCR has repeated cycles of denaturation, primer attachment, and strand elongation by complementary base pairing.

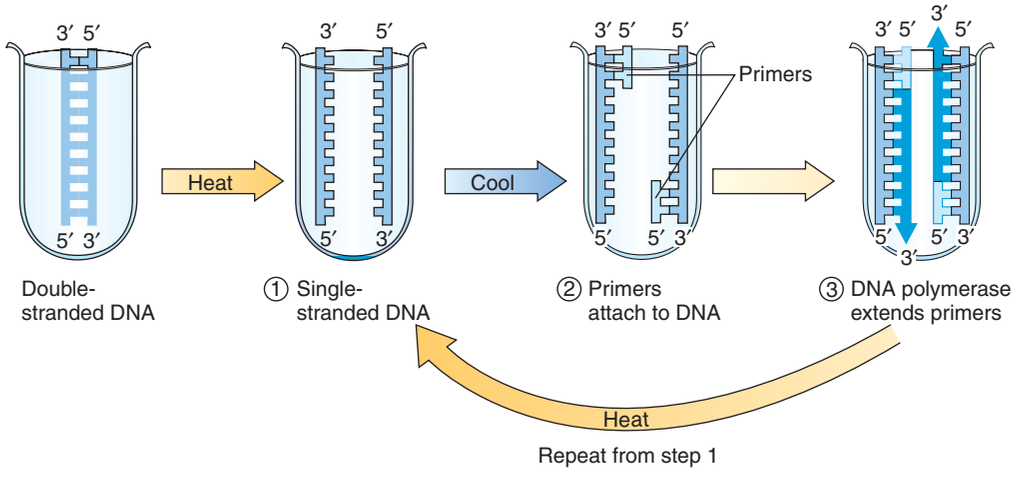


FIGURE **14-7** **Amplification of DNA by PCR.**

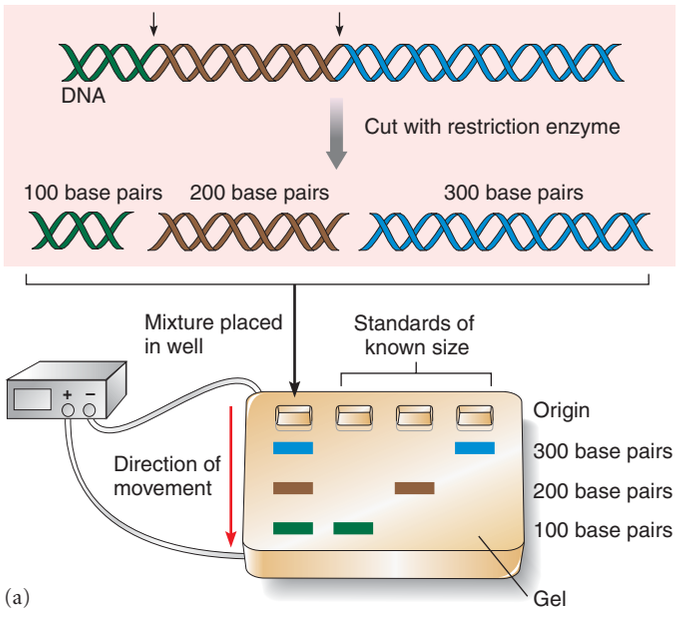
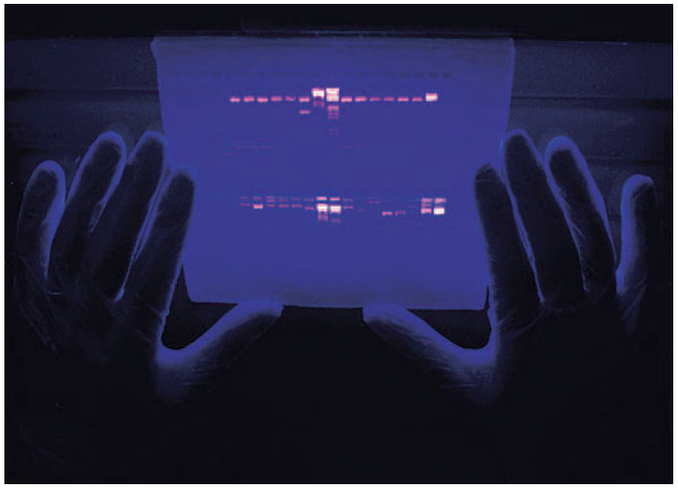
The initial reaction mixture includes a very small amount of double-stranded DNA, DNA precursors (deoxyribonucleotides), specific nucleic acid primers, and heat-resistant *Taq* DNA polymerase.
① The DNA is denatured (separated into single strands) by heat.
② Primers attach to the primer-binding site on each DNA strand.
③ Each DNA strand acts as a template for DNA synthesis catalyzed by the *Taq* DNA polymerase. The number of double-stranded DNA molecules doubles each time the cycle of heating and cooling is repeated.





(b)

FIGURE **14-8** **Gel electrophoresis.**

(a) A researcher sets up an electrical field in a gel material, consisting of agarose or polyacrylamide, which is poured as a thin slab on a glass or Plexiglas holder. After the gel has solidified, the researcher loads samples containing a mixture of macromolecules of different sizes in wells formed at one end of the gel, then applies an electrical current. The smallest DNA fragments *(green)* travel the longest distance. **(b)** A gel containing separated DNA fragments. The gel is stained with ethidium bromide, a dye that binds to DNA and is fluorescent under UV light.

may become amplified if it includes a DNA sequence complementary to the primers, potentially leading to an erroneous conclusion. Researchers take appropriate precautions to avoid this and other technical pitfalls.

Gel electrophoresis is used for separating macromolecules

Mixtures of certain macromolecules—proteins, polypeptides, DNA fragments, or RNA—are separated by **gel electrophoresis,** a method that exploits the fact that these molecules carry charged groups that cause them to migrate in an electrical field. Figure 14-8 illustrates gel electrophoresis of DNA molecules. Both DNA and RNA migrate through the gel toward the positive pole of the electrical field because they are negatively charged, due to their phosphate groups. Because the gel slows down the large molecules more than the small molecules, they travel at a rate inversely proportional to their length (that is, molecular weight). Including DNA fragments of known size as standards ensures accurate measurements of the molecular weights of the unknown fragments.

Geneticists can identify specific DNA fragments that hybridize with a complementary genetic probe. However, it is impossible to hybridize a probe to DNA fragments contained in a gel. For this reason the DNA is usually denatured and then transferred to a nitrocellulose or nylon membrane, which picks up the DNA like a blotter picks up ink. The resulting blot, which is essentially a replica of the gel, is incubated with a DNA probe, which hybridizes with any complementary DNA fragments. If the probe is radioactive, the blot is subjected to autoradiography. The resulting spots on the x-ray film correspond to the locations of the fragments in the gel that are complementary to the probe. Today many radioactive probes are detected by chemical luminescence, which is analyzed by computer scanners, eliminating the need for autoradiography.

This method of detecting DNA fragments—separating them by gel electrophoresis and then transferring them to a nitrocellulose or nylon membrane—is called a **Southern blot,** named for its inventor, Edward M. Southern of Edinburgh University in Scotland. The procedure has widespread applications. It is often used to diagnose certain types of genetic disorders. For example, in some cases the DNA of a mutant allele is detected because it migrates differently in the gel from the DNA of its normal counterpart.

Similar blotting techniques are used to study RNA and proteins. When RNA molecules separated by electrophoresis are transferred to a membrane, the result is called, rather in jest, a **Northern blot.** In the same spirit, the term **Western blot** is applied to a blot consisting of proteins or polypeptides previously separated by gel electrophoresis. (So far, no one has invented a type of blot that could be called an Eastern blot.) In the case of Western blotting, scientists recognize the polypeptides of interest by labeled antibody molecules that bind to them specifically. For example, Western blotting is used diagnostically to detect the presence of proteins specific to HIV-1, the AIDS virus.

One way to characterize DNA is to determine its sequence of nucleotides

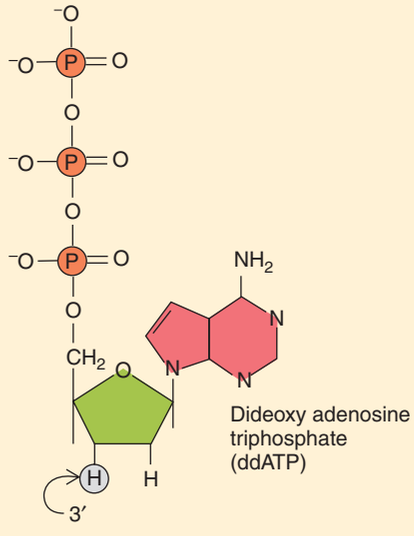
Investigators use a cloned piece of DNA as a research tool for many different applications. For example, they may clone a gene to obtain the encoded protein for some industrial or pharmaceutical process. Regardless of the particular application, before engineering a gene researchers must know a great deal about the gene and how it functions. The usual first step is determining the sequence of nucleotides.

DNA sequencing is based on methods that Sanger and Gilbert developed

In the 1990s, the advent of automated **DNA-sequencing** machines connected to powerful computers let scientists sequence huge amounts of DNA quickly and reliably. Automated DNA sequencing relies on the *chain termination method* that British biochemist Fred Sanger and U.S. biochemist Walter Gilbert developed in 1974. In 1980, Sanger and Gilbert shared the Nobel Prize in Chemistry for this contribution. (This was Sanger's second Nobel Prize. His first was for his work on the structure of the protein insulin.) Although DNA sequencing is now fully automated, we briefly consider the essential steps of the chain termination method.

This method of DNA sequencing is based on the fact that a replicating DNA strand that has incorporated a modified synthetic nucleotide, known as a *dideoxynucleotide,* cannot elongate beyond that point. Unlike a "normal" deoxynucleotide, which lacks a hydroxyl group on its 2′ carbon, a dideoxynucleotide also lacks a hydroxyl group on its 3′ carbon (Fig. 14-9). Recall from Chapter 11 that a 3′ hydroxyl group reacts each time a phosphodiester linkage is formed. Thus, dideoxynucleotides terminate elongation during DNA replication.

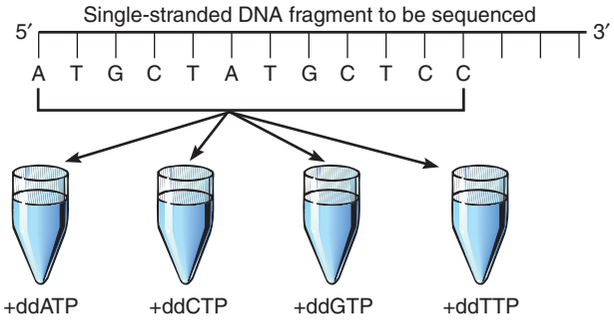
FIGURE **14-9** **Dideoxynucleotide.**
Dideoxynucleotides are modified nucleotides that lack a 3′ hydroxyl group and thus block further elongation of a new DNA chain.



O
O
P
O
O
O

FIGURE **14-10**

The chain termination method of DNA sequencing.



(a) Four different reaction mixtures are used to sequence a DNA fragment; each contains a small amount of a single dideoxynucleotide, such as ddATP. Larger amounts of the four normal deoxynucleotides (dATP, dCTP, dGTP, and dTTP) plus DNA polymerase and radioactively labeled primers are also included.

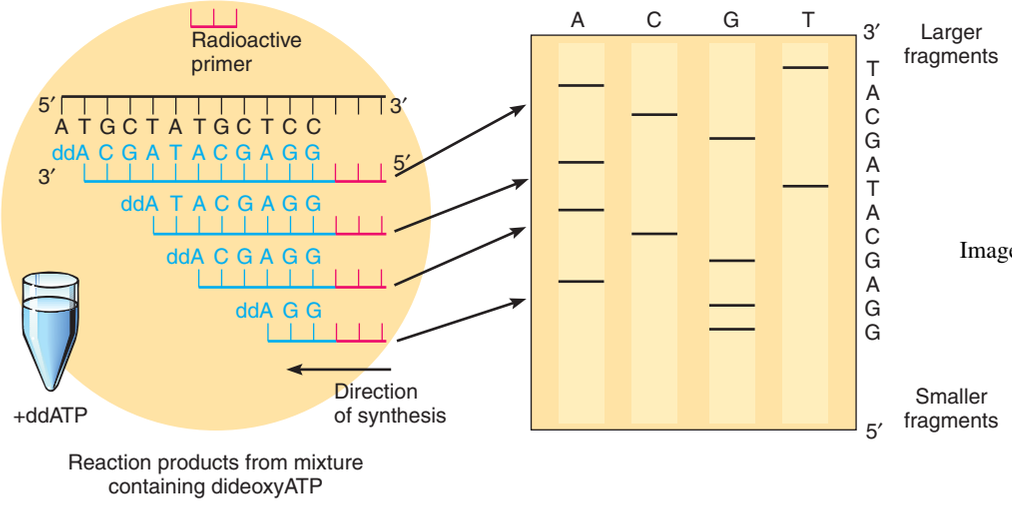


Image not available due to copyright restrictions

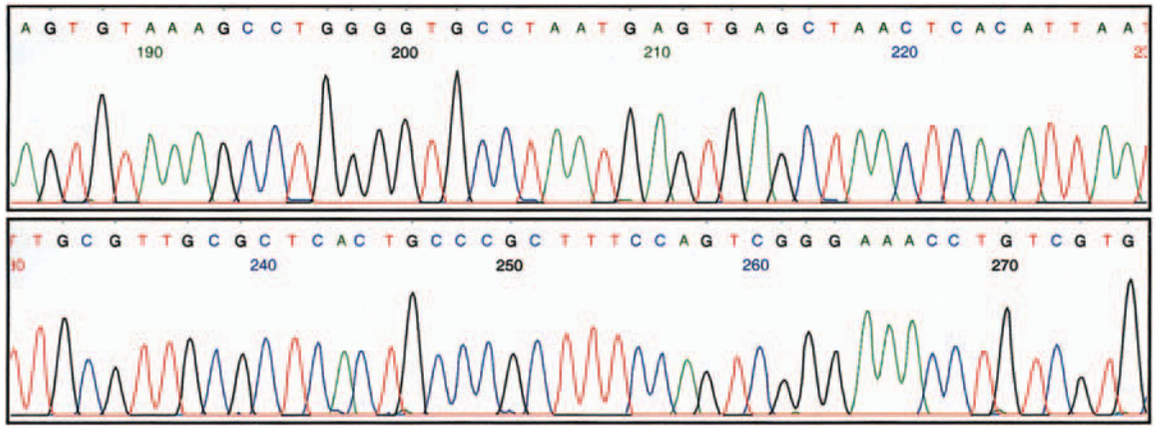
(b) The random incorporation of dideoxyATP (ddATP) into the growing chain generates a series of smaller DNA fragments ending at all the possible positions where adenine is found in the newly synthesized fragments. These correspond to positions where thymine occurs in the original template strand.

(c) The radioactive products of each reaction mixture are separated by gel electrophoresis and located by exposing the gel to x-ray film. The nucleotide sequence of the newly synthesized DNA is read directly from the film (5′ → 3′). The sequence in the original template strand is its complement (3′ → 5′).



Microchemical Core Facility/San Diego State University

Entire genomes have been sequenced using automated DNA sequencing

Today sequencing machines are very powerful and can decode about 1.5 million bases in a 24-hour period. These advances in sequencing technology have made it possible for researchers to study the nucleotide sequences of entire genomes in a wide variety of organisms, both prokaryotic and eukaryotic. Much of this research received its initial impetus by the Human Genome Project, which began in 1990. The sequencing of the 3 billion base pairs of the human genome was essentially completed in 2001. By 2003, the genomes of more than 100 different organisms had been sequenced, and several hundred more were in various stages of planning or completion. We are in the middle of an extraordinary explosion of gene sequence data, largely due to automated sequencing methods.

DNA sequence information is now kept in large computer databases, many of which are accessed through the Internet. Examples are databases maintained by the National Center for Biotechnology Information (a service of the U.S. National Library of Medicine and the National Institutes of Health) and by the Human Genome Organization (HUGO). Geneticists use these databases to compare newly discovered sequences with those already known, to identify genes, and to access many other kinds of information. By searching for DNA (and amino acid) sequences in a database, researchers can gain a great deal of insight into the function and structure of the gene product, the evolutionary relationships among genes, and the variability among gene sequences within a population.

APPLICATIONS OF DNA TECHNOLOGIES

Learning Objective

6 Describe at least one important application of recombinant DNA technology in each of the following fields: medicine and pharmacology, DNA typing, and transgenic organisms.

Recombinant DNA technology has provided not only a new and unique set of tools for examining fundamental questions about cells, but also new approaches to applied problems in many other fields. In some areas, the production of genetically engineered proteins and organisms has begun to have considerable impact on our lives. The most striking of these has been in the fields of pharmacology and medicine.

DNA technology has revolutionized medicine and pharmacology

In increasing numbers of cases, doctors perform **genetic tests** to determine whether an individual has a particular genetic mutation associated with such disorders as Huntington's disease, hemophilia, cystic fibrosis, Tay-Sachs disease, and sickle cell anemia. **Gene therapy,** the use of specific DNA to treat a genetic disease by correcting the genetic problem, is another application of DNA technology that is currently in its infancy. Because genetic testing and gene therapy focus almost exclusively on humans, these applications of DNA technology are discussed in Chapter 15. We focus our discussion here on the use of DNA technology to produce pharmaceutical products (Fig. 14-12).

Human insulin produced by *E. coli* became one of the first genetically engineered proteins approved for use by humans. Before the use of recombinant DNA techniques to generate genetically altered bacteria capable of producing the human hormone, insulin was derived exclusively from other animals. Many diabetic patients become allergic to the insulin from animal sources, because its amino acid sequence differs slightly from human insulin. The ability to produce the human hormone by recombinant DNA methods has resulted in significant medical benefits to insulin-dependent diabetics.

Rosenfeld Images Ltd/Science Photo Library/Photo Researchers, Inc.

FIGURE **14-12** **A bioreactor.**
This automated bioreactor produces an optimal environment for genetically engineered bacteria that make proteins for use in pharmaceutical products.

Genetically engineered human growth hormone (GH) is available to children who need it to overcome growth deficiencies, specifically pituitary dwarfism (see Chapter 47). In the past, human GH was obtainable only from cadavers. Only small amounts were available, and evidence suggested that some of the preparations from human cadavers were contaminated with infectious agents similar to those that cause bovine spongiform encephalopathy (mad cow disease; see Chapter 23).

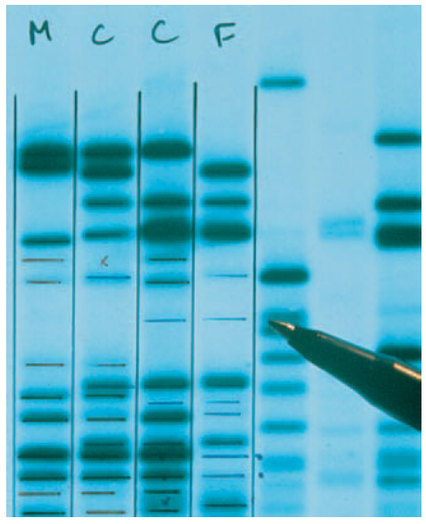
The list of products produced by genetic engineering is continually growing. For example, *tissue plasminogen activator (TPA),* a protein that prevents or dissolves blood clots, is used to treat cardiovascular disease. If administered shortly after a heart attack, TPA reduces the risk of a subsequent attack. *Tissue growth factor–beta (TGF-β)* promotes the growth of blood vessels and skin and is used in wound and burn healing. Researchers also use TGF-β in **tissue engineering,** a developing technology to meet the pressing need for human tissues and, eventually, organs for transplantation by growing them from cell cultures. The U.S. Food and Drug Administration (FDA) has approved tissue-engineered skin grafts, and tissue-engineered cartilage is in clinical trials. Hemophilia A is treated with *human blood clotting factor VIII*. Before the development of recombinant DNA techniques, factor VIII was available only from human- or animal-derived blood, which posed a risk of transmitting of infectious agents, such as HIV. And *Dornase Alpha (DNase)* improves respiratory function and general well-being in people with cystic fibrosis.

Recombinant DNA technology is increasingly used to produce vaccines that provide safe and effective immunity against infectious diseases in humans and animals. One way to develop a recombinant vaccine is to clone a gene for a surface protein produced by the pathogen (the disease-causing agent); the researcher then introduces the gene into a nonpathogenic vector. When the vaccine is delivered into the human or animal host, it stimulates an immune response to the surface-exposed protein; as a result, if the pathogen carrying that specific surface protein is encountered, the immune system targets it for destruction. Human examples of antiviral recombinant vaccines are vaccines for influenza A, hepatitis B, and polio. Recombinant vaccines are also being developed against certain bacterial diseases and human cancers.

DNA typing has applications ranging from forensics to analyzing ancient DNA

The analysis of DNA extracted from an individual, which is unique to that individual, is known as **DNA typing,** also called *DNA fingerprinting* or *DNA profiling*. DNA typing has many applications, such as investigating crime, identifying mass disaster victims, identifying human cancer cell lines, tracking tainted foods, studying the genetic ancestry of human populations, and clarifying disputed parentage (Fig. 14-13).

DNA typing relies on PCR amplification and gel electrophoresis to detect molecular markers. The most useful molecular markers are highly polymorphic within the human population. In molecular biology, a **polymorphism** is the presence of detectable variation in the genomes of different individuals in a population; a marker that is highly polymorphic has a great deal of variation. **Short tandem repeats (STRs)** are molecular markers that are short sequences of repetitive DNA—up to 200 nucleotide bases with a simple repeat pattern such as GTGTGTGTGT or CAGCAGCAGCAG. STRs are highly polymorphic because they vary in length from one individual to another, and this characteristic makes them useful in identifying individuals with a high degree of certainty.



David Parker/Science Photo Library/Photo Researchers, Inc.

ACTIVE FIGURE **14-13** **DNA typing.**

These gels show DNA profiles of a mother (lane labeled M), father (F), and their two children (C). Note that every band present in one of the children is also found in at least one of the parents.

BiologyNow™ Solve a murder case with **DNA fingerprinting** by clicking on this figure on your BiologyNow CD ROM.

If enough markers are compared, the odds that two people taken at random from the general population would have identical DNA profiles may be as low as one in several billion. The FBI uses a set of STRs from 13 different markers to establish a unique DNA profile for an individual. Such a profile distinguishes that person from every other individual in the United States, except for an identical twin.

Recall that DNA is also found in the cell's mitochondria. Whereas nuclear DNA occurs in two copies per cell (one on each of the homologous chromosomes), mitochondrial DNA has as many as 100,000 copies per cell. Therefore, mitochondrial DNA is the molecule of choice for DNA typing in which biological samples have been damaged—identifying exhumed human remains, for example.

DNA typing has revolutionized law enforcement. The FBI established the Combined DNA Index System (CODIS) in 1990, consisting of DNA databases from all 50 states. Today a DNA profile of an unknown suspect can be compared to millions of DNA profiles of convicted offenders in the database, often resulting in identification of the suspect. (The DNA from the unknown suspect may come from blood, semen, bones, teeth, hair, saliva, urine, or feces left at the crime scene. Tiny amounts of human DNA have even been extracted from cigarette butts, licked envelopes or postage stamps, dandruff, fingerprints,

razor blades, chewing gum, wrist watches, ear wax, debris from under fingernails, and toothbrushes.)

If applied properly, DNA typing has the power to identify the guilty and exonerate the innocent. Hundreds of convicted individuals have won new trials and have been subsequently released from incarceration, based on correlating DNA profiles with physical evidence from the crime scene. Such evidence has been ruled admissible in many court cases, including certain trials that have received a great deal of attention in recent years. One limitation arises from the fact that the DNA samples are usually small and may have been degraded. Obviously, great care must be taken to prevent contamination of the samples. This is especially crucial if the PCR technique is used to amplify DNA.

Transgenic organisms have incorporated foreign DNA into their cells

Plants and animals in which foreign genes have been incorporated are referred to as **transgenic organisms.** Researchers use varied approaches to insert foreign genes into plant or animal cells. They often use viruses as vectors, although other methods, such as the direct injection of DNA into cells, have also been applied.

R.L. Brinster, University of Pennsylvania Medical School

FIGURE **14-14** **A transgenic mouse.**
The mouse on the right is normal, whereas the mouse on the left is a transgenic animal that expresses rat growth hormone.

Transgenic animals are valuable in research

PROCESS OF SCIENCE

Transgenic animals are usually produced by injecting the DNA of a particular gene into the nucleus of a fertilized egg cell or of **embryonic stem cells (ES cells)** (see Chapter 1). The researcher then implants the eggs into the uterus of a female and lets them develop. Alternatively, the researcher injects genetically modified ES cells into isolated *blastocysts,* a stage in embryonic development, and then implants them into a foster mother.

Injecting DNA into cells is not the only way to produce transgenic animals. Researchers may use viruses as recombinant DNA vectors. RNA viruses called **retroviruses** make DNA copies of themselves by reverse transcription. Sometimes the DNA copies become integrated into the host chromosomes, where they are replicated along with host DNA.

Transgenic animals provide valuable applications over a wide range of research areas, such as regulation of gene expression, immune system function, genetic diseases, viral diseases, and genes involved in the development of cancer. The laboratory mouse has become a particularly important model organism for these studies.

In a classic study of the control of gene expression, University of Pennsylvania geneticist Ralph L. Brinster in 1983 produced transgenic mice carrying a gene for rat growth hormone (see Fig. 16-17). Brinster and his coworkers wanted to understand the controls that let certain genes be expressed in some tissues and not in others. The pituitary gland of a mouse normally produces small amounts of GH, and these researchers reasoned that other tissues might also be capable of producing the hormone. First they isolated the GH gene from a library of genomic rat DNA. They combined it with the promoter region of a mouse gene that normally produces metallothionein, a protein that is active in the liver and whose synthesis is stimulated by the presence of toxic amounts of heavy metals such as zinc. The researchers used metallothionein regulatory sequences as a switch to turn the production of rat GH on and off at will. After injecting the engineered gene into mouse embryo cells, they implanted the embryos into the uterus of a mouse and let them develop. Because of the difficulty in manipulating the embryos without damaging them, the gene transplant succeeded in only a small percentage of the animals. When exposed to small amounts of zinc, these transgenic mice produced large amounts of growth hormone, because the liver is a much larger organ than the pituitary gland. The mice grew rapidly, and one mouse, which developed from an embryo that had received two copies of the GH gene, grew to more than double the normal size (Fig. 14-14). As might be expected, such mice often transmit their increased growth capability to their offspring.

Gene targeting reveals gene function

PROCESS OF SCIENCE

One extremely powerful research tool is **gene targeting,** a procedure in which the researcher chooses and "knocks out" (inactivates) a single gene in an organism. *Knockout mice* are common models for studying the roles of genes of unknown function in mammals, including humans. The roles of the inactivated gene are determined by observing the phenotype of the mice bearing the knockout gene. If the gene codes for a protein, for example, studying individuals who lack that protein helps the researcher identify the function of the protein. Because at least 99% of the loci of mice have human counterparts (although the

specific alleles are usually different), information about knockout genes in mice also provides details about human genes.

Gene targeting, pioneered by Mario R. Capecchi, a molecular geneticist at the University of Utah School of Medicine, is a lengthy procedure; it takes about a year to develop a new strain of knockout mice. A nonfunctional (knockout) gene is introduced into mouse ES cells. ES cells are particularly easy to handle because, like cancer cells, they grow in culture indefinitely. Most importantly, if placed in a mouse embryo, ES cells divide and produce all the cell types normally found in the mouse. In a tiny fraction of these ES cells, the introduced knockout gene becomes physically associated with the corresponding gene in a chromosome. If this occurs, the chromosomal gene and the knockout gene tend to exchange DNA segments in a process called *homologous recombination.* In this way, the knockout allele replaces the normal allele in the mouse chromosome.

Researchers inject into early mouse embryos ES cells they hope are carrying a knockout gene and let the mice develop to maturity. If the gene is not lethal when inactivated, the researchers generally study animals that carry the knockout gene in every cell. However, because many genes are essential to life, researchers have modified the knockout technique to develop strains in which a specific gene is selectively inactivated in only one cell type. Research laboratories around the world have developed about 3000 different strains of knockout mice, each displaying its own characteristic phenotype, and the number continues to grow.

Gene targeting in mice is providing answers to basic biological questions relating to the development of embryos, the development of the nervous system, and the normal functioning of the immune system. This technique has great potential for revealing more about various human diseases, especially as scientists have learned that many thousands of diseases have a genetic component. Geneticists are using gene targeting to study cancer, heart disease, sickle cell anemia, respiratory diseases such as cystic fibrosis, and other disorders.

Mutagenesis screening reveals the genes involved in a particular phenotype

Many large-scale mutagenesis screening projects in mice are currently underway. In **mutagenesis screening,** researchers treat male mice with chemical *mutagens* that cause mutations in DNA. They then breed the males and screen their offspring for unusual phenotypes. Unlike gene targeting, mutagenesis does not disable a gene completely; instead it causes small, random mutations that change the properties of the proteins that the DNA encodes. The scale of mutagenesis screening is enormous; one screening project in Germany has screened some 28,000 different mouse mutants for changes in phenotypes.

Transgenic animals can produce genetically engineered proteins

Certain transgenic animal strains produce foreign proteins of therapeutic or commercial importance that are secreted into milk. For example, researchers have introduced into sheep the gene for the human protein TPA. Producing transgenic livestock, such as pigs, sheep, cows, and goats, that secrete foreign proteins in their milk is known informally as "pharming," a combination of "pharmaceuticals" and "farming" (Fig. 14-15).

In pharming, recombinant genes are fused to the regulatory sequences of the milk protein genes, and such genes are therefore activated only in mammary tissues involved in milk production. The advantages of obtaining the protein from milk are that potentially it can be produced in large quantities and that it can be harvested simply by milking the animal. The protein is then purified from the milk. The introduction of the gene does not harm the animals, and because the offspring of the transgenic animal usually produce the recombinant protein, transgenic strains are established.

Transgenic plants are increasingly important in agriculture

People have selectively bred plants for thousands of years. The success of such efforts depends on desirable traits in the variety of plant selected, or in closely related wild or domesticated plants whose traits are transferred by cross-breeding. Local varieties or closely related species of cultivated plants often have traits, such as disease resistance, that agriculturalists could advantageously introduce into varieties more suited to modern human needs. If genes are introduced into plants from strains or species with which they do not ordinarily interbreed, the possibilities for improvement increase greatly.

The most widely used vector system for introducing recombinant genes into many types of plant cells is the crown gall bacterium, *Agrobacterium tumefaciens.* This bacterium normally

produces plant tumors by introducing a plasmid, called the *Ti plasmid,* into the cells of its host (*Ti* stands for "tumor-inducing"). The Ti plasmid induces abnormal growth by forcing the plant cells to produce elevated levels of a plant growth hormone called *cytokinin* (see Chapter 36).

Geneticists "disarm" the Ti plasmid so that it does not induce tumor formation and then use it as a vector to insert genes into plant cells. The cells into which the altered plasmid is introduced are essentially normal except for the inserted genes. Genes placed in the plant genome in this fashion may be transmitted sexually, via seeds, to the next generation, but they can also be propagated asexually (for example, by taking cuttings).

Unfortunately, not all plants take up DNA readily, particularly the cereal grains that are a major food source for humans. One useful approach has been the development of a genetic "shotgun." Researchers coat microscopic gold or tungsten fragments with DNA and then shoot them into plant cells, penetrating the cell walls. Some of the cells retain the DNA, which transforms them. Those cells can then be cultured and used to regenerate an entire plant (see Chapter 16). For example, geneticists have successfully used such an approach to transfer a gene for resistance to a bacterial disease into cultivated rice from one of its wild relatives.

An additional complication of plant genetic engineering is that about 120 plant genes lie in the DNA of the chloroplasts. (The other 3000 or so genes that plastids require to function are in the nucleus.) Chloroplasts are essential in photosynthesis, which is the basis for plant productivity. Because great agricultural potential hinges on improving the productivity of photosynthesis, developing methods for changing the part of the plant's DNA within the chloroplast is desirable. Dozens of labs are currently studying methods of chloroplast engineering, although progress has been slow. In 2001 Australian plant physiologists reported that they had altered **Rubisco,** the key carbon-fixing enzyme of photosynthesis (see Chapter 8) by changing one of the genes in the chloroplast genome.

Selected applications of transgenic plants Agricultural geneticists are developing transgenic plants, known as **genetically modified (GM) crops,** that are resistant to insect pests, viral diseases, drought, heat, cold, herbicides, and salty or acidic soil. For example, consider the European corn borer, which is the most damaging insect pest in corn in the United States and Canada (Fig. 14-16a). Efforts to control the European corn borer cost farmers more than $1 billion each year. Corn has been genetically modified to contain the *Bt* gene, a bacterial gene that codes for a protein with insecticidal properties (*Bt* stands for the scientific name, *Bacillus thuringiensis*). *Bt* corn, introduced in the United States in 1996, doesn't need periodic sprays of chemical insecticides to control the European corn borer.

DNA technology also has the potential to develop crops that are more nutritious. For example, in the 1990s geneticists engineered rice to produce high quantities of β-carotene, which the human body uses to make vitamin A (Fig. 14-16b; see also Fig. 3-14). In developing countries, vitamin A deficiency is a leading cause of blindness in children. According to the World Health Organization, 275 million children are vitamin A deficient, and 250,000 to 500,000 become irreversibly blind each year. Vitamin A deficiency also makes children more susceptible to measles and other infectious diseases. Because rice is the staple diet in many countries with vitamin A deficiency, the widespread use of GM rice with β-carotene has the potential to prevent vitamin A deficiency in many of the world's children.

Like some transgenic animals, certain transgenic plants can potentially be "pharmed" to produce large quantities of medically important proteins, such as antibodies against the herpes virus. Methods for developing transgenic plants are well established, but it has been difficult to get plants to produce the de-

U.S. Department of Agriculture

ACTIVE FIGURE **14-16** **Uses of transgenic plants.**

(a) The European corn borer, shown in the larval form, is the most destructive pest on corn in North America. Genetic engineers have designed *Bt* corn to control the European corn borer without heavy use of chemical insecticides. **(b)** "Golden rice," shown here intermixed with regular white rice, contains high concentrations of β-carotene. To make golden rice, scientists took the gene for β-carotene in daffodil flowers and inserted it into the endosperm cells of rice.

BiologyNow™ Learn more about the development of **transgenic rice** by clicking on this figure on your BiologyNow CD ROM.

sired protein in large enough quantities. To date, most transgenic plants developed for pharming have produced foreign proteins equal to only about 1% of the plant's total protein output. The developers of this technology are working to increase the production of foreign proteins, to demonstrate the feasibility of these production methods.

Some people are concerned about the health effects of consuming foods derived from GM crops and think that such foods should be restricted. For example, critics say some consumers may develop food allergies. Scientists also recognize this concern and routinely screen new GM crops for allergenicity. There is also an ongoing controversy as to whether GM foods should be labeled. The FDA and most scientists think such labeling would be counterproductive, because it would increase public anxiety over a technology that is as safe as traditional breeding methods. In 1996, the U.S. Court of Appeals upheld the FDA position that labeling should not be required.

SAFETY GUIDELINES FOR DNA TECHNOLOGY

Learning Objective

7 Describe at least two safety issues associated with recombinant DNA technology, and explain how these issues are being addressed.

When recombinant DNA technology was introduced in the early 1970s, many scientists considered the potential misuses at least as significant as the possible benefits. The possibility that an organism with undesirable environmental effects might be accidentally produced was of great concern, because scientists feared that totally new strains of bacteria or other organisms, with which the world has no previous experience, might be difficult to control. The scientists who developed the recombinant DNA methods insisted on stringent guidelines for making the new technology safe.

Experiments in thousands of university and industrial laboratories over more than 30 years have shown that recombinant DNA manipulations can be carried out safely. Geneticists have designed laboratory strains of *E. coli* to die in the outside world. Researchers carry out experiments that might present unusual risks in facilities designed to hold pathogenic organisms; this precaution ensures that researchers can work with them safely. So far no evidence suggests that researchers have accidentally cloned hazardous genes or have released dangerous organisms into the environment. However, malicious *intentional* manipulations of dangerous genes certainly remain a possibility.

As the safety of the experiments has been established, scientists have relaxed many of the restrictive guidelines for using recombinant DNA. Stringent restrictions still exist, however, in certain areas of recombinant DNA research where there are known dangers, or where questions about possible effects on the environment are still unanswered.

These restrictions are most evident in research that proposes to introduce transgenic organisms into the wild, such as agricultural strains of plants whose seeds or pollen might spread in an uncontrolled manner. A great deal of research now focuses on determining the effects of introducing transgenic organisms into a natural environment. Carefully conducted tests have shown that transgenic organisms are not dangerous to the environment simply because they are transgenic.

However, it is important to assess the risks of each new recombinant organism. Scientists determine whether the organism has characteristics that might cause it to be environmentally hazardous under certain conditions. For example, if geneticists have engineered a transgenic crop plant to resist an herbicide, could that gene be transferred, via pollen or some other route, to that plant's weedy relatives, generating herbicide-resistant "superweeds"? In 2003, ecologists at the University of Tennessee, Knoxville, announced the crossing of transgenic oilseed rape plants that contained the *Bt* gene with its wild relative (a weed). They crossed the resulting hybrids with the wild relative again and then tested its ability to compete with other weeds in a field of wheat. The transgenic weed was a poor competitor and had less effect on wheat production than its wild relatives in a control field. These results, although encouraging, must be interpreted with care. Scientists must evaluate each transgenic crop plant individually to see if there is gene flow to wild relatives, and, if so, the resulting effect.

Other concerns relate to plants engineered to produce pesticides, such as the *Bt* toxin. The future of the *Bt* toxin in transgenic crops is not secure, because low levels of the insecticide could potentially provide ideal conditions for selection for resistant individuals in the insect population. It appears certain insects may evolve genetic resistance to the *Bt* toxin in transgenic plants in the same way they evolve genetic resistance to chemical insecticides.

Another concern is that non-pest species could be harmed. For example, people paid a great deal of attention to the finding that monarch butterfly larvae raised in the laboratory are harmed if they are fed pollen from *Bt* corn plants. Although more recent studies suggest that monarch larvae living in a natural environment do not consume enough pollen to cause damage, such concerns persist and will have to be addressed individually.

Environmental concerns about transgenic animals also exist. Several countries are in the process of developing fast-growing transgenic fish, usually by inserting a gene that codes for a growth hormone. Transgenic Atlantic salmon, for example, grow up to six times faster than nontransgenic salmon grown for human consumption. (The transgenic fish do not grow larger than other fish, just faster.) The benefits of such genetically enhanced fish include reduced pressure on wild fisheries and less

pollution from fish farms. However, if the transgenic fish escaped from the fish farm, what effect would they have on wild relatives? (To address this concern, the transgenic salmon being developed in the United States are all nonreproducing females.)

To summarize, DNA technology in agriculture offers many potential benefits, including higher yields (by providing disease resistance), more nutritious foods, and the reduced use of chemical pesticides. However, like other kinds of technology, genetic engineering poses some risks, such as the risk that genetically modified plants and animals could pass their foreign genes to wild relatives, causing unknown environmental problems. The science of risk assessment, which uses statistical methods to quantify risks so they can be compared and contrasted, will help society decide whether to ignore, reduce, or eliminate specific risks of genetically engineered organisms.

Review

- Why are some people concerned about plants that have been genetically engineered to produce insecticides?
- What is the potential problem with transgenic salmon? How are scientists addressing this concern?

SUMMARY WITH KEY TERMS

1 Explain how a typical restriction enzyme cuts DNA molecules, and give examples of the ways in which these enzymes are used in recombinant DNA technology.

- **Recombinant DNA technology** isolates and amplifies specific sequences of DNA by incorporating them into **vector** DNA molecules. Researchers then propagate and amplify the resulting recombinant DNA in organisms such as *E. coli*.
- Researchers use **restriction enzymes** to cut DNA into specific fragments. Each type of restriction enzyme recognizes and cuts DNA at a highly specific base sequence. Many restriction enzymes cleave DNA sequences to produce complementary, single-stranded sticky ends.
- Geneticists construct the most common recombinant DNA vectors from naturally occurring circular bacteria DNA molecules called **plasmids,** or from bacterial viruses called **bacteriophages.**
- Geneticists often construct recombinant DNA molecules by allowing the ends of a DNA fragment and a plasmid (both cut with the same restriction enzyme) to associate by complementary base pairing. Then **DNA ligase** covalently links the DNA strands to form a stable recombinant molecule.

2 Distinguish among a genomic library, a chromosome library, and a complementary DNA (cDNA) library; explain why one would clone the same eukaryotic gene from both a genomic library and a cDNA library.

- A **genomic library** contains thousands of DNA fragments that represent the total DNA of an organism, and a **chromosome library** contains all the DNA fragments from a specific chromosome. Each DNA fragment of a genomic or chromosome library is stored in a specific bacterial strain. Analyzing DNA fragments in genomic and chromosome libraries yields useful information about genes and their encoded proteins.
- A **cDNA library** is produced using **reverse transcriptase** to make DNA copies of mature mRNA isolated from eukaryotic cells. These copies, known as **complementary DNA (cDNA),** are then incorporated into recombinant DNA vectors.
- Genes present in genomic and chromosome libraries from eukaryotes contain **introns,** regions that do not code for protein. Those genes are amplified in bacteria, but the protein is not properly expressed. Because the introns have been removed from mRNA molecules, eukaryotic genes in cDNA libraries can sometimes be expressed in bacteria, which produce functional protein products.

3 Identify some uses of DNA hybridization probes.

- Researchers use a radioactive DNA or RNA sequence as a **genetic probe** to identify complementary nucleic acid sequences. Each spot on the x-ray film identifies a colony containing a plasmid that includes the DNA of interest.
- In the **Southern blot technique,** researchers separate DNA fragments by **gel electrophoresis,** denature them, and then blot them onto a nitrocellulose or nylon membrane. A radioactive probe is then **hybridized** by complementary base pairing to the DNA bound to the membrane, and the radioactive band or bands of DNA are identified by autoradiography or chemical luminescence.

4 Describe how the polymerase chain reaction amplifies DNA in vitro.

- The **polymerase chain reaction (PCR)** is a widely used, automated, in vitro technique in which researchers target a particular DNA sequence by specific primers and then **clone** it by a heat-resistant DNA polymerase.
- Using PCR, scientists amplify and analyze tiny DNA samples taken from various sites, from crime scenes to archaeological remains.

5 Describe the chain termination method of DNA sequencing.

- **DNA sequencing** yields information about the structure of a gene and the probable amino acid sequence of its encoded proteins. Geneticists compare DNA sequences with other sequences stored in massive databases.
- Automated DNA sequencing is based on the chain termination method, which uses dideoxynucleotides, each tagged with a differently colored fluorescent dye, to terminate elongation during DNA replication. Gel electrophoresis separates the resulting fragments, and a laser identifies the nucleotide sequence.

6 Describe at least one important application of recombinant DNA technology in each of the following fields: medicine and pharmacology, DNA typing, and transgenic organisms.

- Genetically altered bacteria produce many important human protein products, including insulin, growth hormone, tissue plasminogen activator (TPA), tissue growth factor-beta (TGF-β, blood clotting factor VIII, and Dornas Alpha (DNase).
- **DNA typing** is the analysis of an individual's DNA. It is based on a variety of **short tandem repeats (STRs),** molecular markers that are highly **polymorphic** within the human population. DNA typing has applications in law enforcement, issues of disputed parentage, and tracking tainted foods, to name a few.
- **Transgenic organisms** have foreign DNA incorporated into their genetic material. **Gene targeting** and **mutagenesis screening** in mice help identify the function of a gene and its protein product. Transgenic livestock produce foreign proteins in their milk. Transgenic plants have great potential in agriculture.

SUMMARY WITH KEY TERMS *(continued)*

7 Describe at least two safety issues associated with recombinant DNA technology, and explain how these issues are being addressed.

- Some consumers are concerned about the safety of genetically engineered organisms. To address these concerns, scientists carry out recombinant DNA technology under specific safety guidelines.
- The introduction of transgenic plants and animals into the natural environment, where they may spread in an uncontrolled manner, is an ongoing concern that must be evaluated on a case-by-case basis.

POST-TEST

1. A plasmid (a) is used as a DNA vector (b) is a type of bacteriophage (c) is a type of cDNA (d) is a retrovirus (e) b and c
2. DNA molecules with complementary sticky ends associate by (a) covalent bonds (b) hydrogen bonds (c) ionic bonds (d) disulfide bonds (e) phosphodiester linkages
3. Human DNA and a particular plasmid both have sites that are cut by the restriction enzymes *Hin*dIII and *Eco*RI. To make recombinant DNA, the scientist should (a) cut the plasmid with *Eco*RI and the human DNA with *Hin*dIII (b) use *Eco*RI to cut both the plasmid and the human DNA (c) use *Hin*dIII to cut both the plasmid and the human DNA (d) a or b (e) b or c
4. Which of the following sequences is *not* palindromic?
   (a) 5′—AAGCTT—3′ / 3′—TTCGAA—5′
   (b) 5′—GATC—3′ / 3′—CTAG—5′
   (c) 5′—GAATTC—3′ / 3′—CTTAAG—5′
   (d) 5′—CTAA—3′ / 3′—GATT—5′
   (e) b and d
5. The PCR technique uses (a) heat-resistant DNA polymerase (b) reverse transcriptase (c) DNA ligase (d) restriction enzymes (e) b and c
6. A cDNA clone contains (a) introns (b) exons (c) anticodons (d) a and b (e) b and c
7. The dideoxynucleotides ddATP, ddTTP, ddGTP, and ddCTP are important in DNA sequencing because they (a) cause premature termination of a growing DNA strand (b) are used as primers (c) cause the DNA fragments that contain them to migrate more slowly through a sequencing gel (d) are not affected by high temperatures (e) have more energy than deoxynucleotides
8. In the Southern blot technique, _____ is/are transferred from a gel to a nitrocellulose or nylon membrane. (a) protein (b) RNA (c) DNA (d) bacterial colonies (e) reverse transcriptase
9. Gel electrophoresis separates nucleic acids on the basis of differences in (a) length (molecular weight) (b) charge (c) nucleotide sequence (d) relative proportions of adenine and guanine (e) relative proportions of thymine and cytosine
10. The Ti plasmid, carried by *Agrobacterium tumefaciens,* is especially useful for introducing genes into (a) bacteria (b) plants (c) animals (d) yeast (e) all eukaryotes
11. A genomic library (a) represents all the DNA in a specific chromosome (b) is made using reverse transcriptase (c) is stored in a collection of recombinant bacteria (d) is a DNA copy of mature mRNAs (e) allows researchers to amplify a tiny sample of DNA
12. Tissue growth factor-beta (a) is a genetic probe for recombinant plasmids (b) is a product of DNA technology used in tissue engineering (c) is necessary to make a cDNA library (d) cannot be synthesized without a heat-resistant DNA polymerase (e) is isolated by the Southern blot technique
13. These highly polymorphic molecular markers are useful in DNA typing: (a) short tandem repeats (b) cloned DNA sequences (c) palindromic DNA sequences (d) cosmid cloning vectors (e) complementary DNAs

CRITICAL THINKING

1. What are some of the problems that might arise if you were trying to produce a eukaryotic protein in a bacterium? How might using transgenic plants or animals help solve some of these problems?
2. Would genetic engineering be possible if we did not know a great deal about the genetics of bacteria? Explain.
3. What are some of the environmental concerns regarding transgenic organisms? What kinds of information does society need to determine if these concerns are valid?

DNA sequencing. This is a display on a computer monitor attached to a DNA-sequencing machine. The machine determines the base sequence of a strand of DNA using the chain termination method and tags each of the four bases with a different colored fluorescent dye.

CHAPTER OUTLINE

- Studying Human Genetics
- Abnormalities in Chromosome Number and Structure
- Genetic Diseases Caused by Single-Gene Mutations
- Gene Therapy
- Genetic Testing and Counseling
- Human Genetics, Society, and Ethics

The principles of genetics apply to all organisms, including humans. However, some important differences separate genetic research on humans and genetic research on other organisms. To study aspects of inheritance in other species, geneticists ideally have standard stocks of genetically similar individuals—**true-breeding strains** whose traits remain unchanged for many generations because they are homozygous at virtually all loci. Geneticists conduct *controlled matings* between members of different true-breeding strains and raise the offspring under carefully controlled conditions.

Of course, experimental matings under controlled conditions are not feasible in the human population. In addition, most human families are small, and 20 to 30 years or more elapse between generations. It is therefore virtually impossible to conduct genetic research on humans in the same way as with other sexually reproducing species.

Despite the inherent difficulties of studying inheritance in humans, understanding of **human genetics,** the science of inherited variation in humans, is progressing very rapidly. Researchers traditionally examined human genetics using such approaches as population studies of large extended families. More recently, the field of human genetics has been greatly facilitated by the medical attention given to human genetic diseases. The extensive medical records of diseases serve as a useful database for testing hypotheses. Genetic studies of other organisms also have provided invaluable insights. Indeed, many genetic traits in humans that were initially puzzling have been explained using model organisms, such as bacteria, yeasts, worms, fruit flies, and mice to address analogous inheritance questions.

The **human genome,** which represents the totality of genetic information in human cells, has been mapped and sequenced. In **DNA sequencing,** researchers have identified the order of nucleotides in DNA to help us understand the genetic basis of human similarities and differences (see figure). The human genome includes the DNA content of both the nucleus and the mitochondria. However, nuclear DNA accounts for almost all the genetic information in the human genome. Like

genomes of other eukaryotic organisms, some of the human genome specifies the synthesis of polypeptides or RNA molecules. However, much of the genome consists of noncoding DNA, repetitive sequences (multiple copies) of DNA, and gene segments whose functions remain unknown. Relating specific genes to the proteins they code for, and determining the role these proteins play in the body, are some of the avenues of human genetic research that scientists will pursue during the 21st century.

In this chapter, we first examine how the human genome is studied, including advances in new fields that are developing as a result of the Human Genome Project. Then we discuss a variety of human genetic disorders. We explore the use of gene therapy for some of these disorders, as well as the application of genetic testing, screening, and counseling for families at risk. The chapter concludes with a discussion of ethical issues that relate to the expanding knowledge of the human genome. ■

STUDYING HUMAN GENETICS

Learning Objectives

1. Distinguish between karyotyping and pedigree analysis.
2. Discuss the implications of the Human Genome Project, including the emerging fields of bioinformatics, pharmacogenetics, and proteomics.
3. Discuss the mouse model for studying cystic fibrosis.

Human geneticists use a variety of methods that enable them to make inferences about a trait's mode of inheritance. We consider three of these methods—the identification of chromosomes by karyotyping, the analysis of family inheritance patterns using pedigrees, and DNA sequencing and mapping of genes by genome projects. Investigators often study human inheritance most effectively by combining these and other approaches.

Human chromosomes are studied by karyotyping

Cytogenetics is the study of chromosomes and their role in inheritance. Researchers working with simpler organisms discovered many of the basic principles of genetics. In such organisms, it is often possible to relate genetic data to the number and structure of specific chromosomes. Some organisms used in genetics, such as the fruit fly *Drosophila melanogaster,* have very few chromosomes; the fruit fly has only four pairs. In *Drosophila* larval salivary glands, the chromosomes are large enough that their structural details are readily evident. This organism, therefore, has provided unique opportunities for correlating certain inherited phenotypic changes with alterations in chromosome structure.

PROCESS OF SCIENCE

The normal number of chromosomes for the human species is 46: 44 **autosomes** (22 pairs) and 2 sex chromosomes (one pair). A **karyotype** (from the Greek, for nucleus) is an individual's chromosome composition. Until the mid-1950s, when biologists adopted modern methods of karyotyping, the accepted number of chromosomes for the human species was 48, based on a study of human chromosomes published in 1923. The reason researchers counted 48 human chromosomes was the difficulty in separating the chromosomes so they could be accurately counted. In 1952, University of Texas cell biologist T.C. Hsu treated cells with a hypotonic salt solution by mistake; this caused the cells to swell and the chromosomes to spread apart, thereby making them easier to count. Other techniques were also developed, and in 1956 researchers Jo Hin Tjio and Albert Levan, working in Sweden, reported that humans have 46 chromosomes, not 48. Other researchers subsequently verified this report. The story of the human chromosome number is a valuable example of the "self-correcting" nature of science (although such corrections may take time). The re-evaluation of established facts and ideas, often by using improved techniques or new methods, is an essential part of the scientific process.

Human chromosomes are visible only in dividing cells (see Chapter 9), and it is difficult to obtain dividing cells directly from the human body. Researchers typically use blood, because white blood cells can be induced to divide in a culture medium by treating them with chemicals. Other sources of dividing cells include skin and, for prenatal chromosome studies, chorionic villi or fetal cells shed into the amniotic fluid (discussed later in the chapter).

In karyotyping, biologists culture dividing human cells and then treat them with the drug *colchicine,* which arrests the cells at mitotic metaphase or late prophase, when the chromosomes are most highly condensed. Next the researchers put the cells into a hypotonic solution; the cells swell, and the chromosomes spread out so they are easily observed. The cells are then flattened on microscope slides, and the chromosomes are stained to reveal the patterns of bands unique for each homologous pair. After the microscopic image has been scanned into a computer, the homologous pairs are electronically matched and placed together (Fig. 15-1a).

By convention, geneticists identify chromosomes by length; position of the centromere; banding patterns, which are produced by staining chromosomes with dyes that produce dark and light cross-bands of varying widths; and other features such as *satellites,* tiny knobs of chromosome material at the tips of certain chromosomes. With the exception of the sex chromosomes, the chromosomes are numbered and lined up in order of size, except that chromosome 21 is smaller than chromosome 22. The largest human chromosome (chromosome 1) is about five times as long as the smallest one (chromosome 21), but there are only slight size differences among some of the intermediate-sized chromosomes. The X and Y chromosomes of a normal male are homologous only at their tips; normal females have two X chromosomes and no Y chromosome. Differences from the normal karyotype—that is, deviations in chromosome number or structure—are associated with certain disorders such as Down syndrome (discussed later in the chapter).

Another way to distinguish chromosomes in a karyotype is by **fluorescent in situ hybridization (FISH).** A geneticist tags a

FIGURE **15-1** **Karyotyping.**

(a) Using an image analysis computer to prepare a karyotype, the biologist matches homologous chromosomes and organizes them by size. Before computers, researchers prepared karyotypes by cutting and pasting chromosomes from photographs.

DNA strand complementary to DNA in a specific chromosome with a fluorescent dye. The DNA in the chromosome is denatured—that is, the two strands are separated—so the tagged strand can bind to it. A different dye is used for each chromosome, "painting" each with a different color (Fig. 15-1b). A chromosome that is multicolored (not shown) indicates breakage and fusion of chromosomes, an abnormality associated with certain genetic diseases and many types of cancer.

Family pedigrees help identify certain inherited conditions

Early studies of human genetics usually dealt with readily identified pairs of contrasting traits and their distribution among members of a family. A "family tree" that shows inheritance patterns, the transmission of genetic traits within a family over several generations, is known as a **pedigree.** Pedigree analysis remains widely used, even in today's world of powerful molecular genetic techniques, because it helps molecular geneticists determine the exact interrelationships of the DNA molecules they analyze from related individuals. Pedigree analysis is also an important tool of genetic counselors and clinicians. However, because human families tend to be small and information about certain family members, particularly deceased relatives, may not be available, pedigree analysis has limitations.

Pedigrees are produced using standardized symbols. Examine Figure 15-2, which shows a pedigree for **albinism,** a lack of the pigment melanin in the skin, hair, and eyes. Each horizontal row represents a separate generation, with the earliest generation (roman numeral I) at the top and the most recent generation at the bottom. Within a given generation, the individuals are usually numbered consecutively, from left to right, using arabic numbers. A horizontal line connects two parents, and a vertical line drops from the parents to their children. For example, individuals II-3 and II-4 are parents of four offspring (III-1, III-2, III-3, and III-4). Note that individuals in a given generation can be genetically unrelated. For example, II-1, II-2, and II-3 are unrelated to II-4 and II-5. Within a group of siblings, the oldest is on the left, and the youngest is on the right.

Studying pedigrees enables human geneticists to predict how phenotypic traits that are governed by the genotype at a single locus are inherited. About 10,000 traits have been described in humans. Pedigree analysis most often identifies three modes of single-locus inheritance: autosomal dominant, autosomal recessive, and X-linked recessive. We define and discuss examples of these inheritance modes later in the chapter.

Certain traits that do not show a simple Mendelian inheritance pattern can also be characterized using pedigree analysis. Some of these traits are the result of **genomic imprinting,** in which the expression of a gene in a given tissue or developmental stage is based on its parental origin—that is, whether the individual inherits the gene from the male or female parent. For some imprinted genes, the paternally inherited allele is always repressed (not expressed); for other imprinted genes, the maternally inherited allele is always repressed.

Two rare genetic disorders provide a fascinating demonstration of genomic imprinting. In *Prader-Willi syndrome (PWS),* individuals become compulsive overeaters and obese; they are also short in stature and mildly to moderately retarded. In *Angelman syndrome (AS),* affected individuals are hyperactive, mentally retarded, unable to speak, and suffer from seizures. Both PWS and AS are caused by a small *deletion* of several loci from

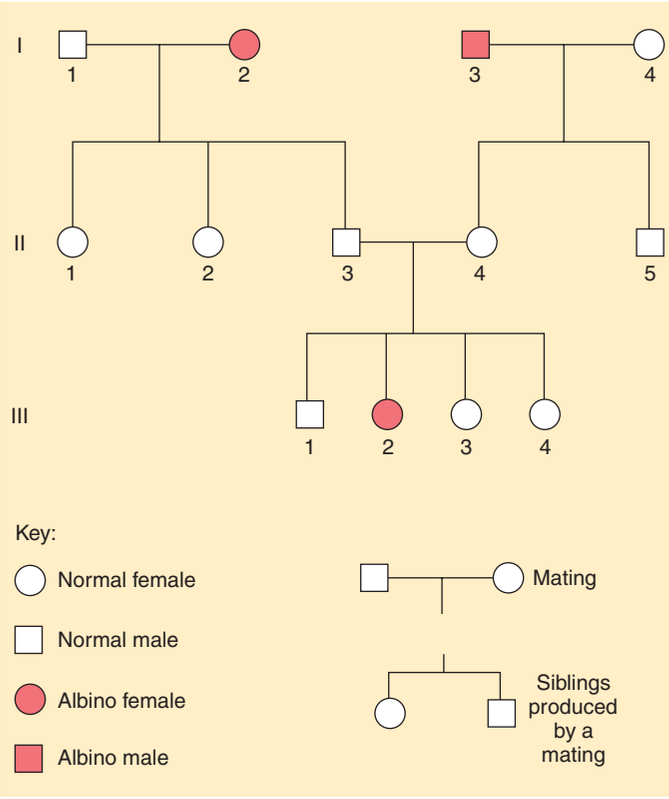

FIGURE 15-2 A pedigree for albinism.

By studying family histories, a researcher can determine the genetic mechanism of an inherited trait. In this example, III-2 represents an albino girl with two phenotypically normal parents, II-3 and II-4. The allele for albinism cannot be dominant because if it were, at least one of III-2's parents would have to be an albino. Also, albinism cannot be an X-linked recessive allele because if it were, her father would have to be an albino (and her mother would have to be a heterozygous carrier). This pedigree is explained if albinism is inherited as an autosomal recessive allele (not carried on a sex chromosome). In such cases, two phenotypically normal parents could produce an albino offspring because they are heterozygotes and could each transmit a recessive allele.

the same region of chromosome 15. One of these deleted loci is responsible for PWS, another for AS. (Chromosome deletions are discussed later in the chapter.)

Pedigree analysis has shown that when the person inherits the deletion from the father, PWS occurs, whereas when the person inherits the deletion from the mother, AS occurs. This inheritance pattern suggests that the normal PWS gene is expressed only in the paternal chromosome, and the normal AS gene is expressed only in the maternal chromosome. PWS occurs because the repressed (imprinted) PWS gene from the mother cannot make up for the absent PWS gene in the paternal chromosome. Similarly, AS occurs because the repressed (imprinted) AS gene from the father cannot make up for the absent AS gene in the maternal chromosome.

The Human Genome Project sequenced the DNA on all human chromosomes

Workers in the **Human Genome Project** have sequenced the DNA in the entire nuclear human genome—about 2.9 billion base pairs. (The human mitochondrial genome was sequenced in 1981.) This international undertaking, based on the DNA from 6 to 10 anonymous individuals, was essentially completed in 2000 and published in 2001 by hundreds of researchers comprising two independent teams, the government-funded International Human Genome Sequencing Consortium and Celera Genomics, a privately funded company. The final completion of the Human Genome Project in 2003 was a significant milestone in genetics (Table 15-1).

Scientists hope to eventually identify where all the genes are located in the sequenced DNA. We do not yet know how many genes are in the human genome. In 2001, the National Human Genome Research Institute (NHGRI) estimated there were 35,000 to 45,000 genes in the human genome, but by 2003 the NHGRI estimate was lowered to under 30,000.

Gene identification represents a formidable challenge. How do you identify a gene in a DNA sequence if you know nothing about it? The human genome is extremely complex. Only 1% to 2% of human DNA codes for protein or RNA. The rest either is noncoding regulatory elements or has some function researchers have yet to discover. In human chromosome 22, for example, the 545 genes identified so far were determined by computers that scanned DNA sequences for identifying markers such as promoter elements typically associated with genes, conserved intron sequences, and coding regions (exons). Many of these identified genes are "potential" genes in that their messenger RNAs (mRNAs) and protein products have not yet been isolated.

PROCESS OF SCIENCE

TABLE 15-1 Major Milestones in Genetics

Year	Scientific Advance
1866	Mendel proposed existence of hereditary factors now known as genes
1869	Nucleic acids discovered
1953	Structure of DNA determined
1960s	Genetic code explained (how proteins are made from DNA)
1977	DNA sequencing began
1986	DNA sequencing automated
1995	Sequencing of first genome (bacterium *Haemophilus influenzae*) completed
1996	Sequencing of first eukaryotic genome (yeast *Saccharomyces cerevisiae*) completed
1998	Sequencing of first multicellular eukaryotic genome (nematode worm *Caenorhabditis elegans*) completed
2001	Draft sequence of entire human genome published
2003	Final completion of DNA sequencing of human genome

Other genes were identified because they code for proteins similar to those previously identified in humans or other organisms. Despite the difficulties, progress is being made, and mapping studies will help scientists understand the physical and functional relationships among genes and groups of genes as revealed by their order on the chromosomes.

Now that the human genome has been sequenced, researchers will be busy for many decades analyzing the growing body of human molecular data. In addition to identifying genes, scientists want to understand each gene's role, how each gene interacts with other genes, and how its expression is regulated in different tissues. Eventually, all the thousands of proteins produced in human cells will be identified, their 3-D structures determined, and their properties and functions evaluated.

Researchers also want to study sequence variations within the human genome, to elucidate differences that might be related to illness or disease. The potential medical applications of the Human Genome Project are extremely promising. Genes on human chromosome 22, for example, are associated with at least 27 diseases known to have a genetic component. The causative genes of many of these disorders have not yet been identified. For example, a gene involved in schizophrenia is strongly linked to human chromosome 22, but scientists do not know its exact location or function.

The Human Genome Project stimulated the genome sequencing of other species

To aid in analyzing the human genome, investigators carried out sequencing and mapping studies simultaneously on the mouse and rat genomes. Mice and rats were obvious choices for DNA sequencing because they have been studied for almost a century and much is known about their biology. Mice and rats are sufficiently different from humans that any conserved sequences found in both rodents and humans are probably functionally important.

In addition, mice are similar enough to humans that both share many physiological traits, including some of the same diseases. To demonstrate the shared similarity between the mouse and human genomes, a consortium of scientists published a study in 2002 that compared the mouse chromosome 16 with the human genome. Only 14 of the 731 known genes on the mouse chromosome had no human counterpart; the remaining 717 genes appeared in one form or another in the human genome.

Comparison of the DNA sequences and chromosome organization of related genes from different species is a powerful tool for identifying the elements essential for their functions. If a human gene has an unknown function, researchers can often deduce clues about its role by studying the equivalent gene in another species, such as a mouse or rat.

Investigators have also sequenced the genomes of other model vertebrate organisms, such as the pufferfish (which has the smallest known genome of all vertebrates) and zebrafish. By comparing the human genome to that of the pufferfish, researchers identified shared sequences that have not changed in several hundred million years. Scientists hypothesize that these sequences may be genes or regulatory elements that are essential in all vertebrates. Further study of the pufferfish genome may help scientists identify the genes that direct vertebrate development. Biologists have used the zebrafish for many years as a model of vertebrate development because it is easy to maintain in the lab; its embryonic stages are transparent and therefore convenient to examine.

Genome analysis of commercially important organisms, such as salmon, chickens, pigs, and rice, is also a priority. Scientists published the rice genome in 2002. Researchers published the genome of the human parasite *Plasmodium,* which causes malaria, in 2002, and are currently sequencing the genome of the parasite *Trypanosoma,* which causes African sleeping sickness. One of the most significant genome-sequencing efforts now underway focuses on one or more nonhuman primates, such as the chimpanzee. Comparing the DNA sequences of humans and our closest living relatives will help biologists understand the genetic changes that occurred during human evolution, including what genes govern mental and linguistic capabilities.

The Human Genome Project has enormous implications for the future

Knowledge of the human genome may revolutionize human health care, and some experts predict that in highly developed countries, the average human life expectancy at birth will be 90 to 95 years by 2050. (As a comparison, the current average life expectancy in the United States is 77 years.) Nearly every week investigators announce new health-related information about the human genome, such as identifying genes associated with hypertension or with specific cancers.

Several scientific fields have emerged in the wake of the Human Genome Project. These include bioinformatics, pharmacogenetics, and proteomics.

Bioinformatics. The discipline known as **bioinformatics,** or *biological computing,* includes the storage, retrieval, and comparison of DNA sequences within a given species and among different species. Bioinformatics uses powerful computers and sophisticated software to manage and analyze large amounts of data generated by sequencing and other technologies. For example, as researchers determine new DNA sequences, automated computer programs scan the sequences for patterns typically found in genes. By comparing the databases of DNA sequences from different organisms, bioinformatics has already led to insights about gene identification, gene function, and evolutionary relationships.

Pharmacogenetics. The new science of gene-based medicine known as **pharmacogenetics** customizes drugs to match a patient's genetic makeup. Currently, a physician does not know in advance whether a particular medication will benefit a patient or cause severe side effects. An individual's genes, especially those that code for drug-metabolizing enzymes, largely determine that person's response to a specific drug. Pharmacogenetics takes into account the subtle genetic differences among individuals. In as few as 5 to 10 years, patients may take routine genetic screening tests before a physician prescribes a drug.

Many of these diagnostic tests may involve **DNA microarrays** (also known as *DNA chips* or *gene chips*), in which thousands of different DNA molecules are placed on a glass slide or chip. Figure 15-3 shows how a DNA microarray might be used. In step ①, a mechanical robot prepares the microarray. It spots each location on the grid with thousands to millions of copies of a specific *complementary DNA (cDNA)* strand. The single-stranded cDNA molecules for each spot, known as a *microdot,* are made using *reverse transcriptase* from a specific mRNA and then amplified using the *polymerase chain reaction* (see Chapter 14).

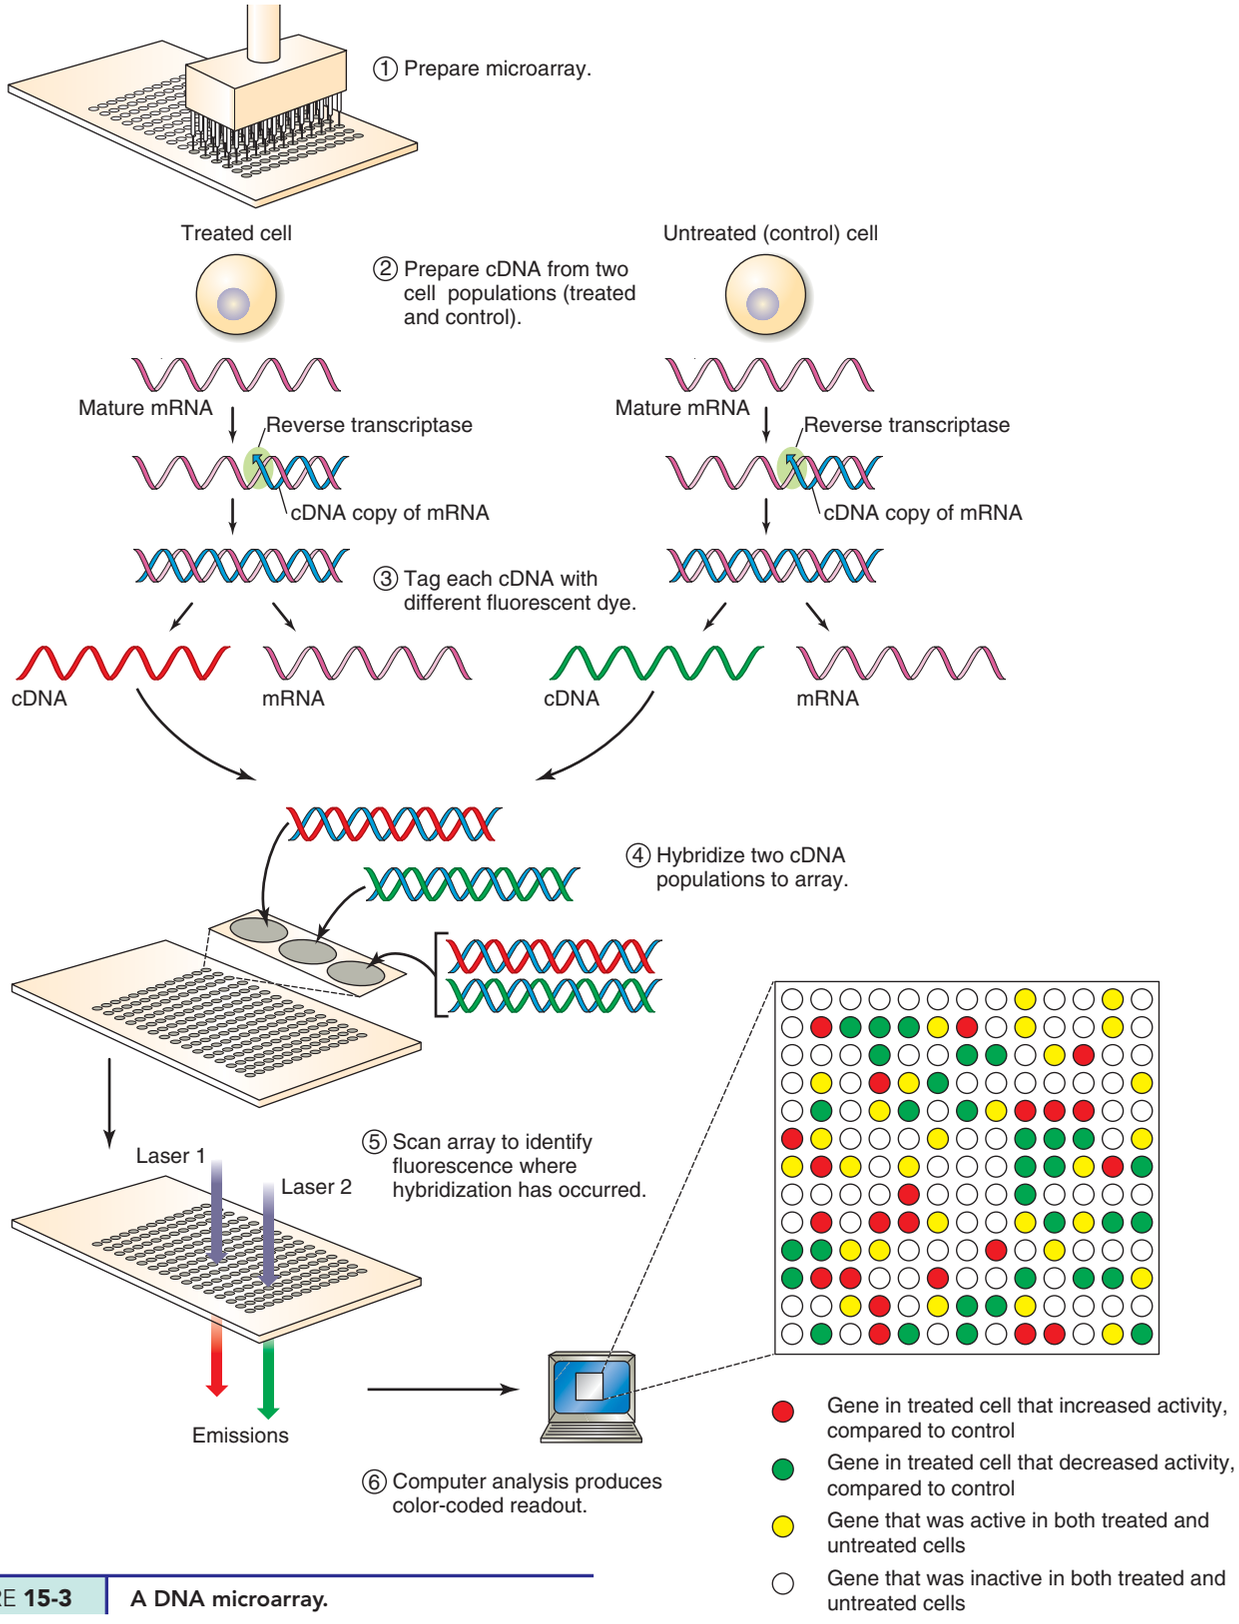

FIGURE **15-3** | **A DNA microarray.**

In step ②, researchers isolate mature mRNA molecules from two cell populations—for example, liver cells treated with a newly developed drug and control liver cells not treated with the drug. (The liver produces many enzymes that metabolize foreign molecules, including drug molecules. Drugs the liver cannot metabolize, or metabolizes weakly, may be too toxic to be used.) Researchers use the isolated mRNA molecules to prepare cDNA molecules for each cell population, which ③ are then tagged with different colored fluorescent dyes. For example, the treated cells' cDNA molecules might be labeled with red dye and the untreated cells' cDNA molecules with green dye. In step ④, researchers add the two cDNA populations to the array, and some of the cDNA subsequently hybridizes (forms base pairs with) the cDNA on the array.

After washing it to remove any cDNA that has not hybridized to the array, ⑤ investigators scan the array with lasers to identify red and green fluorescence where hybridization has occurred. In step ⑥, computer analysis of the ratio of red to green fluorescence at each spot in the array produces a color-coded readout that researchers can further analyze using statistics and bioinformatics. For example, a medical researcher might compare the experimental drug's overall pattern of gene activity with that of known drugs and toxins. If the gene activity for the treated cells matches that of a toxin that damages the liver, the drug will probably not go into clinical trials.

DNA microarrays enable researchers to compare the activities of thousands of genes in normal and diseased cells from tissue samples. Because cancer and other diseases exhibit altered patterns of gene expression, DNA microarrays have the potential to identify genes or the proteins they code for, which can then be targeted by therapeutic drugs.

Here's an example of the application. In 2002 medical researchers identified 17 genes that are active in different kinds of diffuse large B-cell lymphoma. Using DNA microarrays, researchers determined which combination of those 17 genes is active in each subtype of this form of cancer. Armed with the knowledge of which subtype of cancer a patient has, physicians can choose the treatment that will probably be most effective for that patient. Examining patterns of gene activity with DNA microarrays also helps medical scientists identify which patients will probably remain free of cancer after treatment and which will probably relapse.

Pharmacogenetics, like other fields in human genetics, presents difficult ethical questions. The genetic testing that will be an everyday part of pharmacogenetics raises issues of privacy, genetic bias, and potential discrimination. We consider these issues later in the chapter.

Together, the Human Genome Project and pharmacogenetics will advance knowledge of the role of genes in human health and disease. However, individualized genetic testing may cause people to worry unnecessarily about a genetic disease for which they may never develop symptoms. Most common diseases result from a complex interplay between multiple genes and nongenetic, or environmental, factors. Recall from Chapter 10 that the environment is an important factor influencing gene expression. In humans, healthy environmental factors include proper diet, adequate exercise, and not smoking (see Chapter 37, *Focus On: Unwelcome Tissues: Cancers*).

Proteomics. The study of all the proteins encoded by the human genome and produced in a person's cells and tissues is **proteomics** or *functional genomics.* Scientists want to identify all the proteins made by a given kind of cell, but the process is much more complicated than sequencing the human genome. For one thing, some genes encode several different proteins (see Fig. 13-11, differential mRNA processing). Also, every somatic cell in the human body has essentially the same genome, but cells in different tissues vary greatly in the kinds of proteins they produce. Protein expression patterns vary not only in different tissues but also at different stages in the development of a single cell.

Scientists want to understand the role of each protein in a cell, how the various proteins interact, and the 3-D structure for each protein. While advancing biological knowledge, these goals also promise advances in medicine. If they know the shape of a protein associated with a type of cancer or other disease, pharmacologists may be able to develop drugs that bind to active sites on that protein, turning its activity off. Today, the pharmaceutical industry has drugs that target about 500 proteins in the cell. However, they estimate proteomics may yield 10,000 to 20,000 additional protein targets.

Researchers use mouse models to study human genetic diseases

Many questions relating to human genetic diseases are difficult to answer because of the ethical issues involved in using humans as test subjects. However, research on any disease is greatly facilitated if an animal model is used for experimentation. A good example is *cystic fibrosis,* a genetic disease caused by a single gene mutation inherited as a recessive allele (discussed later in the chapter). In 1994, researchers used **gene targeting** to produce strains of mice that were either homozygous or heterozygous for cystic fibrosis (see Chapter 14).

The allele that causes cystic fibrosis is a mutant form of a locus involved in controlling the body's water and electrolyte balance. Geneticists have cloned this gene and found it codes for a protein, the *CFTR protein,* that serves as a chloride ion channel in the plasma membrane. (*CFTR* stands for *cystic fibrosis transmembrane conductance regulator.*) This ion channel transports chloride ions out of the cells lining the digestive tract and the respiratory system. When the chloride ions leave the cells, water follows by osmosis. Thus the normal secretions of these cells are relatively watery. Because the cells of individuals with cystic fibrosis lack normal chloride ion channels, their secretions have a very low water content and their sweat is very salty. Cells of heterozygous individuals have only half the usual number of functional CFTR ion channels, but these are enough to maintain the normal fluidity of their secretions.

Some researchers now focus their efforts on understanding the way in which the CFTR channel is activated or inactivated in mice. They hope to use this information to design drugs that enhance chloride transport through the CFTR channel. Such drugs have the potential to treat cystic fibrosis in humans by activating the mutant channel.

Review

- What kinds of information can a human karyotype provide?
- What is pedigree analysis?
- What are two possible benefits scientists hope to obtain by further study of the human genome?
- How does using a mouse model for a genetic disease overcome some of the difficulties in studying human inheritance?

ABNORMALITIES IN CHROMOSOME NUMBER AND STRUCTURE

Learning Objectives

4 Explain how nondisjunction in meiosis is responsible for chromosome abnormalities such as Down syndrome, Klinefelter syndrome, and Turner syndrome.

5 Distinguish among the following structural abnormalities in chromosomes: translocations, deletions, and fragile sites.

Polyploidy, the presence of multiple sets of chromosomes, is common in plants but rare in animals. It may arise from the failure of chromosomes to separate during meiosis or from the fertilization of an egg by more than one sperm. When it occurs in all the cells of the body, polyploidy is lethal in humans and many other animals. For example, *triploidy* (3*n*) is sometimes found in human embryos that have been spontaneously aborted in early pregnancy.

Abnormalities caused by the presence of a single extra chromosome or the absence of a chromosome—**aneuploidies**—are more common than polyploidy. **Disomy** is the normal state: two of each kind of chromosome. In **trisomy,** a person has an extra chromosome, that is, three of one kind. In **monosomy,** an individual lacks one member of a pair of chromosomes. Table 15-2 summarizes some disorders that aneuploidies produce.

Aneuploidies generally arise as a result of an abnormal meiotic (or, rarely, mitotic) division in which chromosomes fail to separate at anaphase. This phenomenon, called **nondisjunction,** can occur with the autosomes or with the sex chromosomes. In meiosis, chromosome nondisjunction may occur during the first or second meiotic division (or both). For example, two X chromosomes that fail to separate at either the first or the second meiotic division may both enter the egg nucleus. Alternatively, the two joined X chromosomes may go into a *polar body,* leaving the egg with no X chromosome. (Recall from Chapter 9 that a polar body is a nonfunctional haploid cell produced during oogenesis; also see Fig. 48-11.)

Nondisjunction of the XY pair during the first meiotic division in the male may lead to the formation of a sperm with both X and Y chromosomes or a sperm with neither an X nor a Y chromosome (Fig. 15-4). Similarly, nondisjunction at the second meiotic division can produce sperm with two Xs or two Ys. When an abnormal gamete unites with a normal one, the resulting zygote has a chromosome abnormality that will be present in every cell of the body.

Meiotic nondisjunction results in an abnormal chromosome number at the zygote stage of development, so that all cells in the individual have an abnormal chromosome number. In contrast, nondisjunction during a mitotic division occurs sometime later in development and leads to the establishment of a clone of abnormal cells in an otherwise normal individual. Such a mixture of cells with different chromosome numbers may or may not affect somatic (body) or germ-line (reproductive) tissues.

Down syndrome is usually caused by trisomy 21

Down syndrome is one of the most common chromosome abnormalities in humans. (The term *syndrome* refers to a set of symptoms that usually occur together in a particular disorder.) It was named after J. Langdon Down, the British physician who

TABLE **15-2** Chromosome Abnormalities: Disorders Produced by Aneuploidies

Karyotype	Common Name	Clinical Description
Trisomy 13	Patau syndrome	Multiple defects, with death typically by age 3 months.
Trisomy 18	Edwards syndrome	Ear deformities, heart defects, spasticity, and other damage; death typically by age 1 year, but some survive much longer.
Trisomy 21	Down syndrome	Overall frequency is about 1 in 800 live births. True trisomy is most often found among children of older (age 35+) mothers, but translocation resulting in the equivalent of trisomy is not age-related. Trisomy 21 is characterized by a fold of skin above the eye, varying degrees of mental retardation, short stature, protruding furrowed tongue, transverse palmar crease, cardiac deformities, and increased risk of leukemia and Alzheimer's disease.
X0	Turner syndrome	Short stature, webbed neck, sometimes slight mental retardation; ovaries degenerate in late embryonic life, leading to rudimentary sexual characteristics; gender is female; no Barr bodies.
XXY	Klinefelter syndrome	Male with slowly degenerating testes, enlarged breasts; one Barr body per cell.
XYY	XYY karotype	Many males have no unusual symptoms; others are unusually tall, with heavy acne, and some tendency to mild mental retardation.
XXX	Triplo-X	Despite three X chromosomes, usually fertile females with normal intelligence; two Barr bodies per cell.

KEY CONCEPT: Aneuploidy may occur by meiotic nondisjunction, the abnormal segregation of chromosomes during meiosis.

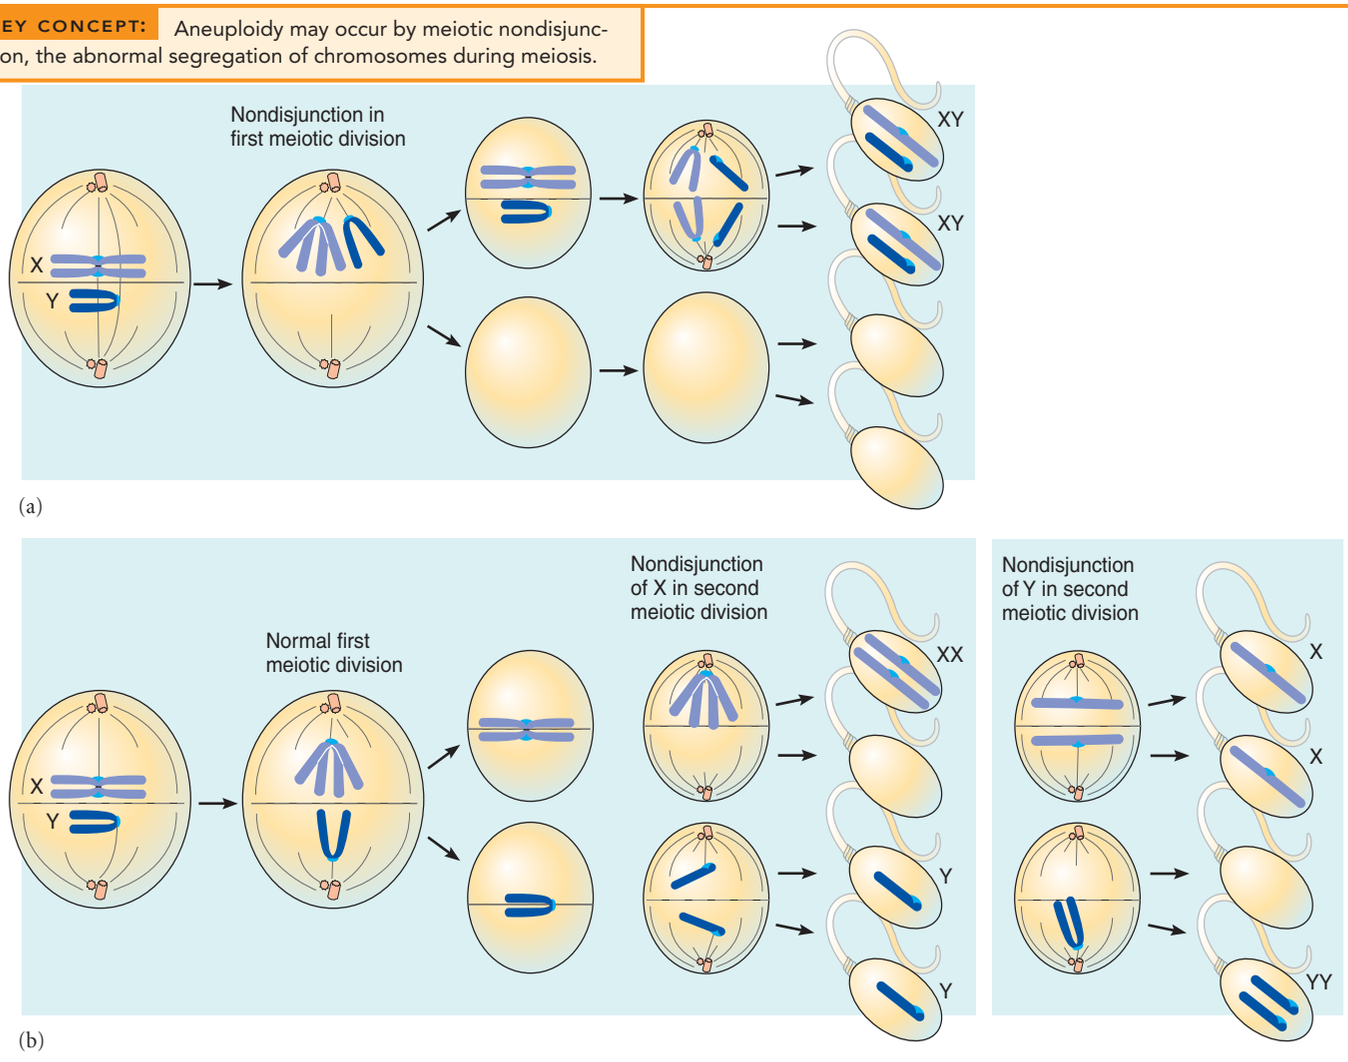

FIGURE **15-4** **Meiotic nondisjunction.**

In these examples of nondisjunction of the sex chromosomes in the human male, only the X *(purple)* and Y *(blue)* chromosomes are shown. **(a)** Nondisjunction in the first meiotic division results in two XY sperm and two sperm with neither an X nor a Y. **(b)** Second-division nondisjunction of the X chromosome results in one sperm with two X chromosomes, two with one Y each, and one with no sex chromosomes. Nondisjunction of the Y chromosome results in one sperm with two Y chromosomes, two with one X each, and one with no sex chromosome *(box on right)*.

in 1866 first described the condition. Affected individuals have abnormalities of the face, eyelids, tongue, hands, and other parts of the body and are often mentally and physically retarded (Fig. 15-5a). They are also unusually susceptible to certain diseases, such as leukemia and Alzheimer's disease.

Cytogenetic studies have revealed that most people with Down syndrome have 47 chromosomes because of *autosomal trisomy:* they are trisomic for chromosome 21 (Fig. 15-5b). This condition is known as **trisomy 21.** Nondisjunction during meiosis is responsible for the presence of the extra chromosome. Although no genetic information is missing in these individuals, the extra copies of chromosome 21 genes bring about some type of genetic imbalance that causes abnormal physical and mental development. Down syndrome is quite variable in expression, with some individuals far more severely affected than others. Researchers are using DNA technologies to attempt to pinpoint genes on chromosome 21 that affect mental development, as well as possible *oncogenes* (cancer-causing genes) and genes that may be involved in Alzheimer's disease.

Down syndrome occurs in all ethnic groups in about 1 out of 800 live births. Its incidence increases markedly with increasing maternal age. The occurrence of Down syndrome is not affected by the father's age (although other disorders are, including schizophrenia and achondroplasia, the most common form of dwarfism). Down syndrome is 68 times more likely in the offspring of mothers of age 45 than in the offspring of mothers age 20. However, most babies with Down syndrome in the United States are born to mothers younger than 35, in part because

these greatly outnumber older mothers, and in part because about 90% of older women who undergo prenatal testing terminate the pregnancy if Down syndrome is diagnosed.

The relationship between increased incidence in Down syndrome and maternal age has been studied for decades, but there is no explanation. Several hypotheses have been proposed to explain the maternal age effect, but none are supported unequivocally. One explanation is that older women have held eggs in suspended meiosis too long, leading to a deterioration of the meiotic spindle apparatus. Another possibility is that an aging womb is less likely to reject an abnormal fetus.

Most sex chromosome aneuploidies are less severe than autosomal aneuploidies

Sex chromosome aneuploidies are tolerated relatively well (see Table 15-2) This is true, at least in part, because of the mechanism of **dosage compensation:** mammalian cells compensate for extra X chromosome material by rendering all but one X chromosome inactive. The inactive X is seen as a **Barr body,** a region of darkly staining, condensed chromatin next to the nuclear envelope of an interphase nucleus (see Fig. 10-17). Investigators have used the presence of the Barr body in the cells of normal females (but not normal males) as an initial screen to determine whether an individual is genetically female or male. However, as you'll see shortly in the context of sex chromosome aneuploidies, the Barr body test has limitations.

Individuals with **Klinefelter syndrome** are males with 47 chromosomes, including two Xs and one Y. They have small testes, produce few or no sperm, and are therefore sterile. The hypothesis that the Y chromosome is the major determinant of the male phenotype has been substantiated by the fact that at least one gene on the Y chromosome acts as a genetic switch, directing male development. Males with Klinefelter syndrome tend to be unusually tall and have female-like breast development. About half show some mental retardation, but many live relatively normal lives. However, each of their cells have one Barr body. On the basis of such a test, they would be erroneously classified as females. About 1 in 600 to 1000 live-born males has Klinefelter syndrome.

The sex chromosome composition for **Turner syndrome,** in which an individual has only one sex chromosome, an X chromosome, is designated X0. The 0 refers to the absence of a second sex chromosome. Because they lack the male-determining effect of the Y chromosome, individuals with Turner syndrome develop as females. However, both their internal and their external genital structures are underdeveloped, and they are sterile. Apparently a second X chromosome is necessary for normal development of ovaries in a female embryo. Examination of their cells reveals no Barr bodies, because there is no extra X chromosome to be inactivated. Using the standards of the Barr body test, such an individual would be classified erroneously as a male. About 1 in 2500 live-born females has Turner syndrome.

People with an X chromosome plus two Y chromosomes are phenotypically males, and they are fertile. Other characteristics of these individuals (tall, often with severe acne) hardly qualify

as a syndrome; hence the designation **XYY karotype.** Some years ago, several widely publicized studies suggested that people with this condition are more likely to display criminal tendencies and thus to be imprisoned. However, these studies were flawed because they were based on small numbers of XYY males, without adequate or well-matched control studies of XY males. The prevailing opinion in medical genetics today is that many undiagnosed XYY males in the general population do not have overly aggressive or criminal behaviors and are not incarcerated.

Aneuploidies usually result in prenatal death

Recognizable chromosome abnormalities are seen in less than 1% of all live births, but substantial evidence suggests the rate at conception is much higher. At least 17% of pregnancies recognized at 8 weeks will end in spontaneous abortion (miscarriage). Approximately half of these spontaneously aborted embryos have major chromosome abnormalities, including autosomal trisomies (such as trisomy 21), triploidy, tetraploidy, and Turner syndrome (X0). Autosomal monosomies are exceedingly rare, possibly because they induce a spontaneous abortion very early in the pregnancy, before a woman is even aware she is pregnant. Some investigators give surprisingly high estimates (50% or more) for the loss rate of very early embryos. Chromosome abnormalities probably induce many of these spontaneous abortions.

Abnormalities in chromosome structure cause certain disorders

Chromosome abnormalities are caused not only by changes in chromosome number but also by distinct changes in the structure of one or more chromosomes. Here we consider three simple examples of structural abnormalities: translocations, deletions, and fragile sites.

Translocation is the attachment of part of one chromosome to another

In some cases of **translocation,** a chromosome fragment breaks off and attaches to a nonhomologous chromosome. In a **reciprocal translocation,** two nonhomologous chromosomes exchange parts (Fig. 15-6). The consequences of translocations vary considerably. They include deletions, in which some genes are missing, and **duplications,** which are extra copies of certain genes.

In about 4% of individuals with Down syndrome, only 46 chromosomes are present, but one is abnormal. The large arm of chromosome 21 has been translocated to the large arm of another chromosome, usually chromosome 14. Individuals with **translocation Down syndrome** have one chromosome 14, one combined 14/21 chromosome, and two normal copies of chromosome 21. All or part of the genetic material from chromosome 21 is thus present in triplicate. When geneticists study the karyotypes of the parents in such cases, they usually find either the mother or the father has only 45 chromosomes, although

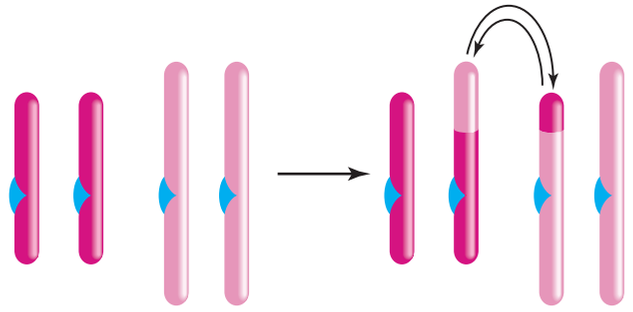

FIGURE **15-6** **Reciprocal translocation, the most common type of translocation.**

Two nonhomologous chromosomes exchange segments. About half of the gametes produced following translocation and meiosis are abnormal and have duplications or deletions. (Unduplicated chromosomes are shown for simplicity.)

she or he is generally phenotypically normal. The parent with 45 chromosomes has one chromosome 14, one combined 14/21 chromosome, and one chromosome 21; although the karyotype is abnormal, there is no extra genetic material. In contrast to trisomy 21, translocation Down syndrome can run in families, and its incidence is not related to maternal age.

A deletion is the loss of part of a chromosome

In the chromosome abnormality known as a **deletion,** part of a chromosome is missing. Sometimes chromosomes break and fail to rejoin. Such breaks result in deletions of as little as a few base pairs to as much as an entire chromosome arm. As you might expect, large deletions are generally lethal, whereas small deletions may have no effect or may cause recognizable human disorders.

One deletion disorder (1 in 50,000 live births) is **cri du chat syndrome,** in which part of the short arm of chromosome 5 is deleted. As in most deletions, the exact point of breakage in chromosome 5 varies from one individual to another; some cases of cri du chat involve a small loss, whereas others involve a more substantial deletion of base pairs. Infants born with cri du chat syndrome typically have a small head with altered features described as a "moon face" and a distinctive cry that sounds like a kitten mewing. (The name literally means "cry of the cat" in French.) Affected individuals usually survive beyond childhood but exhibit severe mental retardation.

Fragile sites are weak points at specific locations in chromatids

A **fragile site** is a place where part of a chromatid appears to be attached to the rest of the chromosome by a thin thread of DNA. Fragile sites may occur at a specific location on both chromatids of a chromosome. They have been identified on the X chromosome as well as on certain autosomes. The location of a fragile site is exactly the same in all of an individual's cells, as well as in cells of other family members. Scientists report growing evi-

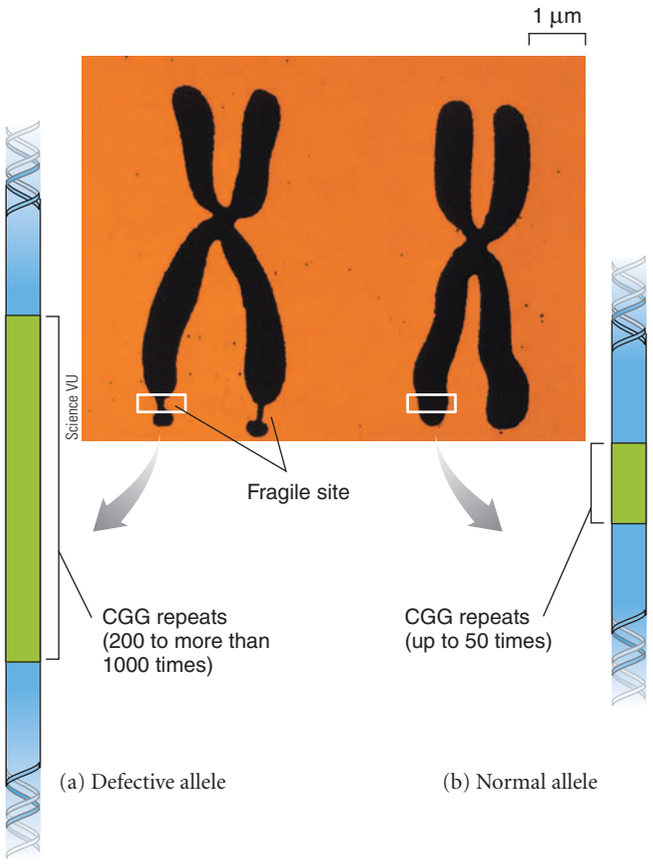

FIGURE **15-7** **Fragile X syndrome.**

This colorized SEM shows an X chromosome with a fragile site and a normal X chromosome. **(a)** The defective allele at the tips of both chromatids of the X chromosome repeats CGG 200 to 1000 times. **(b)** The normal allele repeats CGG up to 50 times.

dence that cancer cells may have breaks at these fragile sites. Whether cancer destabilizes the fragile sites, leading to breakage, or the fragile sites themselves contain genes that contribute to cancer is unknown at this time.

In **fragile X syndrome** a fragile site occurs near the tip of the X chromosome, where the fragile X gene contains a nucleotide triplet CGG that repeats 200 to more than 1000 times (Fig. 15-7a). In a normal chromosome, CGG repeats up to 50 times (Fig. 15-7b).

Fragile X syndrome is the most common cause of inherited mental retardation. The effects of fragile X syndrome, which are more pronounced in males than in females, range from mild learning and attention deficit to severe mental retardation and hyperactivity. According to the National Fragile X Foundation, about 80% of boys and 35% of girls with fragile X syndrome are at least mildly mentally retarded. Females with fragile X syndrome are usually heterozygous (because their other X chromosome is normal) and are therefore more likely to have normal intelligence.

The discovery of the fragile X gene in 1991, as well as the development of the first fragile X mouse model in 1994, have provided researchers with ways to develop and test potential treatments, including gene therapy. At the microscopic level, the nerve cells of individuals with fragile X syndrome have malformed dendrites (the part of the nerve cell that receives nerve impulses from other nerve cells). At the molecular level, the triplet repeats associated with fragile X syndrome disrupt the functioning of a gene that codes for a certain protein, designated *fragile X mental retardation protein (FMRP)*. In normal cells, FMRP binds to dozens of different mRNA molecules (exactly why it binds is not yet understood), but in cells of individuals with fragile X syndrome the mutated allele does not produce functional FMRP.

Review

GENETIC DISEASES CAUSED BY SINGLE-GENE MUTATIONS

Learning Objective

6 State whether each of the following genetic defects is inherited as an autosomal recessive, autosomal dominant, or X-linked recessive: phenylketonuria (PKU), sickle cell anemia, cystic fibrosis, Tay-Sachs disease, Huntington's disease, and hemophilia A.

You have seen that several human disorders involve chromosome abnormalities. Hundreds of human disorders, however, involve enzyme defects caused by mutations of single genes. *Phenylketonuria (PKU)* and *alkaptonuria* (see Chapter 12) are examples of these disorders, which are sometimes referred to as an **inborn error of metabolism,** a metabolic disorder caused by the mutation of a gene that codes for an enzyme needed in a biochemical pathway. Both PKU and alkaptonuria involve blocks in the metabolism of the amino acid phenylalanine.

Most genetic diseases are inherited as autosomal recessive traits

Many human genetic diseases have a simple autosomal recessive inheritance pattern and therefore appear only in the homozygous state. Why are these traits recessive? Most recessive mutations result in a mutant allele that encodes a product that no longer works (either there is not enough gene product, or it is a defective gene product). In the heterozygous state, there is one functional copy of the gene and one mutated, nonfunctional copy. The normal copy of the gene generally produces enough protein to meet the cell's needs. In homozygous recessive individuals, *both* alleles of the gene are nonfunctional, and the cell's needs are not met. As a result, the person shows symptoms of disease.

Phenylketonuria results from an enzyme deficiency

Phenylketonuria (PKU), which is most common in individuals of western European descent, is an autosomal recessive disease caused by a defect of amino acid metabolism. It affects about 1 in 10,000 live births in North America. Homozygous recessive individuals lack an enzyme that converts the amino acid phenylalanine to another amino acid, tyrosine. They accumulate high levels of phenylalanine, phenylpyruvic acid, and similar compounds. The accumulating phenylalanine is converted to phenylketones, which damage the central nervous system, including the brain, in children. The ultimate result in untreated cases is severe mental retardation. An infant with PKU is usually healthy at birth because its mother, who is heterozygous, breaks down excess phenylalanine for both herself and her fetus. However, during infancy and early childhood the accumulation of toxic products eventually causes irreversible damage to the central nervous system.

In the 1950s, infants with PKU were identified early and placed on a low-phenylalanine diet, dramatically alleviating their symptoms. The diet is difficult to adhere to because it contains no meat, fish, dairy products, breads, or nuts. Also, individuals with PKU should not consume the sugar substitute aspartame, found in many diet drinks and foods, because it contains phenylalanine. Biochemical tests for PKU have been developed, and screening of newborns through a simple blood test is required in the United States. Because of these screening programs and the availability of effective treatment, thousands of PKU-diagnosed children have not developed severe mental retardation. Most must continue the diet through at least adolescence. Doctors now recommend that patients stay on the diet throughout life, because some adults who have discontinued the low-phenylalanine diet experience certain mental problems, such as concentration difficulty and short-term memory loss.

Ironically, the success of PKU treatment in childhood presents a new challenge today. If a homozygous female who has discontinued the special diet becomes pregnant, the high phenylalanine levels in her blood can damage the brain of the fetus she is carrying, even though that fetus is heterozygous. Therefore, she must resume the diet, preferably before becoming pregnant. This procedure is usually (although not always) successful in preventing the effects of **maternal PKU.** It is especially important for women with PKU to be aware of maternal PKU and to obtain appropriate counseling and medical treatment during pregnancy.

Sickle cell anemia results from a hemoglobin defect

Sickle cell anemia is inherited as an autosomal recessive trait. The disease is most common in people of African descent (approximately 1 in 500 African Americans), and about 1 in 12 African Americans is heterozygous. Under low oxygen conditions, the red blood cells of an individual with sickle cell anemia are shaped like sickles, or half-moons, whereas normal red blood cells are biconcave discs.

The mutation that causes sickle cell anemia was first identified more than 50 years ago. The sickled cells contain abnormal hemoglobin molecules, which have the amino acid valine instead of glutamic acid at position 6 (the sixth amino acid from the amino terminal end) in the β-globin chain (see Chapter 3). The substitution of valine for glutamic acid makes the hemoglobin molecules stick to one another to form fiber-like structures that change the shape of the red blood cells. This sickling occurs in the veins after the oxygen has been released from the hemoglobin. The blood cells' abnormal sickled shape slows blood flow and blocks small blood vessels (Fig. 15-8), resulting in tissue damage from lack of oxygen and essential nutrients and episodes of pain. Sickled red blood cells also have a shorter life span than normal red blood cells, leading to severe anemia in many affected individuals.

Treatments for sickle cell anemia include pain relief measures, transfusions, and, more recently, medicines such as hydroxyurea, which activates the gene for the production of normal fetal hemoglobin (this gene is generally not expressed after birth). The presence of normal fetal hemoglobin in the red blood cells dilutes the sickle cell hemoglobin, thereby minimizing the painful episodes and reducing the need for blood transfusions. The long-term effects of hydroxyurea are not known at this time, but there are concerns that it may induce tumor formation.

Ongoing research is directed toward providing gene therapy for sickle cell anemia. The development of a mouse model for studying sickle cell anemia has enabled researchers to test gene therapy. The first gene therapy treatments in mice used a mouse

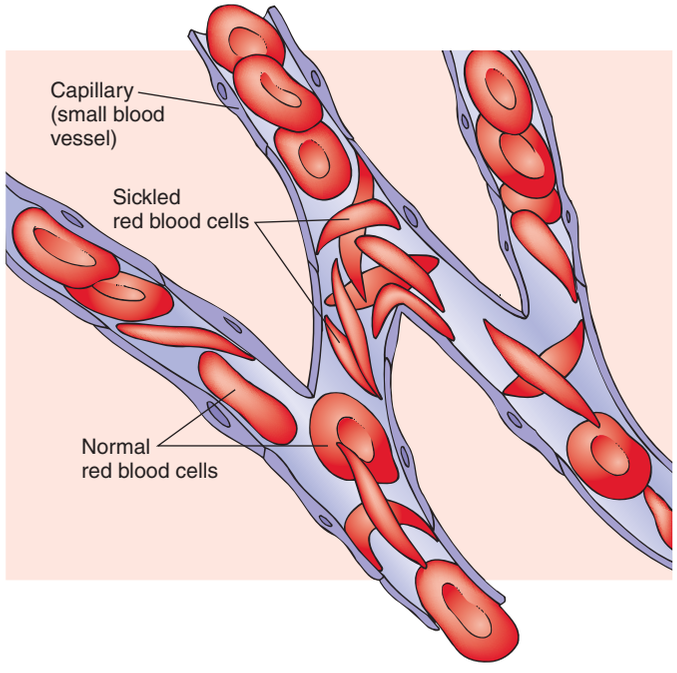

FIGURE **15-8** **Sickle cell anemia.**

Sickled red blood cells do not pass through small blood vessels as easily as normal red blood cells. The sickled cells can cause blockages that prevent oxygen from being delivered to tissues.

retrovirus as a **vector,** a carrier that transfers the genetic information. However, the retrovirus did not effectively transport the normal gene for hemoglobin into the bone marrow, where stem cells produce new blood cells. In 2001, researchers cured sickle cell anemia in mice using a modified HIV as a vector. Before this treatment can be tested in humans, however, researchers must demonstrate that the HIV vector is safe. Bone marrow transplants are also a promising future treatment for seriously ill individuals.

The reason the sickle cell allele occurs at a higher frequency in parts of Africa is well established. Individuals who are heterozygous *(Hb^AHb^S)* and carry alleles for both normal hemoglobin *(Hb^A)* and sickle cell hemoglobin *(Hb^S)* are more resistant to the malarial parasite, *Plasmodium falciparum,* which causes a severe, often fatal, form of malaria. The malarial parasite, which spends part of its life cycle inside red blood cells, does not thrive when sickle cell hemoglobin is present. (An individual heterozygous for sickle cell anemia produces both normal and sickle cell hemoglobin.) Areas in Africa where falciparum malaria occurs correlate well with areas in which the frequency of the sickle cell allele is more common in the human population. Thus, Hb^AHb^S individuals, who possess one copy of the mutant sickle cell allele, have a selective advantage over homozygous individuals, both Hb^AHb^A (who may die of malaria) and Hb^SHb^S (who may die of sickle cell anemia). This phenomenon, known as **heterozygote advantage,** is discussed further in Chapter 18 (see Fig. 18-6).

Image not available due to copyright restrictions

Cystic fibrosis results from defective ion transport

Cystic fibrosis is the most common autosomal recessive disorder in children of European descent (1 in 2500 births). About 1 in 25 individuals in the United States is a heterozygous carrier of the mutant cystic fibrosis allele. Abnormal secretions characterize this disorder. Its most severe effect is on the respiratory system, where abnormally viscous mucus clogs the airways. The cilia that line the bronchi (see Chapter 44) cannot easily remove the mucus, and it thus becomes a growth medium for dangerous bacteria. These bacteria or their toxins attack the surrounding tissues, leading to recurring pneumonia and other complications. The heavy mucus also occurs elsewhere in the body, causing digestive difficulties and other effects.

As discussed earlier, the gene responsible for cystic fibrosis codes for CFTR, the protein that regulates the transport of chloride ions across cell membranes. The defective protein, found in plasma membranes of epithelial cells lining the passageways of the lungs, intestines, pancreas, liver, sweat glands, and reproductive organs, results in the production of an unusually thick mucus that eventually leads to tissue damage. Although many forms of cystic fibrosis exist that vary somewhat in the severity of symptoms, the disease is almost always very serious.

Antibiotics are used to control bacterial infections, and daily physical therapy is required to clear mucus from the respiratory system (Fig. 15-9). Treatment with *Dornase Alpha (DNase*), an enzyme produced by recombinant DNA technology, helps break down the mucus. Without treatment, death would occur in infancy. With treatment, the average life expectancy for individuals with cystic fibrosis is now about 30 years. Because of the serious limitations of available treatments, gene therapy for cystic fibrosis is under development.

The most severe mutant allele for cystic fibrosis predominates in northern Europe, and another, somewhat less serious, mutant allele is more prevalent in southern Europe. Presumably these mutant alleles are independent mutations that have been maintained by natural selection. Some experimental evidence supports the hypothesis that heterozygous individuals are less likely to die from infectious diseases that cause severe diarrhea, another possible example of heterozygote advantage.

Tay-Sachs disease results from abnormal lipid metabolism in the brain

Tay-Sachs disease is an autosomal recessive disease that affects the central nervous system and results in blindness and severe mental retardation. The symptoms begin within the first year of life and result in death before the age of 5 years. Because of the absence of an enzyme, a normal membrane lipid in brain cells fails to break down properly and accumulates in intracellular organelles called *lysosomes.* The lysosomes swell and cause the nerve cells to malfunction. Although research is ongoing, no effective treatment for Tay-Sachs disease is available at this time. However, an effective treatment strategy in a mouse model was reported in 1997: Oral administration of an inhibitor reduced

the synthesis of the lipid that accumulates in the lysosomes. This treatment offers the hope of future breakthroughs to deal more effectively with Tay-Sachs disease in humans.

The abnormal allele is especially common in the United States among Jews whose ancestors came from eastern and central Europe (Ashkenazi Jews). The disease occurs in about 1 in 4000 live births in the North American Jewish population. In contrast, Jews whose ancestors came from the Mediterranean region (Sephardic Jews) have a very low frequency of the allele.

Some genetic diseases are inherited as autosomal dominant traits

Huntington's disease (HD), named after George Huntington, the U.S. physician who first described it in 1872, is caused by a rare autosomal dominant allele that affects the central nervous system. The disease causes severe mental and physical deterioration, uncontrollable muscle spasms, and personality changes; death ultimately results. No effective treatment has been found. Every child of an affected individual has a 50% chance of also being affected (and, if affected, of passing the abnormal allele to his or her offspring). Ordinarily we would expect a dominant allele with such devastating effects to occur only as a new mutation and not to be transmitted to future generations. Because HD symptoms do not appear until relatively late in life (most people do not develop the disease until they are in their thirties or forties), a person may have children before the disease develops (Fig. 15-10). In North America, HD occurs in 1 in 20,000 live births.

The gene responsible for HD was identified in 1993. It is found at one end of chromosome 4. The mutation is a nucleotide triplet (CAG) that is repeated many times; the normal allele repeats CAG from 6 to 35 times, whereas the mutant allele repeats CAG from 40 to more than 150 times. Because CAG codes for the amino acid glutamine, the resulting protein, called *huntingtin,* has a long strand of glutamines. The number of nucleotide triplet repeats seems to be important in determining the age of onset and the severity of the disease; larger numbers of repeats correlate with an earlier age of onset and greater severity.

Much research now focuses on how the mutation is linked to neurodegeneration in the brain. A mouse model of HD is providing valuable clues about the development of the disease. Using this model, researchers have demonstrated that the defective version of huntingtin binds to enzymes called *acetyltransferases* in brain cells, blocking their action. Acetyltransferases are involved in turning genes on for expression, so in the brain cells of HD individuals, much of normal transcription cannot occur. Once neurologists better understand HD's mechanism of action on nerve cells, it may be possible to develop effective treatments to slow the progression of the disease.

Cloning of the *HD* allele became the basis for tests that allow those at risk to learn presymptomatically if they carry the allele. The decision to be tested for any genetic disease is understandably a highly personal one. The information is, of course, invaluable for those who must decide whether or not to have children. However, someone who tests positive for the *HD* allele must then live with the virtual certainty of eventually developing this devastating and incurable disease. Researchers hope that information from affected individuals who choose to be identified before the onset of symptoms may ultimately contribute to the development of effective treatments.

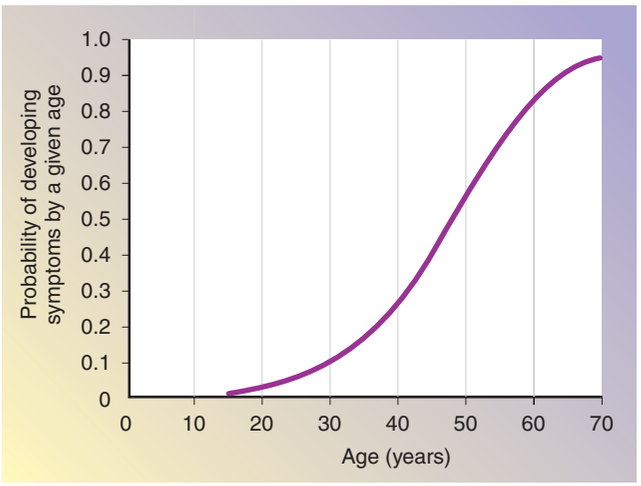

FIGURE **15-10** **The age of onset of Huntington's disease.**
The graph shows the cumulative probability that an individual affected with a Huntington's disease allele will have developed symptoms at a given age. *(Adapted from P. S. Harper,* Genetic Counseling, *5th edition, Butterworth-Heinemann, Oxford, 1998)*

Some genetic diseases are inherited as X-linked recessive traits

Hemophilia A was once referred to as a disease of royalty because of its high incidence among male descendants of Queen Victoria, but it is also found in many nonroyal pedigrees. Caused by the absence of blood-clotting factor VIII, **hemophilia A** is characterized by severe internal bleeding in the head, joints, and other areas from even a slight wound. The mode of inheritance is X-linked recessive. Thus, affected individuals are almost exclusively male, having inherited the abnormal allele on the X chromosome from their heterozygous carrier mothers. (For a female to be affected by an X-linked trait, she would have to inherit the defective allele from both parents, whereas an affected male need only inherit one defective allele from his mother.)

Treatments for hemophilia A consist of blood transfusions and the administration of clotting factor VIII (the missing gene product) by injection. Unfortunately, these treatments are costly. During the 1980s, many clotting factor VIII preparations made from human plasma were contaminated with HIV, and many men with hemophilia subsequently died from AIDS. Since 1992, virus-free clotting factor VIII has been available from both human plasma and recombinant DNA technology.

Review

- Which of the following genetic diseases is/are inherited as an autosomal dominant: sickle cell anemia, hemophilia A, Huntington's disease?
- Which of the following genetic diseases is/are inherited as an X-linked recessive: hemophilia A, cystic fibrosis, Tay-Sachs disease?

BiologyNow™ Assess your understanding of **genetic diseases caused by single-gene mutations** by taking the pretest on your BiologyNow CD-ROM.

GENE THERAPY

Learning Objective

7 Briefly discuss the process of gene therapy, including some of its technical challenges.

Because serious genetic diseases are difficult to treat, scientists have dreamed of developing actual cures. Today, advances in genetics may bring these dreams closer to reality. One strategy is **gene therapy,** which aims to replace a mutant allele in certain body cells with a normal allele. The rationale is that, although a particular allele may be present in all cells, it is expressed only in some. Expression of the normal allele in only the cells that require it may be sufficient to yield a normal phenotype.

This approach presents several technical problems. The solutions to these problems must be tailored to the nature of the gene itself, as well as to its product and the types of cells in which it is expressed. First the gene is cloned and the DNA introduced into the appropriate cells. One of the most successful techniques is packaging the normal allele in a viral vector, a virus that moves the normal allele into target cells that currently have a mutant allele. Ideally the virus should infect a high percentage of the cells. Most importantly, the virus should do no harm, especially over the long term.

Although many obstacles must be overcome, gene therapies for several genetic diseases are under development or are being tested on individuals in clinical trials. Scientists are currently addressing some of the unique problems presented by each disease.

Gene therapy programs are carefully scrutinized

Until recently, major technical advances caused the number of clinical studies involving gene therapy to grow dramatically. However, the death of a young man in a gene therapy trial in 1999, and two more recent cases of cancer (leukemia) in children, led to a shutdown of many trials, pending the outcome of investigations about health risks. The main safety concern in these inquiries is the potential toxicity of viral vectors. The vector used in the young man who died was an adenovirus (see Fig. 23-1b), a virus required in large doses to transfer enough copies of the normal alleles for effective therapy. Unfortunately, the high viral doses triggered a fatally strong immune response in the patient's body. Both children who developed leukemia were being treated for severe combined immunodeficiency disease (SCID). The vector in these cases was a retrovirus. The virus inserted itself into the children's DNA near or in a gene that can cause childhood leukemia.

Performing clinical trials on humans always has inherent risks. Researchers carefully select patients and thoroughly explain the potential benefits and risks, as far as they are known, so the patient—or, in the case of children, the parents—can give informed consent for the procedure. However, the problems in gene therapy trials in recent years have researchers busy developing safer alternatives to viral vectors.

Review

- How are viruses used in human gene therapy?
- Why are viral vectors of potential concern in human gene therapy?

GENETIC TESTING AND COUNSELING

Learning Objectives

8 State the relative advantages and disadvantages of amniocentesis, chorionic villus sampling, and preimplantation genetic diagnosis in the prenatal diagnosis of human genetic abnormalities.

9 Distinguish between genetic screening programs for newborns and adults, and discuss the scope and implications of genetic counseling.

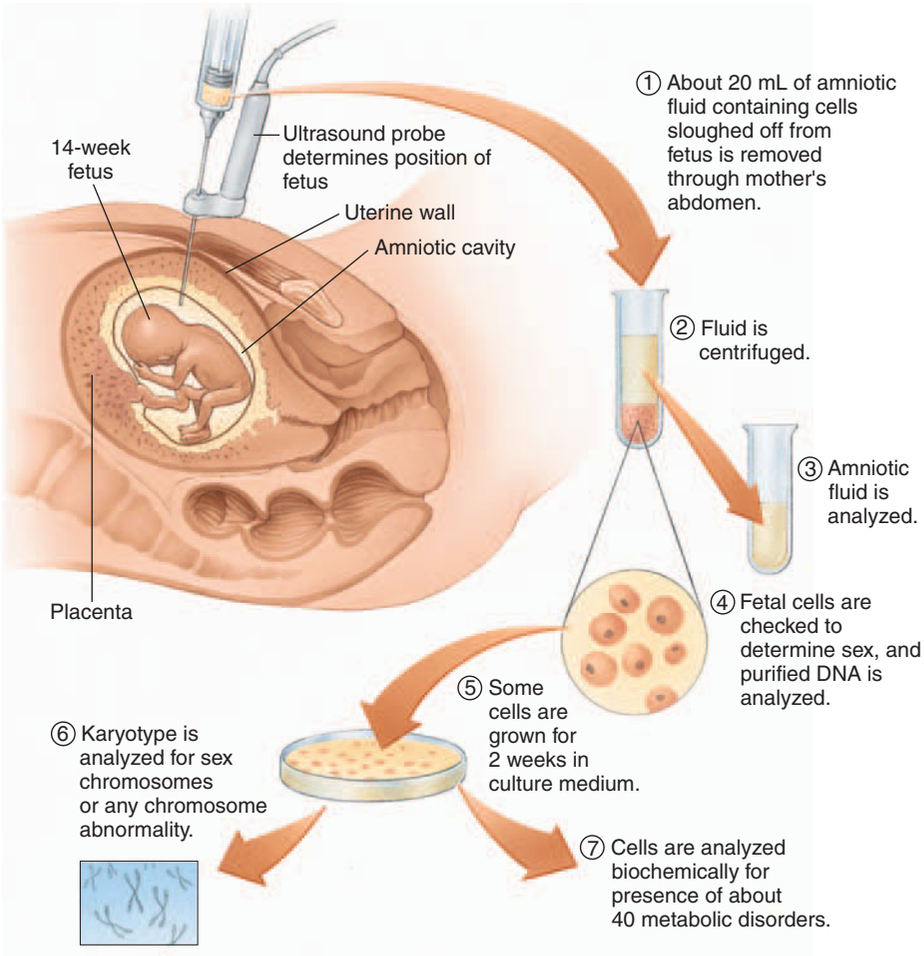
Geneticists have made many advances in detecting genetic disorders in individuals in recent years, including in prenatal diagnosis and genetic screening. With these advances comes increased information for couples at risk of having children with genetic diseases. Helping couples understand and deal with the genetic information now available is part of the rapidly expanding field of genetic counseling.

Prenatal diagnosis detects chromosome abnormalities and gene defects

Health care professionals are increasingly successful at diagnosing genetic diseases prenatally. In the diagnostic technique called **amniocentesis,** a sample of the *amniotic fluid* surrounding the fetus is obtained. A technician inserts a needle through the pregnant woman's abdomen, into the uterus, and then into the amniotic sac surrounding the fetus. Some of the amniotic fluid is withdrawn from the amniotic cavity into a syringe (Fig. 15-11). The fetus is normally safe from needle injuries because **ultrasound imaging** helps determine the positions of the fetus, placenta, and the needle (see Fig. 49-18). However, there is a 0.5%, or 1 in 200, chance that amniocentesis will induce a miscarriage.

Amniotic fluid contains living cells sloughed off the body of the fetus and hence genetically identical to the cells of the fetus. After cells grow for about 2 weeks in culture in the lab, technicians karyotype dividing cells to detect chromosome abnormalities. Other DNA tests have also been developed to identify

FIGURE **15-11** **Amniocentesis.**
Certain genetic diseases and other abnormal conditions are diagnosed prenatally by amniocentesis.



most chromosome abnormalities. Amniocentesis, which has been performed since the 1960s, is routinely offered for pregnant women older than age 35 because their fetuses have a higher-than-normal risk of Down syndrome.

Other prenatal tests have been developed to detect many genetic disorders with a simple inheritance pattern, but these disorders are rare enough that physicians usually order the tests performed only if they suspect a particular problem. Enzyme deficiencies can often be detected by incubating cells recovered from amniotic fluid with the appropriate substrate and measuring the product; this technique has been useful in prenatal diagnosis of disorders such as Tay-Sachs disease. The tests for several other diseases, including sickle cell anemia, Huntington's disease, and cystic fibrosis, involve directly testing the individual's DNA for the mutant allele.

Amniocentesis is also useful in detecting a condition known as *spina bifida,* in which the spinal cord does not close properly during development. A relatively common malformation (about 1 in 300 births), this birth defect is associated with abnormally high levels of a normally occurring protein, *α-fetoprotein,* in the amniotic fluid. Some of this protein crosses the placenta into the mother's blood, which is tested for *maternal serum α-fetoprotein (MSAFP)* as a screen for spinal cord defects. If an elevated level of MSAFP is detected, diagnostic tests, such as ultrasound imaging and amniocentesis, are performed. (Interestingly, abnormally *low* levels of MSAFP are associated with Down syndrome and other trisomies.)

One problem with amniocentesis is that most of the conditions it detects are unpreventable and incurable, and the results are generally not obtained until well into the second trimester, when terminating the pregnancy is both psychologically and medically more difficult than earlier. Therefore, tests that yield results earlier in the pregnancy have been developed. **Chorionic villus sampling (CVS)** involves removing and studying cells that will form the fetal contribution to the placenta (Fig. 15-12). CVS, which has been performed in the United States since about 1983, is associated with a slightly greater risk of infection or miscarriage than amniocentesis, but its advantage is that results are obtained earlier than in amniocentesis, usually within the first trimester.

A relatively new embryo-screening process, known as **preimplantation genetic diagnosis (PGD),** is available for couples who carry alleles for Tay-Sachs disease, hemophilia, sickle cell anemia, and dozens of other inherited genetic conditions. Conception is by in vitro fertilization (see *Focus On: Novel Origins,* in Chapter 48). The embryos are then screened for one or more genetic diseases before a physician places a healthy embryo into the woman's uterus. PGD differs from amniocentesis and CVS in that the test is performed *before* a woman is pregnant, so it eliminates the decision of whether or not to terminate the pregnancy if an embryo has a genetic abnormality. However, PGD is not as accurate as amniocentesis or CVS, and it is more expensive. Moreover, PGD is sometimes controversial, because some couples use it to choose the gender of their offspring, not to screen for genetic diseases.

Although using amniocentesis, CVS, and PGD can help physicians diagnose certain genetic disorders with a high degree of accuracy, they are not foolproof, and many disorders cannot be diagnosed at all. Therefore, the lack of an abnormal finding is no guarantee of a normal pregnancy.

Genetic screening searches for genotypes or karyotypes

Genetic screening is a systematic search through a population for individuals with a genotype or karyotype that might cause a serious genetic disease in themselves or their offspring. There are

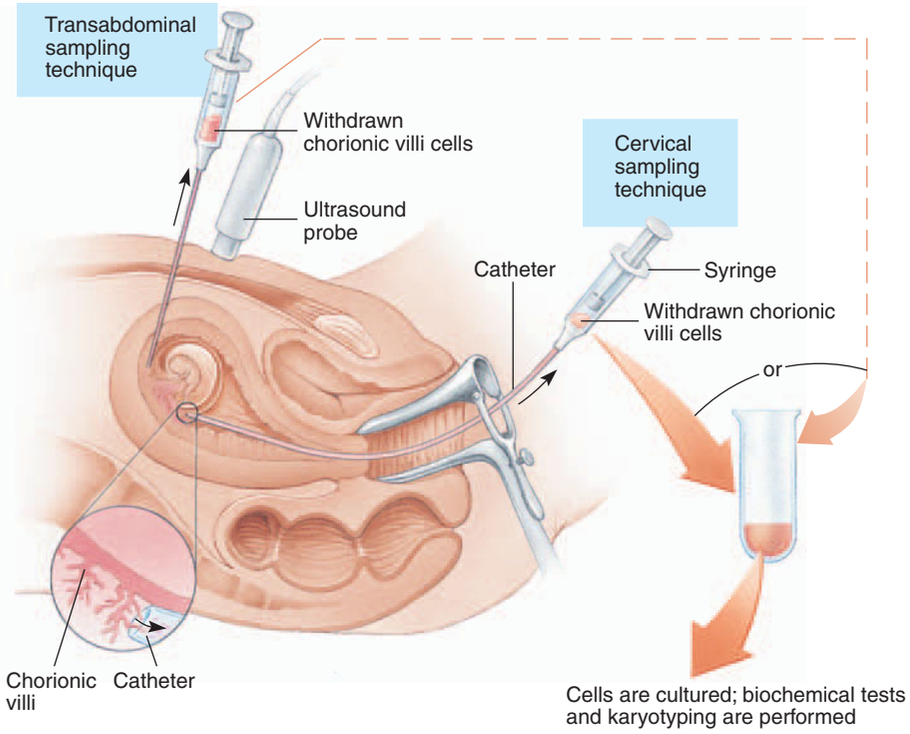


FIGURE 15-12 Chorionic villus sampling (CVS).

This test allows the early diagnosis of some genetic abnormalities. Samples may be obtained by inserting a needle through the uterine wall or the cervical opening.

two main types of genetic screening, for newborns and for adults, and each serves a different purpose. Newborns are screened primarily as the first step in preventive medicine, and adults are screened to help them make informed reproductive decisions.

Newborns are screened to detect and treat certain genetic diseases before the onset of serious symptoms. The routine screening of infants for PKU began in 1962 in Massachusetts. Laws in all 50 states of the United States, as well as in many other countries, currently require PKU screening. Sickle cell anemia is also more effectively treated with early diagnosis. Screening newborns for sickle cell anemia reduces infant mortality by about 15% because doctors can administer daily doses of antibiotics, thereby preventing bacterial infections common to newborns with the disease. The number of genetic disorders that can be screened in newborns is rapidly increasing, and many countries are trying to decide how best to implement the additional procedures.

Genetic screening of adults identifies carriers (heterozygotes) of recessive genetic disorders. If both prospective parents are heterozygous, the carriers are counseled about the risks involved in having children. Since the 1970s, about 1 million young Jewish adults in the United States, Israel, and other countries have been screened voluntarily for Tay-Sachs disease, and about 1 in 30 has been identified as a carrier. Tay-Sachs screening programs have reduced the incidence of Tay-Sachs disease by more than 90%.

Genetic counselors educate people about genetic diseases

Couples who are concerned about the risk of abnormality in their children, because they have either an abnormal child or a relative affected by a hereditary disease, may seek **genetic counseling** for medical and genetic information as well as support and guidance. Genetic clinics, available in most major metropolitan centers, are usually affiliated with medical schools.

Genetic counselors, who have received training in counseling, medicine, and human genetics, provide people with the information they need to make reproductive decisions. They offer advice, tempered with respect and sensitivity, in terms of risk estimates—that is, the *probability* that any given offspring will inherit a particular condition. The counselor uses the complete family histories of both the man and the woman, and a clinical geneticist (a doctor who specializes in genetics) may screen for the detection of heterozygous carriers of certain conditions.

When a disease involves only a single gene locus, probabilities can usually be easily calculated. For example, if one prospective parent is affected with a trait that is inherited as an autosomal dominant disorder, such as Huntington's disease, the probability that any given child will have the disease is 0.5, or 50%. The birth to phenotypically normal parents of a child affected with an autosomal recessive trait, such as albinism or PKU, establishes that both parents are heterozygous carriers, and the probability that any subsequent child will be affected is therefore 0.25, or 25%. For a disease inherited through a recessive allele on the X chromosome, such as hemophilia A, a normal woman and an affected man will have daughters who are carriers and sons who are normal. The probability that the son of a carrier mother and a normal father will be affected is 0.5, or 50%; the probability that their daughter will be a carrier is also 0.5.

It is important for identified carriers to receive appropriate genetic counseling. A genetic counselor is trained not only to provide information pertaining to reproductive decisions but also to help individuals understand their situation and avoid feeling stigmatized.

Review

- What are the relative advantages and disadvantages of amniocentesis, chorionic villus sampling, and preimplantation genetic diagnosis?
- What is the purpose of genetic screening for newborns?
- What is the purpose of genetic screening for adults?

BiologyNow™ Assess your understanding of **genetic testing and counseling** by taking the pretest on your BiologyNow CD-ROM.

HUMAN GENETICS, SOCIETY, AND ETHICS

Learning Objective

10 Discuss the controversies of genetic discrimination.

Many misconceptions exist about genetic diseases and their effects on society. Some people erroneously think of certain individuals or populations as genetically unfit and thus responsible for many of society's ills. They argue, for example, that medical treatment of people affected with genetic diseases, especially those who reproduce, increases the frequency of abnormal alleles in the population. However, such notions are incorrect. Genetic disorders are so rare that modern medical treatments will have only a negligible effect on their incidience.

Recessive mutant alleles are present in *all* individuals and *all* ethnic groups; no one is exempt. According to one estimate, each of us is heterozygous for several (3 to 15) very harmful recessive alleles, any of which could cause debilitating illness or death in the homozygous state. Why, then, are genetic diseases relatively uncommon? Each of us has many thousands of essential genes, any of which can be mutated. It is very unlikely that the abnormal alleles that one individual carries are also carried by that individual's mate. Of course, this possibility is more likely if the harmful allele is a relatively common one, such as the one responsible for cystic fibrosis.

Relatives are more likely than nonrelatives to carry the same harmful alleles, having inherited them from a common ancestor. In fact, a greater-than-normal frequency of a particular genetic disease among offspring of **consanguineous matings,** matings between genetically related individuals, is often the first clue that the mode of inheritance is autosomal recessive. The offspring of consanguineous matings have a small but significantly increased risk of genetic disease. In fact, they account for a disproportionately high percentage of those individuals in the population with autosomal recessive disorders. Because of this perceived social cost, marriages of close relatives, including first-cousins, are prohibited by about half the states in the United States. However, consanguineous marriages are still relatively common in many other countries.

Genetic discrimination provokes heated debate

One of the fastest growing areas of medical diagnostics is genetic screening and testing, and the number of new genetic tests that screen for diseases such as cystic fibrosis, sickle cell anemia, HD, colon cancer, and breast cancer increases each year. However, genetic testing raises many social, ethical, and legal issues that we as a society must address.

One of the most difficult issues is whether genetic information should be available to health insurance and life insurance companies. Many people think genetic information should not be given to insurance companies, but others, including employers, insurers, and many organizations representing people affected by genetic disorders, say such a view is unrealistic. If people use genetic tests to help them decide when to buy insurance and how much, then insurers insist they should also have access to this information. Insurers say they need access to genetic data to help calculate equitable premiums (insurance companies average risks over a large population). However, some are concerned that insurers might use the results of genetic tests to discriminate against people with genetic diseases or to deny them coverage.

Doctors argue that people at risk for a particular genetic disease might delay being tested because they fear genetic discrimination from insurers and employers. **Genetic discrimination** is discrimination against an individual or family members because of differences from the "normal" genome in that individual. The perception of genetic discrimination already exists in society. A 1996 study found that 25% of 332 people with family histories of one or more genetic disorders thought they had been refused life insurance, 22% thought they had been refused health insurance, and 13% thought they had been denied employment because of genetic discrimination. In a 1998 survey by the National Center for Genetic Resources, 63% of respondents said they probably or definitely would not take a genetic test if the results could be disclosed to either their employers or insurers.

Complicating the issue even more, genetic tests are sometimes difficult to interpret, in part because of the many complex interactions between genes and the environment. If a woman tests positive for an allele that has been linked to breast cancer, for example, she is at significant risk, but testing positive does not necessarily mean she will develop breast cancer. These uncertainties also make it hard to decide what form of medical intervention, from frequent mammograms to surgical removal of healthy breasts, is appropriate.

The Ethical, Legal, and Social Implications (ELSI) Research Program of the National Human Genome Research Institute has developed principles designed to protect people against genetic discrimination. The Health Insurance Portability and Accountability Act of 1996 provides some safeguards against genetic discrimination, and the Americans with Disabilities Act may also apply to genetic discrimination. As this book goes to press, bills that extend significant protection against workplace discrimination, health discrimination, and invasion of privacy based on genetic information are up for consideration by both federal and state legislatures. These issues will be debated for years to come.

Many ethical issues related to human genetics must be addressed

Genetic discrimination is only one example of ethical issues arising from our expanding knowledge of human genetics. Consider the following questions, all of which deal with the broad ethical issue of individual rights: What is the youngest age at which genetic testing should be permitted for adult-onset diseases, such as Huntington's disease? What are the emotional and psychological effects on individuals who are told they have tested positive for an incurable genetic disease? Should testing

be performed when some family members want testing and others do not? Should parents be able to test their minor children? Should access to genetic test data be permitted in cases of paternity or kinship testing? Should states be able to collect genetic data on their residents? Should school administrators or law enforcement agencies have access to genetic data? These questions are only a sample of the many issues that ethicists must consider, both now and in the future. As human genetics assumes an increasingly important role in society, issues of genetic privacy and the confidentiality of genetic information must be addressed.

Review

- Why is it incorrect to assume that certain individuals or populations carry most abnormal alleles found in humans?
- To be expressed, an autosomal recessive genetic disease must be homozygous. What relationship does this fact have to consanguineous matings?
- Why do health and life insurance companies want genetic information about their clients?

BiologyNow™ Assess your understanding of **human genetics, society, and ethics** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Distinguish between karyotyping and pedigree analysis.

- Studies of an individual's **karyotype,** the number and kinds of chromosomes present in the nucleus, enable researchers to identify various chromosome abnormalities.
- A **pedigree** is a "family tree" that shows the transmission of genetic traits within a family over several generations. Pedigree analysis is useful in detecting autosomal dominant mutations, autosomal recessive mutations, X-linked recessive mutations, and defects due to **genomic imprinting,** expressions of a gene based on its parental origin, within a family.

2 Discuss the implications of the Human Genome Project, including the emerging fields of bioinformatics, pharmacogenetics, and proteomics.

- **Human genetics** is the science of inherited variation in humans. The **human genome** is the total genetic information in human cells. The **Human Genome Project** sequenced all the DNA in the nuclear human genome.
- **Bioinformatics** includes the storage, retrieval, and comparison of DNA sequences within a given species and among different species.
- The Human Genome Project has given rise to the emerging field of **pharmacogenetics,** in which drugs are customized to match a patient's genetic makeup.
- **Proteomics** is the study of all the proteins encoded by the human genome and produced in a person's cells and tissues.

3 Discuss the mouse model for studying cystic fibrosis.

- The use of animal models greatly helps researchers investigate human disease. Researchers used **gene targeting** to produce strains of mice that are either homozygous or heterozygous for **cystic fibrosis.** Results from these studies may yield more effective drugs for treating the disease.

4 Explain how nondisjunction in meiosis is responsible for chromosome abnormalities such as Down syndrome, Klinefelter syndrome, and Turner syndrome.

- In **aneuploidy,** there are either missing or extra copies of certain chromosomes. Aneuploidies include **trisomy,** in which an individual possesses an extra chromosome, and **monosomy,** in which one member of a pair of chromosomes is missing.
- **Trisomy 21,** the most common form of **Down syndrome,** and **Klinefelter syndrome** (XXY) are examples of trisomy. **Turner syndrome** (X0) is an example of monosomy.
- Trisomy and monosomy are caused by meiotic **nondisjunction,** in which sister chromatids or homologous chromosomes fail to move apart properly during meiosis.

5 Distinguish among the following structural abnormalities in chromosomes: translocations, deletions, and fragile sites.

- In a **translocation,** part of one chromosome becomes attached to another. About 4% of individuals with Down syndrome have a translocation in which the long arm of chromosome 21 is attached to the long arm of one of the larger chromosomes, such as chromosome 14.
- A **deletion** can result in chromosome breaks that fail to rejoin. The deletion may range in size from a few base pairs to an entire chromosome arm. One deletion disorder in humans is **cri du chat syndrome,** in which part of the short arm of chromosome 5 is deleted.
- **Fragile sites** may occur at specific locations on both chromatids of a chromosome. In **fragile X syndrome,** a fragile site occurs near the tip on the X chromosome, where the nucleotide triplet CGG is repeated many more times than is normal. Fragile X syndrome is the most common cause of inherited mental retardation.

6 State whether each of the following genetic defects is inherited as an autosomal recessive, autosomal dominant, or X-linked recessive: phenylketonuria (PKU), sickle cell anemia, cystic fibrosis, Tay-Sachs disease, Huntington's disease, and hemophilia A.

- Most human genetic diseases that show a simple inheritance pattern are transmitted as autosomal recessive traits. An **inborn error of metabolism** is a metabolic disorder caused by the mutation of a gene that codes for an enzyme needed for a biochemical pathway.
- **Phenylketonuria (PKU)** is an autosomal recessive disorder in which toxic phenylketones damage the developing nervous system. **Sickle cell anemia** is an autosomal recessive disorder in which abnormal hemoglobin (the protein that transports oxygen in the blood) is produced.
- **Cystic fibrosis** is an autosomal recessive disorder in which abnormal secretions are produced primarily in organs of the respiratory and digestive systems. **Tay-Sachs disease** is an autosomal recessive disorder caused by abnormal lipid metabolism in the brain.
- **Huntington's disease** has an autosomal dominant inheritance pattern that results in mental and physical deterioration, usually beginning in adulthood.

SUMMARY WITH KEY TERMS *(continued)*

- **Hemophilia A** is an X-linked recessive disorder that results in a defect in a blood component required for clotting.

7 Briefly discuss the process of gene therapy, including some of its technical challenges.

- In **gene therapy,** the normal allele is cloned and the DNA introduced into certain body cells, where its expression may be sufficient to yield a normal phenotype.
- One technical challenge in gene therapy is finding a safe, effective **vector,** usually a virus, to deliver the gene of interest into the cells. Ideally, the virus should infect a high percentage of the cells and do no harm, especially over the long term.

8 State the relative advantages and disadvantages of amniocentesis, chorionic villus sampling, and preimplantation genetic diagnosis in the prenatal diagnosis of human genetic abnormalities.

- In **amniocentesis,** the amniotic fluid surrounding the fetus is sampled and the fetal cells suspended in the fluid are cultured and screened for genetic defects. Amniocentesis provides results in the second trimester of pregnancy.
- In **chorionic villus sampling (CVS),** some fetal cells are removed and studied. CVS provides results in the first trimester of pregnancy but is associated with a slightly greater risk of infection and miscarriage than amniocentesis.
- In **preimplantation genetic diagnosis (PGD),** couples conceive by in vitro fertilization. The embryos are screened for one or more genetic diseases before placing a healthy embryo into the woman's uterus. PGD is not as accurate as amniocentesis or CVS, and it is more expensive.

9 Distinguish between genetic screening programs for newborns and adults, and discuss the scope and implications of genetic counseling.

- **Genetic screening** identifies individuals who might carry a serious genetic disease. Screening of newborns is the first step in preventive medicine, and screening of adults helps them make informed reproductive decisions.
- Couples who are concerned about the risk of abnormality in their children may seek **genetic counseling.** Genetic counselors provide medical and genetic information.

10 Discuss the controversies of genetic discrimination.

- **Genetic discrimination** is discrimination against an individual or family members because of differences from the "normal" genome in that individual.
- One of the most difficult issues in avoiding genetic discrimination is whether genetic information should be available to employers and to health and life insurance companies. Physicians are concerned that people at risk for a particular genetic disease might delay being tested because they fear genetic discrimination from insurers and employers.
- As human genetics assumes an increasingly important role in human society, issues of genetic privacy and the confidentiality of genetic information must be addressed.

POST-TEST

1. The most important tool in bioinformatics is (a) controlled matings (b) karyotyping (c) pedigree analysis (d) a computer (e) chorionic villus sampling
2. A diagram of a pedigree shows (a) controlled matings between members of different true-breeding strains (b) the total genetic information in human cells (c) a comparison of DNA sequences among genomes of humans and other species (d) the subtle genetic differences among unrelated people (e) the expression of genetic traits in the members of two or more generations of a family
3. The Human Genome Project (a) sequenced all the DNA in the nuclear human genome (b) was exclusively concerned with the comparisons of DNA sequences between human DNA and DNA of other species (c) customized drugs to match an individual's genetic makeup (d) searched for individuals with a genotype that might cause a serious genetic disease in them or their offspring (e) provided risk estimates on human genetic diseases
4. An abnormality in which there is one more or one fewer than the normal number of chromosomes is called a(an) (a) karyotype (b) fragile site (c) aneuploidy (d) trisomy (e) translocation
5. An individual with one extra chromosome (three of one kind) is said to be (a) monosomic (b) triploid (c) trisomic (d) consanguineous (e) true-breeding
6. An individual who is missing one chromosome, having only one member of a given pair, is said to be (a) monosomic (b) haploid (c) trisomic (d) consanguineous (e) true-breeding
7. The failure of chromosomes to separate normally during cell division is called (a) a fragile site (b) an inborn error of metabolism (c) a satellite knob (d) a translocation (e) nondisjunction
8. The transfer of a part of one chromosome to a nonhomologous chromosome is called a(an) (a) karyotype (b) inborn error of metabolism (c) pedigree (d) translocation (e) nondisjunction
9. A photomicrograph of the stained metaphase chromosomes present in a given cell is called a (a) karyotype (b) nucleotide triplet repeat (c) pedigree (d) DNA microarray (e) translocation
10. Individuals with trisomy 21, or _____, are mentally and physically retarded and have abnormalities of the face, tongue, and eyelids. (a) Down syndrome (b) Klinefelter syndrome (c) Turner syndrome (d) Huntington's disease (e) Tay-Sachs disease
11. An inherited disorder caused by a defective or absent enzyme is called a(an) (a) karyotype (b) trisomy (c) reciprocal translocation (d) inborn error of metabolism (e) aneuploidy
12. In _____, a genetic mutation codes for an abnormal hemoglobin molecule that is less soluble than usual and more likely than normal to deform the shape of the red blood cell. (a) Down syndrome (b) Tay-Sachs disease (c) sickle cell anemia (d) PKU (e) hemophilia A
13. In an individual with _____, the mucus is abnormally viscous and tends to plug the ducts of the pancreas and liver and to accumulate in the lungs. (a) Down syndrome (b) Tay-Sachs disease (c) sickle cell anemia (d) PKU (e) cystic fibrosis

POST-TEST *(continued)*

14. During this procedure, a sample of the fluid that surrounds the fetus is obtained by inserting a needle through the walls of the abdomen and uterus. (a) DNA marker (b) chorionic villus sampling (c) ultrasound imaging (d) preimplantation genetic diagnosis (e) amniocentesis
15. For which of the following situations would a genetic counselor *not* recommend prenatal diagnosis involving amniocentesis or chorionic villus sampling? (a) an increased risk of a chromosomal abnormality (b) an increased risk of a single-locus (Mendelian) disease (c) an increased risk of a spinal cord defect (d) a desire to know the sex of the fetus (e) a pregnant woman is older than 35
16. A DNA microarray (a) represents the totality of genetic information in human cells (b) can compare the activities of thousands of genes in normal and diseased cells (c) is the study of the role of chromosomes in inheritance (d) is the chromosome composition of an individual (e) charts the transmission of genetic traits within a family
17. Examine the following pedigrees, and decide whether each disorder is most likely inherited by an autosomal recessive, an autosomal dominant, or an X-linked recessive allele. Determine the probable genotypes for all individuals shown.

(a)  (b)  (c) 
18. Complete the table by checking the correct box for each genetic disorder.

Disease	Chromosome Abnormality	Autosomal Recessive	Autosomal Dominant	X-Linked Recessive
Down syndrome				
Tay-Sachs disease				
Phenylketonuria				
Hemophilia A				
Sickle cell anemia				
Turner syndrome				
Huntington's disease				
Klinefelter syndrome				
Cri du chat syndrome				
Fragile X syndrome				

CRITICAL THINKING

1. Imagine you're a genetic counselor. What advice or suggestions might you give in the following situations?
   a. A couple has come for advice because the woman had a sister who died of Tay-Sachs disease.
   b. A young man and woman who are not related are engaged to be married. However, they have learned that the man's parents are first cousins. They are worried about the possibility of increased risk of genetic defects in their own children.
   c. A young woman's paternal uncle (her father's brother) has hemophilia A. Her father is free of the disease, and there has never been a case of hemophilia A in her mother's family. Should she be concerned about the possibility of hemophilia A in her own children?
   d. A 20-year-old man is seeking counseling because his father was recently diagnosed with Huntington's disease.
2. A common belief about human genetics is that an individual's genes alone determine his or her destiny. Explain why this is a misconception.

Genes and Development

Image not available due to copyright restrictions

CHAPTER OUTLINE

- Cell Differentiation and Nuclear Equivalence
- The Genetic Control of Development
- Cancer and Cell Development

The study of **development,** which is broadly defined as all the changes that occur in the life of an individual, encompasses some of the most fascinating and difficult problems in biology today. Of particular interest is the process by which cells specialize and organize into a complex organism. During the many cell divisions required for a single cell to develop into a multicellular organism, groups of cells become gradually committed to specific patterns of gene activity through the process of **cell determination.** The final step leading to cell specialization is **cell differentiation.** A differentiated cell has a characteristic appearance and characteristic activities.

An even more intriguing part of the developmental puzzle is the building of the body. In **morphogenesis,** the development of form, cells in specific locations differentiate and become spatially organized into recognizable structures. Morphogenesis proceeds through the multistep process of **pattern formation,** which includes signaling between cells, changes in cell shape, and cell migrations.

Until the late 1970s, biologists knew little about how genes interact with signals from within the organism and from the environment to control development. Although certain genes affecting developmental pathways had been identified, their specific functions in the organism were not well understood. Unraveling genetic interactions that take place during development was an intractable problem using traditional methods. However, rapid progress in recombinant DNA technology led scientists to search for developmental mutants and to apply the most sophisticated techniques to study them.

Today scientists interested in development study a variety of genetic mutants of model organisms with altered developmental patterns. They use the tools of genetic engineering, combined with more conventional descriptive and experimental approaches, to derive fresh insights about the role of genetic information in the control of development. The organism in the photograph is a developing embryo of the fruit fly *Drosophila melanogaster.* Geneticists used the technique of **immunofluorescence,** in which a fluorescent dye is joined to an anti-

body that binds to a specific protein, enabling the protein to be localized. In this case researchers bound three different antibodies—one red, one blue, and one yellow—to three specific proteins. The patterns of colored bands indicate that different cells of the embryo have differential gene expression—that is, different genes active at the same time in development.

Drosophila has many attributes that make it unusually attractive for developmental studies. Work with *Drosophila* has profound implications for understanding both normal human development and the kinds of malfunctions that can lead to birth defects and even "normal" aging. Although fruit flies may seem to have little in common with humans, scientists are learning that many genes important in development are quite similar in a wide range of organisms. These similarities have led to new ways of unraveling evolutionary relationships, through the study of developmentally important genetic mechanisms that appear deeply rooted in the evolutionary history of multicellular organisms.

New model organisms, each with characteristics that uniquely suit it for developmental studies, are being added to the list of well-characterized experimental systems. Biologists are now learning how genes are activated, inactivated, and modified to control development. These activities involve the interaction of batteries of master **regulatory genes,** which turn the transcription of other genes on or off. Eventually scientists expect to understand not only how differentiation and morphogenesis are controlled but also how the basic control systems have evolved. The identification of certain features common to many organisms, such as homeobox genes (discussed in the chapter), makes the task easier, but the work has just begun. Many interactions remain to be explored, and many stunning surprises await us. ■

CELL DIFFERENTIATION AND NUCLEAR EQUIVALENCE

Learning Objectives

1. Distinguish between cell determination and cell differentiation, and between nuclear equivalence and totipotency.
2. Define *stem cells,* and describe some of the promising areas of research involving stem cells.
3. Point out some of the known exceptions to the general principle of nuclear equivalence.

The human body, like that of other vertebrates, contains more than 200 recognizably different types of cells (Fig. 16-1). Combinations of these specialized cells, known as **differentiated cells,** are organized into diverse and complex structures—such as the eye, hand, and brain—each capable of carrying out many sophisticated activities. Most remarkable of all is the fact that all the structures of the body and the different cells within them descend from a single **zygote,** a fertilized egg.

All multicellular organisms undergo complex patterns of development. The root cells of plants, for example, have structures and functions very different from those of the various types of cells located in leaves. Diversity is also found at the molecular level; most strikingly, each type of plant or animal cell makes a highly specific set of proteins. In some cases, such as the protein hemoglobin in red blood cells, one cell-specific protein may make up more than 90% of the cell's total mass of protein. Other cells may have a complement of cell-specific proteins, each of which is present in small amounts but still plays an essential role. However, because certain proteins are required in every type of cell (all cells, for example, require the same enzymes for glycolysis), cell-specific proteins usually make up only a fraction of the total number of different kinds of proteins.

When researchers first discovered that each type of differentiated cell makes a unique set of proteins, some scientists hypothesized that each group of cells loses the genes it does not need and retains only those required. However, this does not generally seem true. According to the principle of **nuclear equivalence,** the nuclei of essentially all differentiated adult cells of an individual are genetically (though not necessarily metabolically) identical to each other and to the nucleus of the zygote from which they descended. This means that virtually all somatic cells in an adult have the same genes. However, different cells express different subsets of these genes. **Somatic cells** are all the cells of the body other than **germ line cells,** which ultimately give rise to a new generation. In animals, germ line cells—whose descendants ultimately undergo meiosis and differentiate into gametes—are generally set aside early in development. In plants, the difference between somatic cells and germ line cells is not as distinct, and the determination that certain cells undergo meiosis is made much later in development.

The evidence for nuclear equivalence comes from cases in which differentiated cells or their nuclei have been found to retain the potential of directing the development of the entire organism. Such cells or nuclei are said to exhibit **totipotency.**

A totipotent nucleus contains all the instructions for development

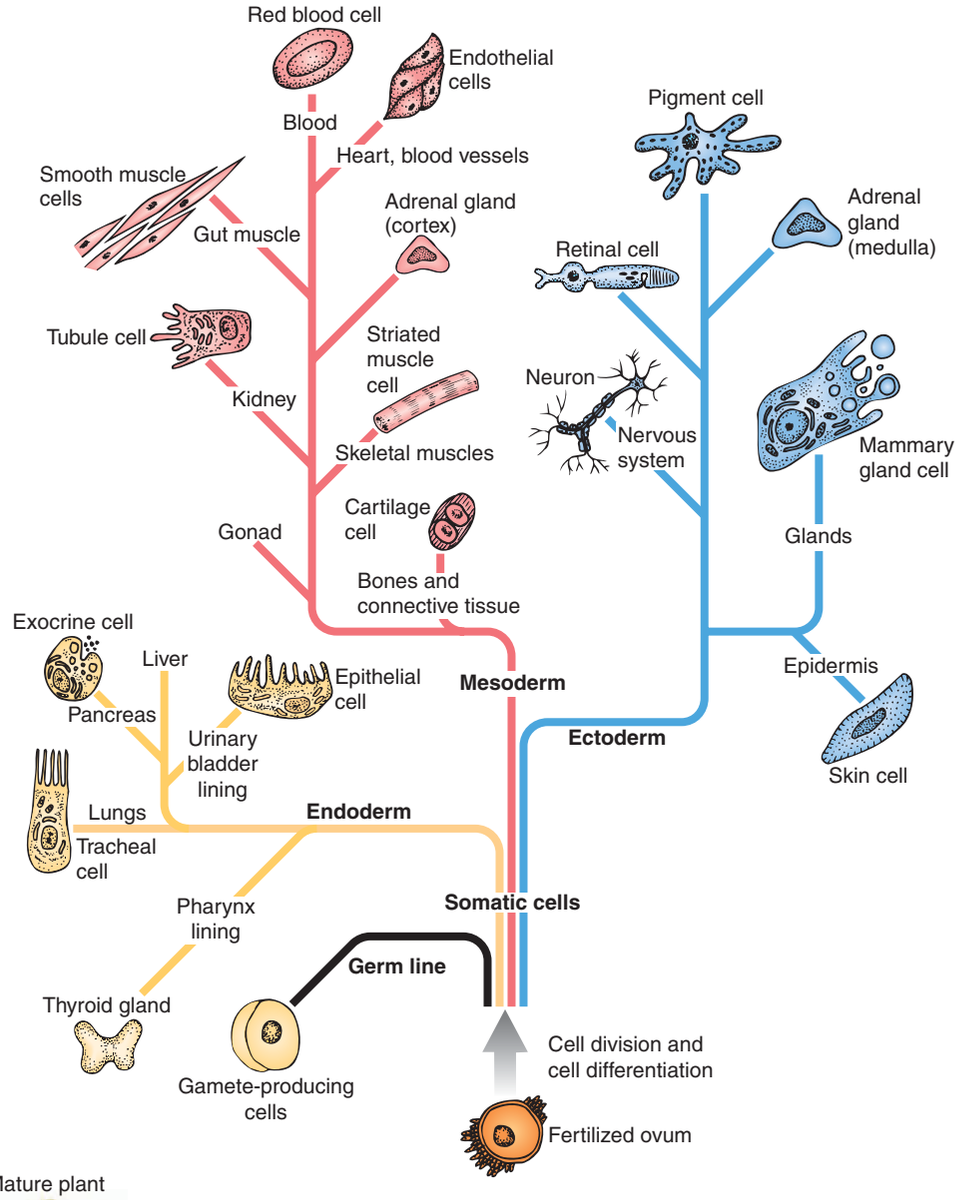
PROCESS OF SCIENCE

In plants, at least some differentiated cells can be induced to become the equivalent of embryonic cells. Biologists use *tissue culture techniques* to isolate individual cells from certain plants and to allow them to grow in a nutrient medium.

In the 1950s F.C. Steward and his coworkers at Cornell University conducted some of the first experiments investigating cell totipotency in plants (Fig. 16-2). They induced root cells from a carrot to divide in a liquid nutrient medium, forming groups of cells called *embryoid* (embryo-like) *bodies.* These clumps of dividing cells were then transferred to an agar medium, which provided nutrients and a solid supporting structure for the developing plant cells. Some of the cells of the embryoid bodies gave rise to roots, stems, and leaves. The resulting small plants, called *plantlets* to distinguish them from true seedlings,

FIGURE **16-1** **Vertebrate cell lineages.**

Repeated divisions of the zygote *(bottom of figure)* result in the establishment of tissues containing groups of specialized cells. Germ line cells (cells that produce the gametes) are set aside early in development. Somatic cells progress along various developmental pathways, undergoing a series of commitments that progressively determine their fates.



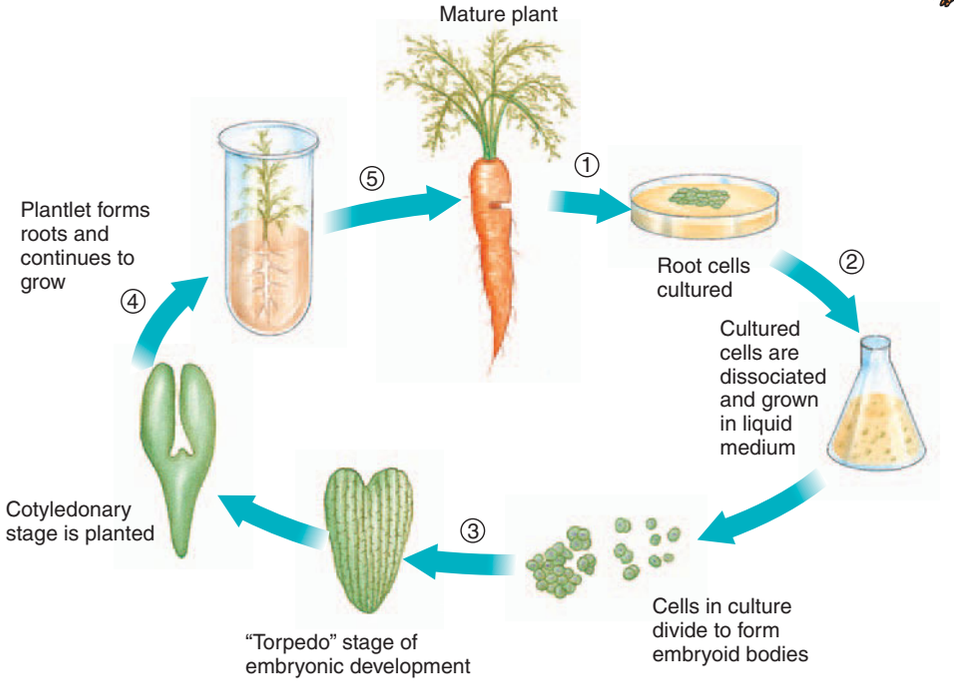


FIGURE **16-2** **Cell totipotency.**

Using tissue culture techniques, researchers developed a complete carrot plant from differentiated somatic cells. ① Carrot root tissues are cut into discs. ② When cultured in a liquid nutrient medium, they divide to form clumps of undifferentiated cells, known as embryoid bodies. ③ The embryoid bodies, which closely resemble plant embryos in their early stages of development, form embryonic shoots and roots. ④ Transferring the embryonic tissue to a solid nutrient medium stimulates the tissues to form small plantlets, which ⑤ develop into mature plants.

were then transplanted to soil, where they ultimately developed into adult plants capable of producing flowers and viable seeds. If these plants are all derived from the same parent plant, they are essentially genetically alike and therefore constitute a **clone.** The methods of plant tissue culture are now extensively used to produce genetically engineered plants, because they enable researchers to regenerate whole plants from individual cells that have incorporated recombinant DNA molecules (see Chapter 36, *Focus On: Cell and Tissue Culture*).

Similar experiments have been attempted with animal cells, but thus far researchers have not been able to induce a fully differentiated somatic cell to behave like a zygote. Instead, they have tested whether steps in the process of determination are reversible by transplanting the *nucleus* of a cell in a relatively late stage of development into an egg cell that has been *enucleated* (that is, its own nucleus has been destroyed).

In the 1950s Robert Briggs and Thomas J. King of the Institute for Cancer Research in Pennsylvania pioneered *nuclear transplantation experiments.* They transplanted nuclei from frog cells at different stages of development into egg cells whose nuclei had been removed. Some of the transplants proceeded normally through several developmental stages, and a few even developed into normal tadpoles. As a rule, the nuclei transplanted from cells at earlier stages were most likely to support development to the tadpole stage. As the fate of the cells became more and more determined, the probability quickly declined that a transplanted nucleus could control normal development.

British biologist John Gurdon carried out experiments on nuclear transplantation in frogs during the 1960s. In a few cases he demonstrated that nuclei isolated from the intestinal epithelial cells of a tadpole directed development up to the tadpole stage (Fig. 16-3). This occurred infrequently (about 1.5% of the time); however, in these kinds of experiments success counts more than failure. Therefore, he could safely conclude that at least some nuclei of differentiated animal cells are in fact totipotent.

For many years these successes with frogs could not be repeated with mammalian embryos, leading many developmental biologists to conclude that some fundamental feature of mammalian reproductive biology might be an impenetrable barrier to mammalian cloning. This perception changed markedly in 1996 and 1997 with the first reports of the birth of cloned mammals.

The first cloned mammal was a sheep

PROCESS OF SCIENCE

In 1996, Ian Wilmut and his coworkers at the Roslin Institute in Edinburgh, Scotland, reported that they had succeeded in cloning sheep, using nuclei from early sheep embryos (the blastocyst stage; see Chapter 49). These scientists received worldwide attention in early 1997 when they announced the birth of a lamb, named Dolly (after the singer Dolly Parton). Dolly's genetic material was derived from a cultured mammary gland

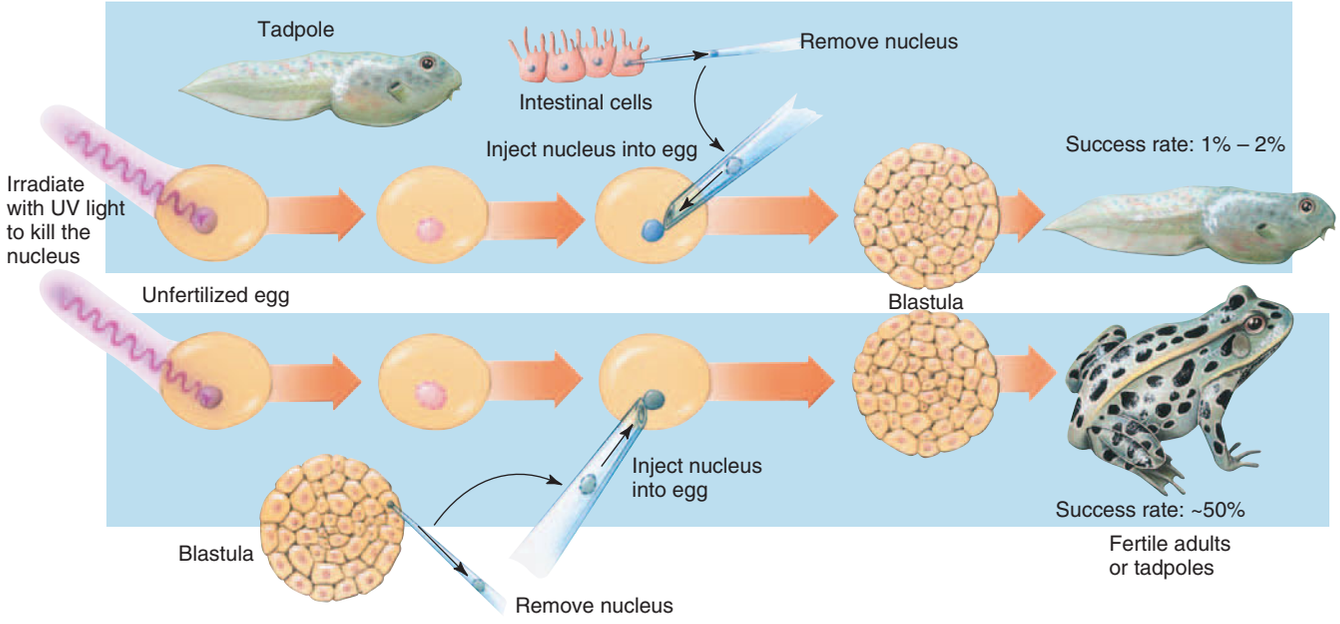

FIGURE **16-3** **Nuclear totipotency.**

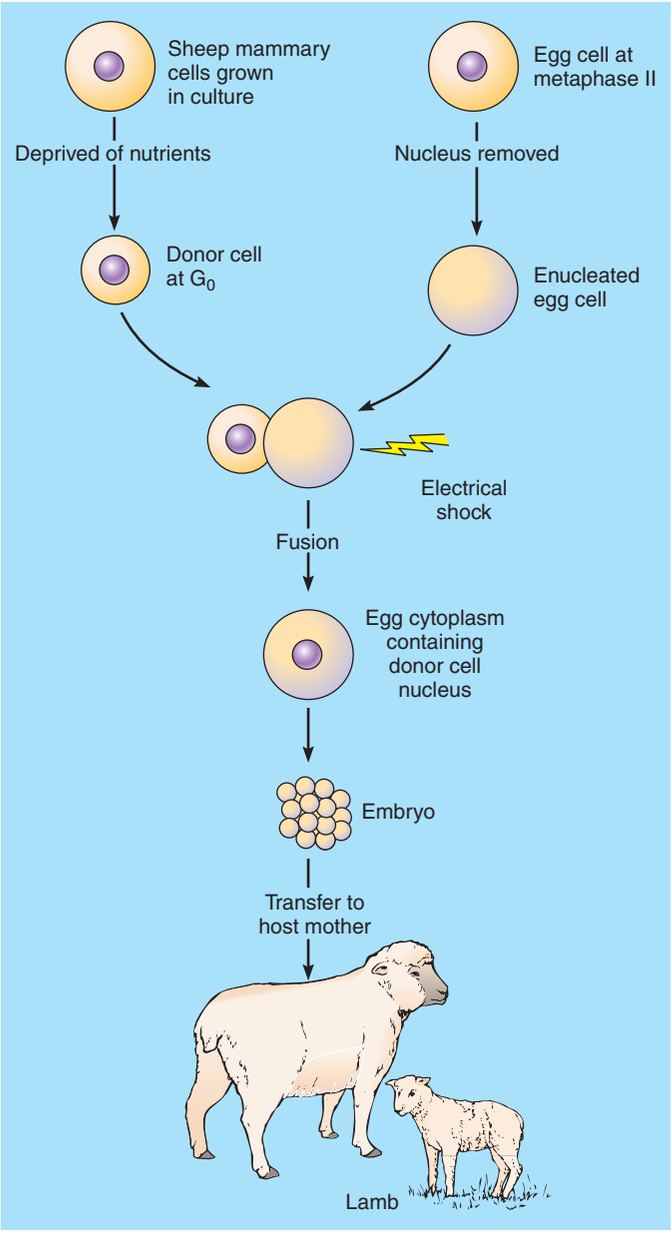
In nuclear transplantation experiments conducted during the 1960s on frogs, biologists injected the nuclei of differentiated cells at different stages of development into eggs whose own nuclei were destroyed by ultraviolet radiation. *Upper panel:* Using nuclei from tadpole intestinal cells (a relatively late developmental stage), normal development proceeded to the tadpole stage in a small number (1% to 2%) of trials. This result indicated that the genes for programming development up to that point were still present and appropriately activated. *Lower panel:* When researchers used nuclei from earlier developmental stages, the success rate improved dramatically. With a nucleus from a blastula (a ball of about 1000 cells), in about half the cases the transplanted nucleus could successfully program normal development to form a tadpole or fertile adult.



ACTIVE FIGURE **16-4** **Mammalian cloning.**

An embryo produced by fusing a cultured adult sheep mammary cell with an enucleated sheep's egg is implanted into the uterus of a host mother. The embryo develops into a lamb.

BiologyNow™ Learn more about **sheep cloning** by clicking on this figure on your BiologyNow CD-ROM.

cell, from an adult sheep, that was fused with an enucleated sheep's egg. The resulting cell divided and developed into an embryo that was then cultured in vitro until it reached a stage at which it could be transferred to a host mother (Fig. 16-4). Not surprisingly, the overall success rate was low: Out of 277 fused cells, only 29 developed into embryos that could be transferred, and Dolly was the only live lamb produced. These researchers have also produced cloned lambs derived from fetal cells.

Why did Wilmut's team succeed when so many other researchers had failed? Applying the basic principles of cell biology, they recognized that the **cell cycles** of the egg cytoplasm and the donor nucleus were not synchronous. The egg cell is arrested at metaphase II of meiosis, whereas the actively growing donor somatic cell is usually in the DNA synthesis phase (S), or in G_2. By withholding certain nutrients from the mammary gland cells used as donors, they cause these cells to enter a nondividing state referred to as G_0 (see Chapter 9). This had the effect of synchronizing the cell cycles of the donor nucleus and the egg. They then used an electrical shock to fuse the donor cell with the egg and initiate embryo development.

Although an extremely high level of technical expertise is required, these and other researchers have modified and extended these techniques to produce cloned calves, goats, pigs, and mice. The list of mammals successfully cloned will likely continue to grow. However, the success rate for each set of trials continues to be low, around 1% to 2%, and the incidence of genetic defects is high. Dolly was euthanized at age 6 because she was suffering from a virus-induced lung cancer that infected several sheep where she was housed. However, she developed arthritis at $5\frac{1}{2}$ years, which is relatively young for a sheep to have this degenerative disease. Some biologists speculate that using adult genetic material to produce a clone might produce an animal with prematurely old cells (see discussion of telomeres and cell aging in Chapter 11). Further research may provide some answers to this potential problem.

The production of **transgenic organisms,** in which foreign genes have been incorporated, continues to be the main focus of cloning research (see Chapter 14). Researchers are actively pursuing new techniques to improve the efficiency of the cloning process. Only then will it be possible to produce large numbers of cloned transgenic animals for a variety of uses, such as increasing the populations of endangered species. For example, the first healthy clone of an endangered species, a wild relative of cattle known as a *banteng,* was born in 2003. The nucleus for this clone came from a frozen skin cell of a banteng that died in 1980 at the San Diego Zoo.

Cloning research continues to fuel an ongoing debate regarding the potential for human cloning and its ethical implications. In the United States, the National Bioethics Advisory Commission has been established to study this and other questions. In considering these issues, it is important to recognize that *cloning* is a broad term that includes several different processes involved in producing biological cells, tissues, organs, or organisms. **Human reproductive cloning** has the goal of making a newborn human that is genetically identical to another, usually adult, human. It would involve placing a human embryo produced by a process other than fertilization into a woman's body. Many countries are opposed to human reproductive cloning.

In contrast, **human therapeutic cloning** involves duplication of human cells for scientific study or medical purposes; no newborn human is formed. In human therapeutic cloning, scientists would take the nucleus from—for example, a skin cell—and place it in an enucleated egg cell, which would then be treated to develop into an embryo. *Stem cells* could be extracted

from the embryo to provide a supply of replacement tissues for revolutionary medical procedures.

Stem cells divide and give rise to differentiated cells

Stem cells are undifferentiated cells that can divide to produce differentiated descendants, yet retain the ability to divide to reproduce themselves, thereby maintaining the stem cell population. The most versatile stem cells are totipotent and have the potential to give rise to all tissues of the body. Other stem cells, known as **pluripotent stem cells,** appear more specialized; they can give rise to many, but not all, of the types of cells in an organism. For example, neural stem cells are pluripotent and differentiate to form all types of brain cells, and stem cells in the bone marrow form various types of blood cells. However, recent studies have shown that even specialized stem cells may be more versatile than once thought. For example, neural stem cells form blood cells when transplanted into bone marrow, and bone marrow stem cells can differentiate into muscle cells.

Stem cells are potential sources for cell transplantation into patients to treat serious degenerative conditions. For example, Parkinson's disease results from a progressive loss of cells that produce the neurotransmitter dopamine in a specific region of the brain. Transplantation of stem cells that have been induced to differentiate as dopamine-producing cells holds great promise as an effective long-term treatment. Similarly, stem cells may become a source of insulin-producing cells for transplantation into the pancreas of individuals with diabetes mellitus. Stem cells might also provide replacement nerve cells in people with spinal cord injury or other types of neurological damage.

Researchers ultimately hope to establish lines of human pluripotent stem cells that can grow indefinitely in culture, be induced to differentiate under controlled conditions and stably maintain their differentiated state, and be manipulated genetically. They particularly want to develop embryonic stem cell lines from patients with cancer, diabetes, cardiovascular disease, and neurogenerative disorders (such as Parkinson's disease); such cell lines would be invaluable in research on these disorders. Although work on stem cells in mice and other mammals has been conducted for many years, similar studies in humans have progressed slowly, despite the great promise of stem cells as a therapeutic tool.

Private companies currently fund these studies, largely because of government restrictions on public funding due to ethical considerations related to the origins of stem cells. Thus far, the only known source of totipotent stem cells is early human embryos left over from **in vitro fertilization** (see Chapter 48). Fetal tissues are also a source of some types of specialized stem cells. For example, pluripotent blood stem cells can be obtained from a newborn's umbilical cord. More recent findings that certain types of specialized stem cells are also present in tissues of adult mice, as well as human adults and children, may alleviate some ethical concerns. Unfortunately, these cells are rare and lack many of the advantages of embryonic stem cells.

Most cell differences are due to differential gene expression

Because genes do not seem to be lost regularly during development (and thus nuclear equivalence is present in different cell types), differences in the molecular composition of cells must be regulated by the activities of different genes. The process of developmental gene regulation is often referred to as **differential gene expression.** As discussed in Chapter 13, the expression of eukaryotic genes is regulated in many different ways and at many levels. For example, a particular enzyme may be produced in an inactive form and then be activated later. However, much of the regulation that is important in development occurs at the transcriptional level. The transcription of certain sets of genes is repressed, whereas that of other sets is activated. Even the expression of genes that are *constitutive*—that is, constantly transcribed—is regulated during development so that the *quantity* of each product varies from one tissue type to another.

We can think of differentiation as a series of pathways leading from a single cell to cells in each of the different specialized tissues, arranged in an appropriate pattern. At times a cell makes genetic commitments to the developmental path its descendants will follow. These commitments gradually restrict the development of the descendants to a limited set of final tissue types. Determination, then, is a progressive fixation of the fate of a cell's descendants.

As the development of a cell becomes determined along a differentiation pathway, its physical appearance may not change significantly. Nevertheless, when a stage of determination is complete, the changes in the cell usually become self-perpetuating and are not easily reversed. Cell differentiation is usually the last stage in the developmental process. At this stage, a precursor cell becomes structurally and functionally recognizable as a bone cell, for example, and its pattern of gene activity differs from that of a nerve cell, or any other cell type.

DNA microarrays track gene expression

PROCESS OF SCIENCE

The science of determining the roles of genes in cells, or **functional genomics,** includes the analysis of patterns of gene expression in different cell types. One approach is the use of **DNA microarrays,** a powerful tool for research as well as for diagnosing and treating human diseases (see Fig. 15-3). Thousands of tiny spots of DNA, known as *microdots,* are spotted on a chip, which is usually a glass microscope slide. Each microdot contains many single-stranded copies of a fragment of DNA from a particular tissue, and collectively all the microdots on a chip are a microarray that contains representative segments of all or most of the DNA in that organism's genome.

The researchers then extract RNA from cells they wish to study, and they synthesize DNA complementary to it (cDNA) using *reverse transcriptase* (see Chapter 14). The single-stranded cDNA molecules are tagged with a fluorescent dye and incubated with the DNA on the chip under conditions that promote complementary base pairing. If a particular segment of DNA on the microarray corresponds to a gene that was actively tran-

scribed in the cells being studied, the corresponding cDNA molecules bind to that microdot, causing it to fluoresce very brightly. Conversely, a microdot that fluoresces dimly or not at all is one that contains DNA that was not actively transcribed in those cells. Instruments that detect the fluorescence patterns then scan the microarrays, and computers analyze the data. These methods allow researchers to compare patterns of gene expression, as measured by RNA synthesis, in various cell types, or in the same cell type under different conditions.

Some exceptions to the principle of nuclear equivalence have been found

Although the principle of nuclear equivalence applies to most cells in multicellular organisms, certain types of developmental regulation can involve physical changes in DNA. Such changes in the structure of the genome are not common. Exceptions to nuclear equivalence include genomic rearrangements and gene amplification.

The activity of some genes may be modified during development by different types of **genomic rearrangements** that lead to actual physical changes in the structure of the gene. In some cases, parts of genes are rearranged to make new coding sequences. Genomic rearrangement is an important mechanism for the development of the immune system. Cells of the immune system rearrange their genetic elements into functional genes that encode a diversity of antibodies (see Chapter 43). Genomic rearrangement of the several hundred known genetic elements has the potential to produce more than 200 million different antibody molecules!

Some gene products are required in such large quantities during development that a single copy of a gene cannot be transcribed, nor can its mRNA be translated, rapidly enough to meet the needs of the developing cells. In some cases, the number of gene copies may be increased, through a process known as **gene amplification,** to meet the demand. For example, the *Drosophila* chorion (eggshell) gene product is a protein made specifically in cells of the female insect's reproductive tract. These cells make massive amounts of the protein that envelops and protects the zygote. Amplifying the chorion protein gene by DNA replication meets the demand for chorion mRNA. In other words, the DNA in that small region of the chromosome is copied many times (Fig. 16-5). In other cells of the insect body, however, the gene appears to exist as a single copy in the chromosome.

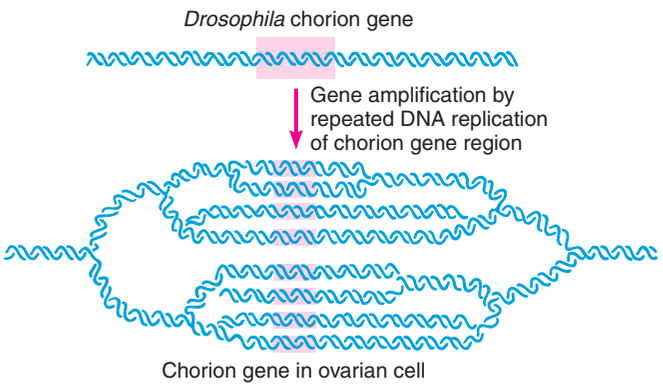


FIGURE **16-5** **Gene amplification.**

In *Drosophila,* multiple replications of a small region of the chromosome amplify the chorion (eggshell) protein genes. Replication is initiated at a discrete chromosome origin of replication *(pink box)* for each copy of the gene that is produced. Replication is randomly terminated, resulting in a series of forked structures in the chromosome.

Review

- What lines of evidence support the principle of nuclear equivalence?
- Why was Wilmut's team successful in mammalian cloning where others had failed?
- What are stem cells?
- Under what conditions do cells use gene amplification?

THE GENETIC CONTROL OF DEVELOPMENT

Learning Objectives

4 Indicate the features of *Drosophila melanogaster, Caenorhabditis elegans, Mus musculus,* and *Arabidopsis thaliana* that have made these organisms valuable models in developmental genetics.

5 Distinguish among maternal effect genes, segmentation genes, and homeotic genes in *Drosophila.*

6 Explain the relationship between transcription factors and genes that control development.

7 Define *induction* and *apoptosis,* and give examples of the roles they play in development.

Development has been an important area of research for many years, and researchers have spent considerable time studying the development of invertebrate and vertebrate animals. By investigating patterns of morphogenesis in different species, researchers have identified similarities, as well as differences, in the basic plan of development from a zygote to an adult in organisms ranging from the sea urchin to mammals (see Chapter 49).

In addition to descriptive studies, many classic experiments have demonstrated how groups of cells differentiate and undergo pattern formation. Researchers have developed elaborate screening programs to detect mutations that let them identify many developmental genes in both plants and animals. They then exploit molecular genetic techniques and other sophisticated methodologies to determine how those genes work and how they interact to coordinate developmental processes.

In studies of the genetic control of development, the choice of organism to use as an experimental model is important. One of the most powerful approaches involves isolating mutants with arrested or abnormal development at a particular stage. Not all organisms have useful characteristics that allow research-

ers to isolate and maintain developmental mutants for future study. Geneticists so thoroughly understand the genetics of the fruit fly, *Drosophila melanogaster,* that this organism has become one of the most important systems for such studies. Other organisms—the nematode worm, *Caenorhabditis elegans;* the laboratory mouse, *Mus musculus;* certain plants, including *Arabidopsis thaliana,* a tiny weed with many convenient features; and some simple eukaryotes, such as the yeast *Saccharomyces cerevisiae*—have also become important models in developmental genetics. Each of these organisms has attributes that make it particularly useful for examining certain aspects of development.

The maternal genome controls early development in *Drosophila melanogaster*

Undoubtedly the most extensive and spectacular examples of genes that control development have been identified in the fruit fly *Drosophila.* The *Drosophila* genome sequence, which was completed in late 1999, includes about 13,600 protein-coding genes. One of the traditional advantages of *Drosophila* as a research organism is the abundance of mutant alleles, including those of developmental genes, available for study and the relative ease with which a new mutation is mapped on the chromosomes.

Genetic analysis in *Drosophila* is greatly facilitated by **polytene chromosomes,** found in certain fly larval tissues with large, metabolically active cells, including the salivary glands. Polytene ("many-stranded") chromosomes are formed when the DNA replicates many times but without mitosis and cytokinesis. A typical polytene chromosome may consist of more than 1000 DNA double helices (along with associated histones and other proteins) aligned side by side. Polytene chromosomes are therefore quite large and show a pattern of bands that is very useful in assigning a particular gene to a specific locus on the chromosome. When a gene is active, the chromosome band in which it resides uncoils and forms a "puff," a site of intense RNA synthesis.

Studies of *Drosophila* are also facilitated by the fact that foreign DNA injected into eggs becomes incorporated into the fly's DNA. This process is called **transformation,** analogous to transformation in prokaryotes.

The Drosophila *life cycle includes egg, larval, pupal, and adult stages*

Development in *Drosophila* consists of several distinct stages (Fig. 16-6). After the egg is fertilized, a period of embryogenesis occurs during which the zygote develops into a sexually immature form known as a **larva** (pl., *larvae*). After hatching from the egg, each larva undergoes several molts (shedding of the external covering or cuticle). Each molt results in a size increase until the larva is ready to become a **pupa.** Pupation involves a molt and the hardening of the new external cuticle, so that the pupa is completely encased. The insect then undergoes **metamorphosis,** a complete change in form. During that time, most of the larval tissues degenerate and other tissues differentiate to form the body parts of the sexually mature adult fly.

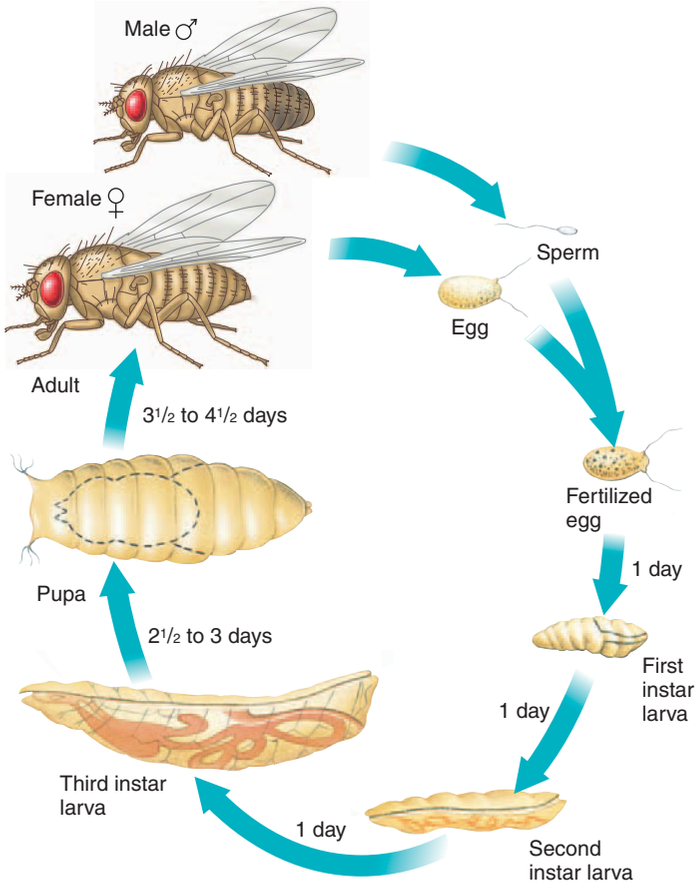

FIGURE **16-6** **The life cycle of *Drosophila*.**

As it develops from a fertilized egg to a sexually mature adult fly, a fruit fly passes through several stages. It takes about 12 days, at 25°C, to complete the life cycle. A juvenile form (larva) hatches from the egg and undergoes a series of molts as it grows. The periods between molts are called instars. The dotted lines within the pupa represent the animal undergoing metamorphosis.

The larvae are wormlike in appearance and look nothing like the adult flies. However, very early in embryogenesis of the developing larvae, precursor cells of many of the adult structures are organized as relatively undifferentiated, paired structures called **imaginal discs.** The name comes from *imago,* the adult form of the insect. Each imaginal disc occupies a definite position in the larva and will form a specific structure, such as a wing or a leg, in the adult body (Fig. 16-7). The discs are formed by the time embryogenesis is complete and the larva is ready to begin feeding. In some respects the larva is a developmental stage that feeds and nurtures the precursor cells that give rise to the adult fly, which is the only form that reproduces.

The organization of the precursors of the adult structures, including the imaginal discs, is under genetic control. Thus far, more than 50 genes have been identified that specify the formation of the imaginal discs, their positions within the larva, and their ultimate functions within the adult fly. Those genes were identified through mutations that either prevent certain discs from forming or alter their structure or ultimate fate.

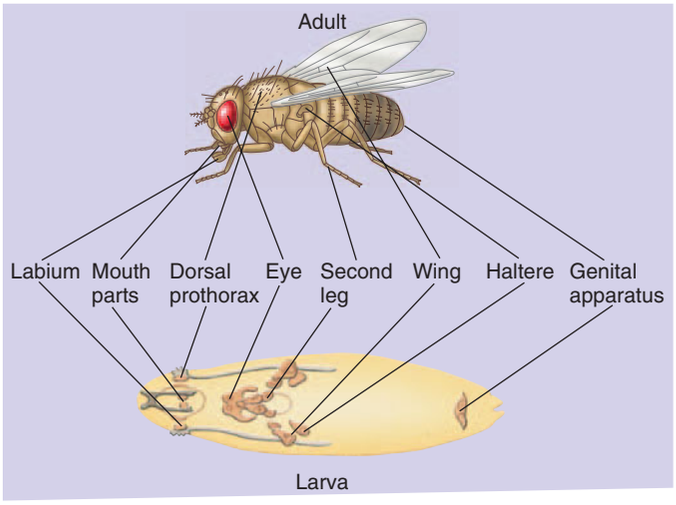

FIGURE **16-7** **The location of imaginal discs.**

Each pair of discs in a *Drosophila* larva *(bottom)* develops into a specific pair of structures in the adult fly.

Drosophila *developmental mutations affect the body plan*

Many developmental mutations have been identified in *Drosophila.* Researchers have examined their effects on development in various combinations and have studied them extensively at the molecular level. In our discussion we pay particular attention to mutations that affect the segmented body plan of the organism, in both the larva and the adult.

Early *Drosophila* development occurs in the following way. The structure of the egg becomes organized as it develops in the ovary of the female. Stores of mRNA, along with yolk proteins and other cytoplasmic molecules, pass from the surrounding maternal cells into the egg. Immediately after fertilization, the zygote nucleus divides, beginning a series of 13 mitotic divisions.

Each division takes only 5 or 10 minutes, which means that the DNA in the nuclei replicates constantly and at a very rapid rate. During that time, the nuclei do not synthesize RNA. Cytokinesis does not take place, and the nuclei produced by the first seven divisions remain at the center of the embryo until the eighth division occurs. At that time, most of the nuclei migrate out from the center and become localized at the periphery of the embryo. This is known as the *syncytial blastoderm* stage, because the nuclei are not surrounded by individual plasma membranes. (A *syncytium* is a structure containing many nuclei residing in a common cytoplasm.) Subsequently, plasma membranes form, and the embryo becomes known as a *cellular blastoderm.*

Maternal effect genes The genes that organize the structure of the egg cell are called **maternal effect genes.** These genes in the surrounding maternal tissues are transcribed to produce mRNA molecules that are transported into the developing egg. Analysis of mutant flies with defective maternal effect genes has revealed that many of the genes are involved in establishing the polarity of the embryo—such as what part of the embryo will become the head and what part will become the tail. Polarity dictates those parts of the egg that are dorsal or ventral and those that are anterior or posterior (see Chapter 28); thus, these genes are known as *egg polarity genes.*

Figure 16-8a illustrates concentration gradients for two specific maternal mRNA molecules in the very early embryo. These mRNA transcripts of some of the maternal effect genes are identified by their ability to hybridize with radioactive DNA probes derived from cloned genes. Alternatively, researchers use fluorescently tagged antibodies (as in the chapter opening photograph) to bind to specific protein products of the maternal effect genes. These protein gradients organize the early pattern of development in the embryo by determining anterior and posterior regions.

A combination of protein gradients may provide positional information that specifies the fate—that is, the developmental path—of each nucleus within the embryo. For example, mutations in certain maternal effect genes cause the absence of specific signals, resulting in an embryo with two heads or two posterior ends.

In many cases, injecting normal maternal mRNA into the mutant embryo reverses the phenotype associated with a mutation in a given maternal effect gene. When this is done, the fly

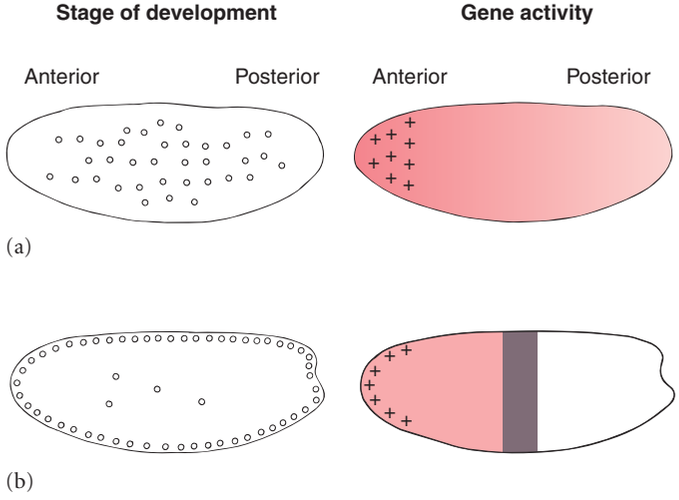

FIGURE **16-8** **Early development in *Drosophila.***

Longitudinal sections on the left show two early stages of development of the *Drosophila* embryo. These are matched with the simplified patterns of gene activity at each stage on the right. **(a)** At 1.25 hours after fertilization, the embryo consists of a common cytoplasm with about 128 nuclei *(small circles).* Maternal effect genes divide the embryo into anterior and posterior sections. The crosses in the anterior region represent mRNA molecules transcribed from one maternal effect gene. The pink shading represents a different maternal mRNA molecule that is more concentrated in the anterior region. **(b)** At 2 hours after fertilization, about 1500 nuclei have migrated into the periphery of the embryo and started to make their own mRNA molecules. The gap genes divide the embryo into anterior, middle, and posterior sections. The maternal RNA shown in pink is now transcribed from segmentation genes *(crosses)* in nuclei in the anterior region. The mRNA from another gap gene is transcribed in the middle of the embryo *(black region). (Adapted from M.E. Akam, "The Molecular Basis for Metameric Pattern in the* Drosophila *embryo,"* Development, *Vol. 101, 1987)*

TABLE 16-1 Classes of Genes Involved in Pattern Formation of Embryonic Segments in *Drosophila*

Class of Gene	Site of Gene Activity	Effects of Mutant Alleles and Proposed Functions of Genes
Maternal effect genes	Maternal tissues surrounding egg	Many maternal effect mutations alter polarity of embryo; initiate pattern formation by activating regulatory genes in nuclei in certain locations in embryo
Segmentation genes		
Gap genes	Embryo	Mutant alleles cause one or more segments to be missing; some may influence activity of pair-rule genes, segment polarity genes, and homeotic genes
Pair-rule genes	Embryo	When mutated, cause alternate segments to be missing; some may influence activity of segment polarity genes and homeotic genes
Segment polarity genes	Embryo	Mutant alleles delete part of every segment and replace it with mirror image of remaining structure; may influence activity of homeotic genes
Homeotic genes	Embryo	Homeotic mutations cause parts of fly to form structures normally formed in other segments; control identities of segments

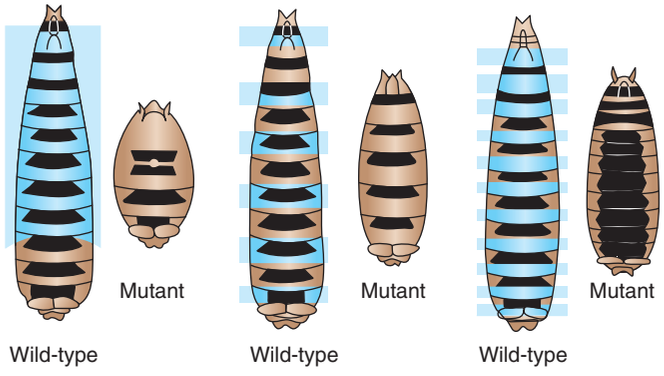
develops normally, indicating that the gene product is needed only for a short time in the earliest stages of development.

Segmentation genes As the nuclei start to migrate to the periphery of the embryo, **segmentation genes** in those nuclei begin to produce embryonic mRNA. Thus far, geneticists have identified at least 24 segmentation genes that are responsible for generating a repeating pattern of body segments within the embryo and adult fly. Based on a study of mutant phenotypes, the segmentation genes fall into three classes—gap genes, pair-rule genes, and segment polarity genes.

Gap genes are the first set of segmentation genes to act. These genes interpret the maternal anterior–posterior information in the egg and begin organization of the body into anterior, middle, and posterior regions (Fig. 16-8b). A mutation in one of the gap genes usually causes the absence of one or more body segments in an embryo (Fig.16-9a).

The other two classes of segmentation genes do not act on small groups of body segments; instead, they affect all segments. Mutations in **pair-rule genes** delete every other segment, producing a larva with half the normal number of segments (Fig. 16-9b). Mutations in **segment polarity genes** produce segments in which one part is missing and the remaining part is duplicated as a mirror image (Fig. 16-9c). Table 16-1 summarizes the effects of the different classes of mutants.

Each segmentation gene has distinctive times and places in the embryo in which it is most active (Fig. 16-10). The observed pattern of expression of maternal effect genes and segmentation genes indicates that a progressive series of developmental events determines cells destined to form adult structures. First,



(a) Gap genes (b) Pair-rule genes (c) Segment polarity genes

FIGURE 16-9 A comparison of mutations in *Drosophila* segmentation genes.

(a) Gap genes, **(b)** pair-rule genes, and **(c)** segment polarity genes control the pattern of body segments in a *Drosophila* embryo. The blue bands mark the regions in which the protein products of these genes are normally expressed in wild-type embryos. These same regions are absent in embryos in which the gene is mutated, and the resulting phenotype is characteristic of the class to which the gene belongs. *(Adapted from C. Nüsslein-Volhard and E. Wieschaus, "Mutations Affecting Segment Number and Polarity in* Drosophila*," Nature, Vol. 287, 1980)*

Image not available due to copyright restrictions

maternal effect genes that form gradients of morphogens in the egg determine the anterior–posterior (head-to-tail) axis and the dorsal and ventral regions of the embryo. A **morphogen** is a chemical agent that affects the differentiation of cells and the development of form. Morphogen gradients are signals that help cells determine their location within the embryo and their eventual differentiation into specialized tissues and organs.

Next, segmentation genes respond to the morphogens at each location to regulate the production of segments from the head to the posterior region. Within each segment, other genes are then activated to specify which body part that segment will become. Every cell's position is further specified with a specific "address" designated by combinations of the activities of the regulatory genes.

The segmentation genes act in sequence, with the gap genes acting first, then the pair-rule genes, and finally the segment polarity genes. In addition, the genes of the three groups interact. Each time a new group of genes acts, cells for that group become more determined in their development. As the embryo develops, each region is progressively subdivided into smaller regions.

Most segmentation genes code for **transcription factors,** DNA-binding proteins that regulate gene transcription in eukaryotic cells (see Chapter 13). For example, some segmentation genes code for a "zinc-finger" type of DNA-binding regulatory protein (see Fig. 13-8b). *Homeotic genes,* discussed next, also code for transcription factors. The fact that many of the genes involved in controlling development code for transcription factors indicates those proteins act as genetic switches regulating the expression of other genes.

Once researchers have identified proteins that function as transcription factors, they can use the purified proteins to determine the DNA target sequences to which the proteins bind. This approach has been increasingly useful in identifying additional parts of the regulatory pathway involved in different stages of development. Transcription factors also play a role in cancer (discussed later in the chapter).

Homeotic Genes After segmentation genes have established the basic pattern of segments in the fly body, **homeotic genes** specify the developmental plan for each segment. Mutations in homeotic genes cause one body part to be substituted for another and therefore produce some peculiar changes in the adult. A striking example is the *Antennapedia* mutant fly, which has legs that grow from the head where the antennae would normally be (Fig. 16-11).

Homeotic genes in *Drosophila* were originally identified by the altered phenotypes produced by mutant alleles. When geneticists analyzed the DNA sequences of several homeotic genes, they discovered a short DNA sequence of approximately 180 base pairs, which characterizes many homeotic genes as well as some other genes that play a role in development. This DNA sequence is called the **homeobox.** Each homeobox codes for a protein functional region called a **homeodomain,** consisting of 60 amino acids that form four α-helices. One of these serves as a recognition helix that binds to specific DNA sequences and thereby affects transcription. Thus the products of homeotic genes, like those of the earlier acting segmentation genes, are transcription factors. In fact, some segmentation genes also contain homeoboxes.

FIGURE **16-11** **The *Antennapedia* locus.**

Antennapedia mutations cause homeotic transformations in *Drosophila* in which legs or parts of legs replace the antennae. **(a)** The head of a normal fly and a fly with an *Antennapedia* mutation. **(b)** SEM of the head of a fly with an *Antennapedia* mutation.

Dr. Thomas Kaufman

Studies of ***Hox* genes,** clusters of homeobox-containing genes that specify the anterior–posterior axis during development, provide insights about evolutionary relationships. *Hox* genes were initially discovered in *Drosophila,* where they are arranged in two adjacent groups on the chromosome: the *Antennapedia complex* and the *bithorax complex.* As *Hox* genes have been identified in other animals, including other arthropods, annelids (segmented worms), roundworms, and vertebrates, researchers have found that these genes are also clustered and that their organization is remarkably similar to that in *Drosophila.*

Figure 16-12 compares the organization of the *Hox* gene clusters of *Drosophila,* the laboratory mouse, and the roundworm *Caenorhabditis elegans.* The *Drosophila* and mouse *Hox* genes are located in the same order along the chromosome, although the correlation is less exact for *C. elegans.* Moreover, the linear order of the genes on the chromosome reflects the order of the corresponding regions they control (from anterior to posterior) in the animal. This organization apparently reflects the need for these genes to be transcribed in a specific temporal sequence.

Drosophila has only one *Antennapedia-bithorax* complex. However, humans and other vertebrates have four similar *Hox* gene clusters, each located in a different chromosome. These complexes probably arose through gene duplication. The fact that extra copies of these genes are present helps explain why mutations causing homeotic-like transformations are seldom seen in vertebrate animals. However, one particular type of *Hox* mutation that has been described in both mice and humans causes abnormalities in the limbs and genitalia. The involvement of the genitalia provides a further explanation for the rarity of these mutant alleles, because affected individuals are unlikely to reproduce.

The fact that very similar developmental controls are seen in organisms as diverse as insects, roundworms, and vertebrates (including humans) indicates that the basic mechanism evolved early and has been highly conserved in all animals that have an anterior–posterior axis, even those that are not segmented. Clearly, once a successful way of regulating groups of genes and integrating their activities evolved, it was retained, although it has apparently been modified to provide for alterations of the body plan.

The finding of homeobox-like genes in plants suggests these genes originated early during eukaryotic evolution. With further investigations, researchers hope to develop an overall model of how the rudiments of morphogenesis are controlled in all multicellular eukaryotes. These systems of master genes that regulate development are a rich source of "molecular fossils" that may illuminate evolutionary history in new and exciting ways.

KEY CONCEPT: *Hox* genes are arranged in the same order on the chromosome as they are expressed along the anterior-posterior axis of the embryo.

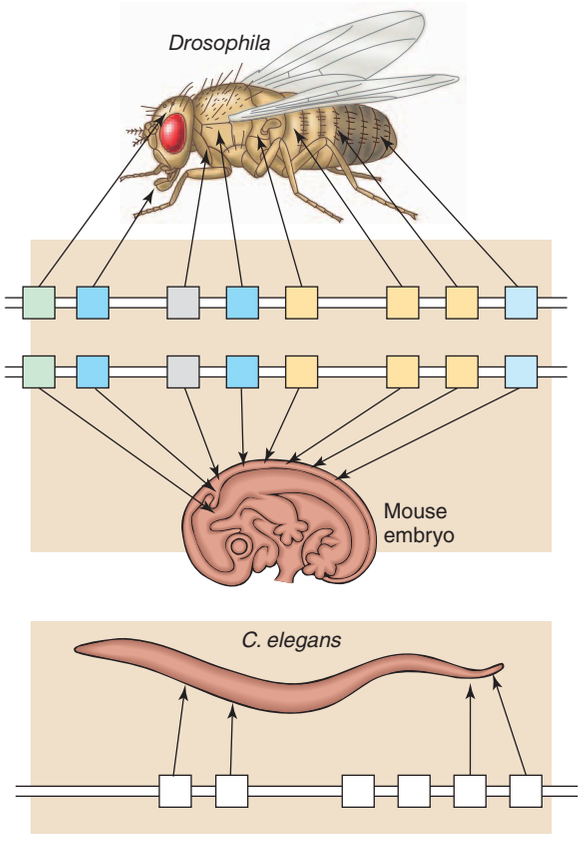

FIGURE **16-12** ***Hox* gene clusters.**

Clusters of *Hox* are found in all animal groups except for sponges and cnidarians (jellyfish and their relatives). Note that in each organism, the order of these developmental genes *(squares)* on the chromosome *(white line)* reflects their spatial order of expression in the embryo. (Only one of the four mouse chromosomes with *Hox* gene clusters is shown.) *C. elegans* also has similar *Hox* gene clusters, although the gene order is not identical to that in *Drosophila* and the mouse. *(Adapted from C. Kenyon and B. Wang,* Science, *Vol. 253, 2 Aug, 1991; and K. Van Auken, et al.,* Proc. Natl. Acad. Sci., *Vol. 97, 25 Apr. 2000)*

Developmental studies of *C. elegans* elucidated apoptosis

The nematode worm *Caenorhabditis elegans* is an ideal model organism because its system for the genetic control of development is relatively easy to study. Sydney Brenner, a British molecular geneticist, began studying molecular development in this animal at Cambridge University in the 1960s. He selected *C. elegans* because it is small, has a short life cycle, and is genetically simple. Consisting of about 19,700 protein-coding genes, it was the first animal genome sequenced. Today, *C. elegans* is an important tool for answering basic questions about the development of individual cells within a multicellular organism.

As an adult, *C. elegans* is only 1.5 mm long and contains only 959 somatic cells. Individuals are either males or **hermaphrodites,** organisms with both sexes in the same individual. Hermaphroditic individuals are capable of self-fertilization, which makes it easy to obtain offspring that are homozygous for newly induced recessive mutations. The availability of males that can mate with the hermaphrodites makes it possible to perform genetic crosses as well.

FIGURE 16-13 ***Caenorhabditis elegans.***

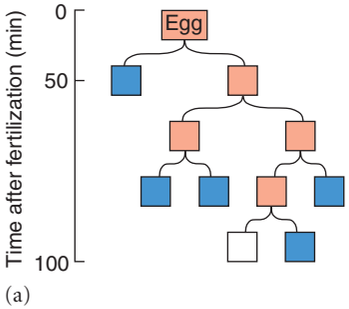
This transparent organism has a fixed number of somatic cells. **(b)** Structures in the adult hermaphrodite. The sperm-producing structures are not shown. *(Adapted from Figure 22-6a in V. Walbot and N. Holder,* Developmental Biology, *1987. Used with permission from McGraw-Hill Companies.)*

Because the worm's body is transparent, researchers can follow the development of literally every one of its somatic cells using a Nomarski differential interference microscope, which provides contrast in transparent specimens (Fig. 16-13). As a result of efforts by several research teams, the lineage of each somatic cell in the adult has now been determined. Those studies have shown that the nematode has a very rigid, or fixed, developmental pattern. After fertilization, the egg undergoes repeated divisions, producing about 550 cells that make up the small, sexually immature larva. After the larva hatches from the egg case, further cell divisions give rise to the adult worm.

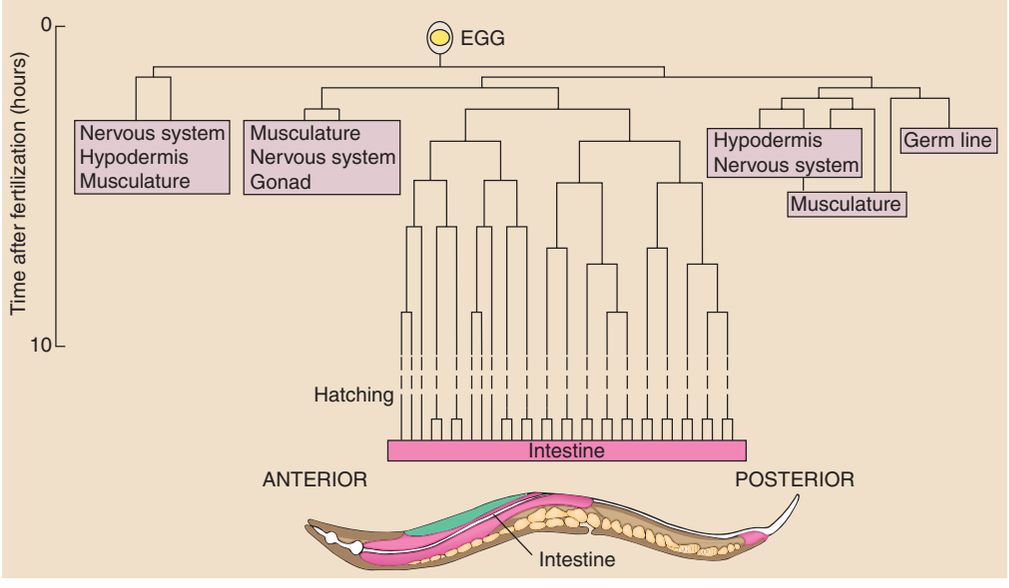
The lineage of each somatic cell in the adult can be traced to a single cell in a small group of **founder cells,** which are formed early in development (Fig. 16-14a). If a particular founder cell is destroyed or removed, the adult structures that would normally develop from that cell are missing. Such a rigid developmental pattern, in which the fates of the cells become restricted early in development, is referred to as **mosaic development.**

FIGURE 16-14 **Cell lineages of *C. elegans.***

(a) All somatic cells of *C. elegans* are derived from five somatic founder cells (*shown in blue*), produced during the early cell divisions of the embryo. The cell shown in white gives rise to germ-line cells. **(b)** This lineage map traces the development of the cells that form the intestine. The dashed lines represent many cell divisions of a particular lineage.



(a)



(b)

Each cell has a specific fate in the embryo, just as each tile in a mosaic design forms part of the pattern.

Scientists initially hypothesized that every organ system in *C. elegans* might be derived from only one founder cell. Detailed analysis of cell lineages, however, reveals that many of the structures found in the adult, such as the nervous system and the musculature, are in fact derived from more than one founder cell (Fig. 16-14b). A few lineages have been identified in which a nerve cell and a muscle cell are derived from the division of a single cell. Mutations affecting cell lineages have been isolated, and many of them appear to have properties that would be expected of genes involved in regulating developmental events.

A researcher who uses microscopic laser beams small enough to destroy individual cells can determine the influence one cell has on the development of a neighboring cell. Consistent with the rigid pattern of cell lineages, the destruction of an individual cell in *C. elegans* results, in most cases, in the absence of all of the structures derived from that cell, but with the normal differentiation of all the neighboring somatic cells. This observation suggests that development in each cell is regulated through its own internal program.

However, the developmental pattern of *C. elegans* is not entirely mosaic. In some cases, cell differentiation is influenced by interactions with particular neighboring cells, a phenomenon known as **induction.** One example is the formation of the vulva (pl., *vulvae*), the reproductive structure through which the eggs are laid. A single nondividing cell, called the *anchor cell,* is a part of the ovary, the structure in which the germ line cells undergo meiosis to produce the eggs. The anchor cell attaches to the ovary and to a point on the outer surface of the animal, triggering the formation of a passage through which the eggs pass to the outside. When the anchor cell is present, it induces cells on the surface to form the vulva and its opening. If the anchor cell is destroyed by a laser beam, however, the vulva does not form, and the cells that would normally form the vulva remain as surface cells (Fig. 16-15).

The analysis of mutations has contributed to our understanding of inductive interactions. For example, several types of mutations cause more than one vulva to form. In such mutant animals, multiple vulvae form even if the anchor cell is destroyed. Thus the mutant cells do not require an inductive signal from an anchor cell to form a vulva. Evidently in these mutants the gene or genes responsible for vulva formation are constitutive. Conversely, mutants lacking a vulva are also known. In some of these, the cells that would normally form the vulva apparently do not respond to the inducing signal from the anchor cell.

Chronogenes are genes involved in developmental timing. Researchers have identified recessive alleles that cause certain cells to adopt fates that would ordinarily occur later in development. Dominant alleles of the same locus cause certain cells to adopt fates that would usually occur earlier. Chronogenes are good candidates for master switches that control developmental timing.

During development in *C. elegans,* there are instances in which cells die by apoptosis shortly after they are produced. **Apoptosis,** or programmed cell death, has been observed in a wide variety of organisms, both plant and animal (see Chapter 4). For example, the human hand is formed as a webbed structure, but the fingers become individualized when the cells between them undergo apoptosis. In *C. elegans,* as in other organisms, apoptosis is under genetic control. In 1986, U.S. molecular geneticist Robert Horvitz discovered mutant worms that do not lose cells to apoptosis. Homologous genes were subsequently identified in other organisms, including humans. The loci code for a family of proteins in mammals known as **caspases,** proteolytic enzymes that are active in the early stages of apoptosis. The molecular events that trigger apoptosis are an area of intense research interest, the results of which will shed considerable light on the general processes of cell aging and apoptosis.

Robert Horvitz and British scientists Sydney Brenner and John Sulston shared the Nobel Prize in 2002 for their work on the genetic regulation of organ development and apoptosis in *C. elegans.* Sulston was one of Brenner's students. He traced the lineage of how a single fertilized egg gives rise to the 959 cells in the nematode adult and also observed that some cells die during normal development. Continuing Sulston's work on apoptosis, Horvitz, as mentioned earlier, was the first to discover genes involved in apoptosis.

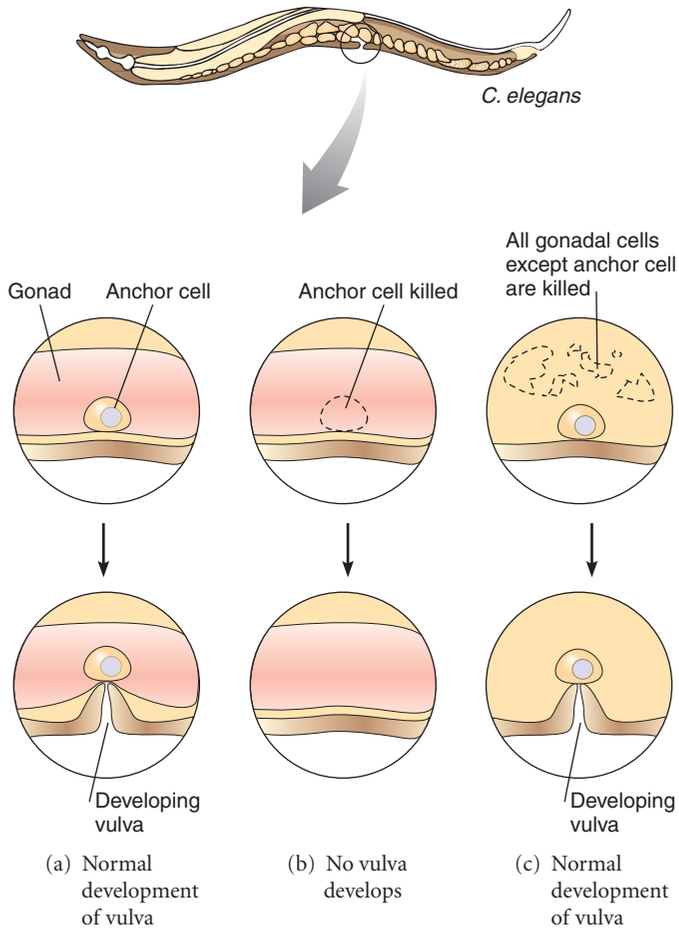


FIGURE **16-15** **Induction.**
A single anchor cell induces neighboring cells to form the vulva in *C. elegans.* This diagram shows how laser destruction of single cells or group of cells demonstrates the influence of a cell on its neighbors.

The mouse is a model for mammalian development

Mammalian embryos develop in markedly different ways from the embryos of *Drosophila* and *C. elegans.* The laboratory mouse, *Mus musculus,* is the best-studied example of mammalian development. Researchers have identified numerous genes affecting development in the mouse. The mouse genome sequence, which was published in 2002, contains 27,000 to 30,000 genes, similar to the number of protein-coding genes in the human genome. Indeed, 99% of the genes in the mouse have counterparts in humans.

The early development of the mouse and other mammals is similar in many ways to human development (see Chapter 49). During the early developmental period, the embryo lives free in the reproductive tract of the female. It then implants itself in the wall of the uterus, after which the mother meets its nutritional and respiratory needs. Consequently, mammalian eggs are very small and contain little in the way of food reserves. Almost all research on mouse development has concentrated on the stages leading to implantation, because in those stages the embryo is free-living and can be experimentally manipulated. During that period, developmental commitments that have a significant effect on the future organization of the embryo take place.

After fertilization, a series of cell divisions gives rise to a loosely packed group of cells. Research shows that in the very early mouse embryo all cells are equivalent. For example, at the two-cell stage of mouse embryogenesis, if researchers destroy one cell and implant the remaining cell into the uterus of a surrogate mother, a normal mouse usually develops.

Conversely, if two embryos at the eight-cell stage of development are fused together and implanted into a surrogate mother, a normal-sized mouse develops (Fig. 16-16). By using two embryos with different genetic characters, such as coat color, researchers demonstrated that the resulting mouse has four genetic parents. These chimeric mice have fur with patches of different colors derived from clusters of genetically different cells. A **chimera** is an organism containing two or more kinds of genetically dissimilar cells arising from different zygotes. (The term is derived from the name of a mythical beast that was said to have the head of a lion, the body of a goat, and a snakelike tail.) Chimeras let researchers use genetically marked cells to trace the fates of certain cells during development.

The responses of mouse embryos to such manipulations contrast with the mosaic or predetermined nature of early *C. elegans* development, in which destroying one of the founder cells results in the loss of a significant portion of the embryo. For this reason, biologists say that the mouse has highly **regulative development**—the early embryo acts as a self-regulating whole that accommodates missing or extra parts. However, thus far researchers have not demonstrated the totipotency of cells from slightly later stages of mouse development. Nevertheless, experiments in which nuclei have been transplanted into mouse eggs, leading to live births, demonstrate that at least some nuclei of differentiated mouse cells are totipotent.

Transgenic mice are used in studies of developmental regulation

In transformation experiments similar to those done with *Drosophila,* foreign DNA injected into fertilized mouse eggs is incorporated into the chromosomes and expressed (Fig. 16-17). The resulting transgenic mice provide insights into how genes are activated during development. In addition, mouse genes can be inactivated (knocked out) by the technique of **gene targeting** (see Chapter 14). For example, when a mouse gene encoding insulin-like growth receptors is knocked out, the resulting mouse dies at birth and exhibits many developmental abnormalities (see *On the Cutting Edge: Studying Aging in Mice* on page 328).

Scientists can identify a *transgene* (foreign gene) that has been introduced into a mouse and determine whether it is active by marking the gene in several ways. Sometimes a similar

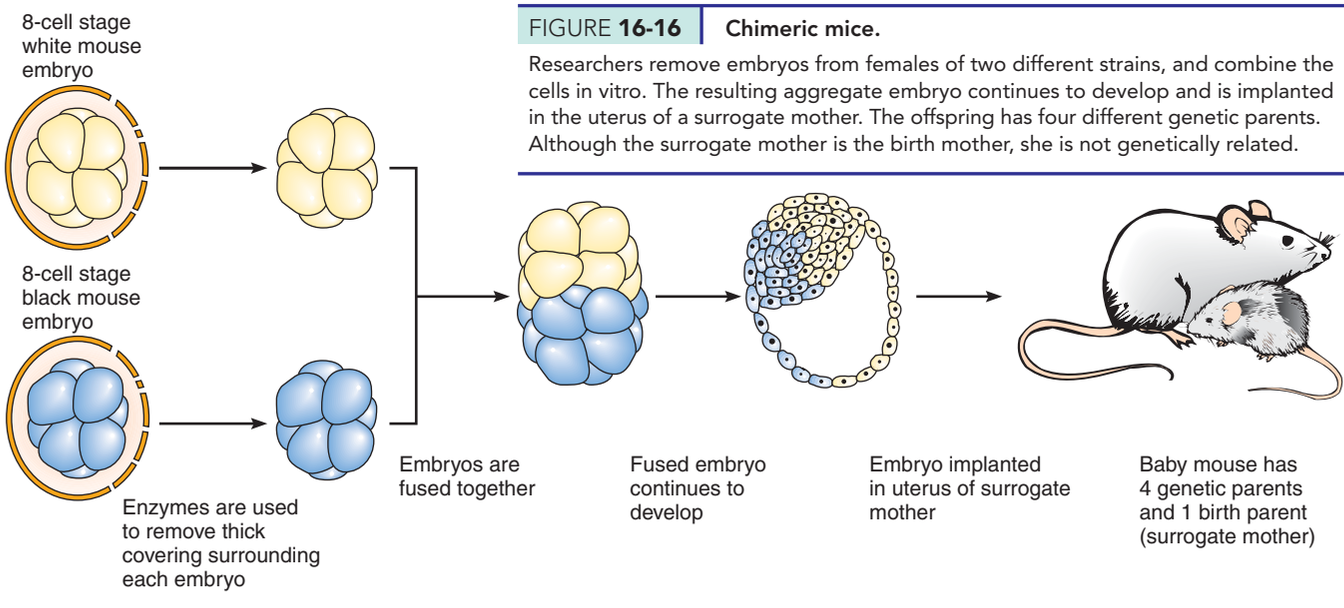

FIGURE **16-16** **Chimeric mice.**

Researchers remove embryos from females of two different strains, and combine the cells in vitro. The resulting aggregate embryo continues to develop and is implanted in the uterus of a surrogate mother. The offspring has four different genetic parents. Although the surrogate mother is the birth mother, she is not genetically related.

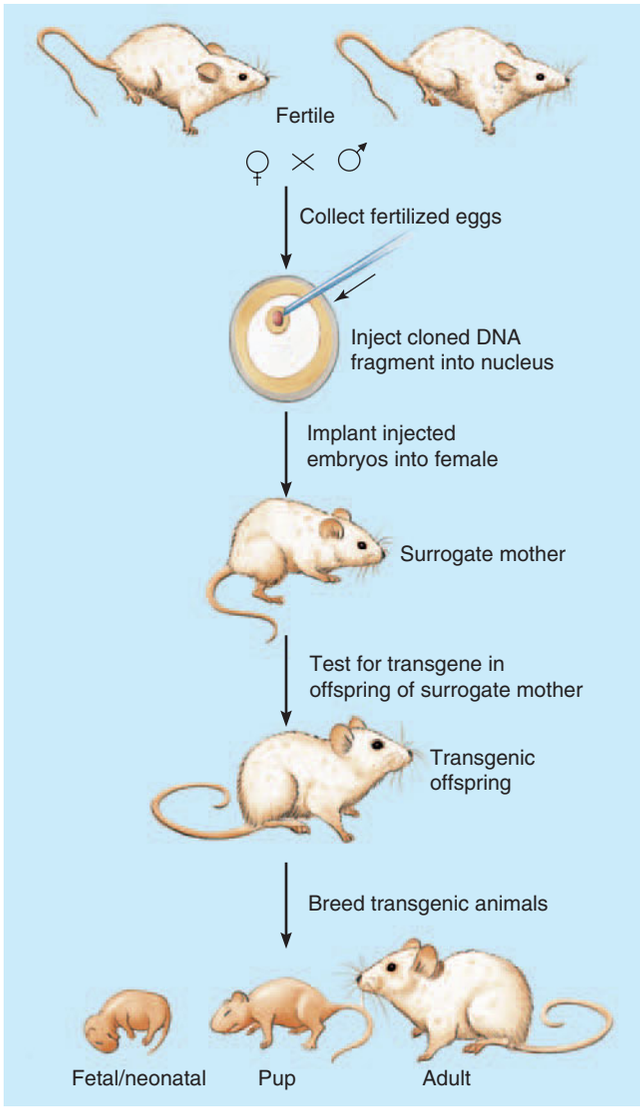

FIGURE **16-17** **Producing a transgenic mouse.**

Researchers inject cloned DNA fragments into the nucleus of a fertilized mouse egg. They then implant the injected eggs into a female, which becomes the surrogate mother. The researchers verify the presence of the foreign gene in the transgenic animal or breed the animal to establish a transgenic line of mice.

gene from a different species is used; its protein is distinguished from the mouse protein by specific antibodies. It is also possible to construct a hybrid gene consisting of the regulatory elements of a mouse gene and part of another, nonmouse gene that codes for a "reporter" protein. For example, the reporter protein could be an enzyme not normally found in mice. Such studies have been important in showing which DNA sequences of a mouse homeobox gene determine where the gene is expressed in the embryo.

Many developmentally controlled genes introduced into mice have yielded important information about gene regulation. When researchers introduce developmentally controlled genes from other species, such as humans or rats, into mice, the genes are regulated the same way they normally are in the donor animal. When introduced into the mouse, for example, human genes encoding insulin, globin, and crystallin—which are normally expressed in cells of the pancreas, blood, and eye lens, respectively—are expressed only in those same tissues in the mouse. That these genes are correctly expressed in their appropriate tissues indicates the signals for tissue-specific gene expression are highly conserved through evolution. Information on the regulation of genes controlling development in one organism can have valuable applications to other organisms, including humans.

Arabidopsis is a model for studying plant development, including transcription factors

Botanists use certain well-characterized plants in studying the genetic control of development. Many of these are economically important crop plants such as corn, *Zea mays.* Genes with developmental effects are known in corn, including some that are analogous (but not homologus) to the homeotic genes of *Drosophila.*

Arabidopsis thaliana, the organism most widely used to study genetics and development in plants, is a member of the mustard family. Although *Arabidopsis* itself is a weed of no economic importance, it has several advantages for research. The plant completes its life cycle in just a few weeks and is small enough to be grown in a petri dish, yielding thousands of individuals in limited space. Botanists use chemical mutagens to produce mutant strains and have isolated many developmental mutants. When they insert cloned foreign genes into *Arabidopsis* cells, the genes integrate into the chromosomes and are expressed. The researchers then induce these transformed cells to differentiate into transgenic plants.

In 2000, the *Arabidopsis* genome became the first plant genome sequenced. Although its genome is relatively small (the rice genome is about four times larger), it includes about 26,000 protein-coding genes. In comparison, *Drosophila* has about 13,600 genes and *C. elegans* about 19,700. Many genes in *Arabidopsis* are functionally equivalent to genes in *Drosophila, C. elegans,* and other animal species.

Of particular importance to development are the more than 1500 genes that code for transcription factors in *Arabidopsis* (compared to 635 at last count for *Drosophila*). Not surprisingly, many genes known to specify identities of parts of the *Arabidopsis* flower, code for transcription factors. During the development of *Arabidopsis* flowers, four distinct flower parts differentiate: sepals, petals, stamens, and carpels (Fig. 16-18a). Sepals cover and protect the flower when it is a bud, petals help attract animal pollinators to the flower, stamens produce pollen grains, and the pistil produces ovules, which develop into seeds following fertilization (see Chapter 27).

The **ABC model** is a working hypothesis that may explain the molecular biology behind how these four organs develop. The *A* gene is needed to specify sepals, both *A* and *B* genes are needed to specify petals, both *B* and *C* genes are needed to spec-

ON THE CUTTING EDGE Studying Aging in Mice

PROCESS OF SCIENCE

Hypothesis: Insulin-like growth factor (IGF) and its membrane receptor influence aging in mammals.

Method: The effects of the IGF receptor on aging were studied in mice using gene targeting to knock out one or both alleles of the gene *igf1r.*

Results: Mice that had one allele of the gene *igf1r* knocked out had an extended life span, whereas mice that had both alleles knocked out died at birth.

Conclusion: Reduced signaling from IGF, caused by the presence of fewer IGF receptors on the cell surface, increases longevity in mice.

Aging, which is defined as a progressive decline in the performance of various parts of the body, is an important field of developmental biology. The study of aging has great practical potential because age-related diseases represent one of the biggest challenges of biomedical research today. Scientists have demonstrated that many environmental factors influence aging. For example, severe calorie restriction in rodents and other mammals delays aging. However, how the mammalian genome interacts with the cell environment during the aging process is not well understood.

As you have learned during your study of genetics, organisms as diverse as worms, fruit flies, and mice provide valuable insights about the biological functioning of other organisms, including humans. Researchers working with model organisms, such as *Drosophila* and *C. elegans,* have found that hundreds of protein-coding genes, when mutated, extend the life span of the organism to variable degrees. One of the most potent life span–extending genes, present in the worm *C. elegans,* codes for a protein that is very similar to the membrane receptor that allows cells to respond to the peptide, **insulin-like growth factor (IGF),** in humans and other mammals (see Chapter 47). The binding of IGF to its receptor triggers **signal transduction** within the cell.

When the allele for this receptor protein mutates in *C. elegans,* the worm has a greatly extended life span. Researchers wondered whether the IGF receptor influences aging in mammals, including humans. To test this hypothesis, Martin Holzenberger at the French National Institute for Biomedical Research (INSERM) and his coworkers produced knockout mice in which they inactivated the gene for the insulin-like growth factor receptor (IGF-1R).[1] Because mice are diploid organisms, they have two copies of the gene, designated *igf1r.* When both alleles of *igf1r* are inactivated, the mice develop many abnormalities and die at birth. However, when one allele of *igf1r* is inactivated and the other left in its normal state, the mice thrive and live an average of 26% longer than control mice.

[1] M. Holzenberger, J. Dupont, B. Ducos, P. Leneuve, A. Géloën, P. Even, P. Cervera, and Y. LeBouc, "IGF-1 Receptor Regulates Lifespan and Resistance to Oxidative Stress in Mice," *Nature,* Vol. 421, 9 Jan. 2003.

Because both genetically manipulated mice and control mice eventually died of a variety of diseases associated with aging, researchers hypothesize that the heterozygous mice have a *decreased rate* of aging, as opposed to a reduction in aging diseases. In all other respects, the heterozygous mice are normal. They are virtually indistinguishable from control mice in their rate of development, metabolic rate, ability to reproduce, and body size.

Mice that are heterozygous at the *igf1r* locus produce fewer IGF receptors, and therefore the cells are not exposed to as much signaling from IGF. As a result, the heterozygous cells may be more resistant to environmental stressors, such as oxygen radicals. (Oxygen radicals and other *free radicals* are atoms, molecules, or ions that have one or more unpaired electrons. Free radicals react readily with biological molecules, often breaking chemical bonds.) When mouse cells that are heterozygous at the *igf1r* locus are grown in culture, they resist attack by oxygen radicals. The same is true at the organism level, for mice that are heterozygous at the *igf1r* locus.

Holzenberger's research on the IGF receptor and aging in mice implies that some of the hundreds of other mutant genes in *C. elegans* that have been associated with aging may also be involved in mammalian aging. Thus the subject of the genetic control of mammalian aging has enough research topics to occupy molecular geneticists for many years.

FIGURE **16-18** **Homeotic mutants in *Arabidopsis* flowers.**

(a) A normal *Arabidopsis* flower has four outer leafy green sepals, four white petals, six stamens (the male reproductive structures), and a central pistil (the female reproductive structure). **(b)** This homeotic mutant is missing petals. **(c)** This homeotic mutant has only sepals and carpels. **(d)** This homeotic mutant has sepals and petals but no other floral structures. The homeotic genes in all these plants code for transcription factors.

ify stamens, and the *C* gene is needed to specify the pistil. Mutations in the *A, B,* or *C* organ-identity genes, all of which are homeotic and code for transcription factors, cause one flower part to be substituted for another. For example, class *C* homeotic mutants (which have an inactive *C* gene) have petals in place of stamens and sepals in place of the pistil. Therefore, the entire flower consists of only sepals and petals. Figure 16-18b, c, and d shows three homeotic mutants of *Arabidopsis.*

The ABC model is not the entire explanation for floral development. Another class of genes, designated *SEPALLATA,* interacts with the *B* and *C* genes to specify the development of petals, stamens, and carpels. Remarkably, when *SEPALLATA* genes are turned on permanently in *Arabidopsis,* the resulting plants have white petals growing where the leaves should be.

These findings in *Arabidopsis* vastly increase the number of molecular probes available from plants. Researchers use these probes to identify other genes that control development in various plant species, and to compare them with genes from a wide range of organisms. The success of the *Arabidopsis* sequencing project led to an international initiative by plant biologists, the 2010 Project, whose goal is to understand the functions of all genes in *Arabidopsis* by the year 2010. This functional genomic information will lead to a far deeper understanding of plant development and evolutionary history.

Review

- What are the relative merits of *Drosophila, C. elegans, Mus musculus,* and *Arabidopsis* as model organisms for the study of development?
- What are transcription factors, and how do they influence development?
- What role does induction play in development?

CANCER AND CELL DEVELOPMENT

Learning Objective

8 Discuss the relationship between cancer and mutations that affect cell developmental processes.

Cancer cells lack normal biological inhibitions. Normal cells are tightly regulated by control mechanisms that prompt them to divide when necessary and prevent them from growing and dividing inappropriately. Cells of many tissues in the adult are normally prevented from dividing; they reproduce only to replace a neighboring cell that has died or become damaged. Cancer cells have escaped such controls and can divide continuously.

As a consequence of their abnormal growth pattern, some cancer cells eventually form a mass of tissue called a **tumor.** If the tumor remains at the spot where it originated, it can usually be removed by surgery. One of the major problems with certain forms of cancer is that the cells can escape from the controls that maintain them in one location. **Metastasis** is the spreading of cancer cells to different parts of the body. Cancer cells invade other tissues and form multiple tumors. Lung cancer, for example, is particularly deadly because its cells are highly metastatic; they enter the bloodstream, spread, and form tumors in other parts of the lungs and in other organs, such as the liver and the brain. Tumors with cells that can metastasize are referred to as **malignant tumors.**

Biologists now know that cancer is caused by the altered expression of specific genes critical for cell division. Using recombinant DNA methods, researchers have identified many of the genes that, when they function abnormally, transform normal cells into cancer cells. The traits of each kind of cancer cell come from at least one, and probably several, **oncogenes,** or cancer-causing genes. Oncogenes arise from changes in the expression of certain genes called **proto-oncogenes,** which are *normal* genes found in all cells and are involved in the control of growth and development.

Investigators first discovered oncogenes in viruses that infect mammalian cells and transform them into cancer cells *(malignant transformation).* Such viruses have oncogenes as part of their genomes. When these viruses infect a cell, the viral oncogenes are expressed, causing the cell to divide. The viral oncogenes resemble proto-oncogenes normally present in the cell.

A proto-oncogene in a cell that has not been infected by a virus can also mutate and become an oncogene. One of the first oncogenes researchers identified was isolated from a tumor in a human urinary bladder. In the cell that gave rise to the tumor, a proto-oncogene had undergone a single base-pair mutation; the result was that the amino acid valine replaced the amino acid glycine in the protein product of the gene. This subtle change was apparently a critical factor in converting the normal cell into a cancer cell.

Some of the control mechanisms of cell growth are illustrated in greatly simplified form in Figure 16-19. One or more external signal molecules trigger the growth and division of cells. Some of these substances are **growth factors** that bind to specific **growth factor receptors** associated with the cell surface, initiating a cascade of events inside the cell. Often the growth factor receptor complex acts as a **protein kinase,** an enzyme that phosphorylates proteins, which then phosphorylates specific amino acids of several cytoplasmic proteins. This post-translational modification usually results in the activation of previously inactive enzymes. These activated enzymes then catalyze the activation of certain nuclear proteins, many of which are transcription factors. Activated transcription factors bind to their DNA targets and stimulate the transcription of specific sets of genes that initiate growth and cell division (see Chapter 9).

Even in the simplified scenario presented in the figure, it is evident that multiple steps are required to control cell proliferation. Researchers have identified the proto-oncogenes that encode the products responsible for many of these steps. The current list of known proto-oncogenes includes genes that code for various growth factors or growth factor receptors and genes that respond to stimulation by growth factors, including many transcription factors. When a proto-oncogene mutates or is expressed inappropriately (when it becomes an oncogene), the cell may misinterpret the signal and respond by growing and di-

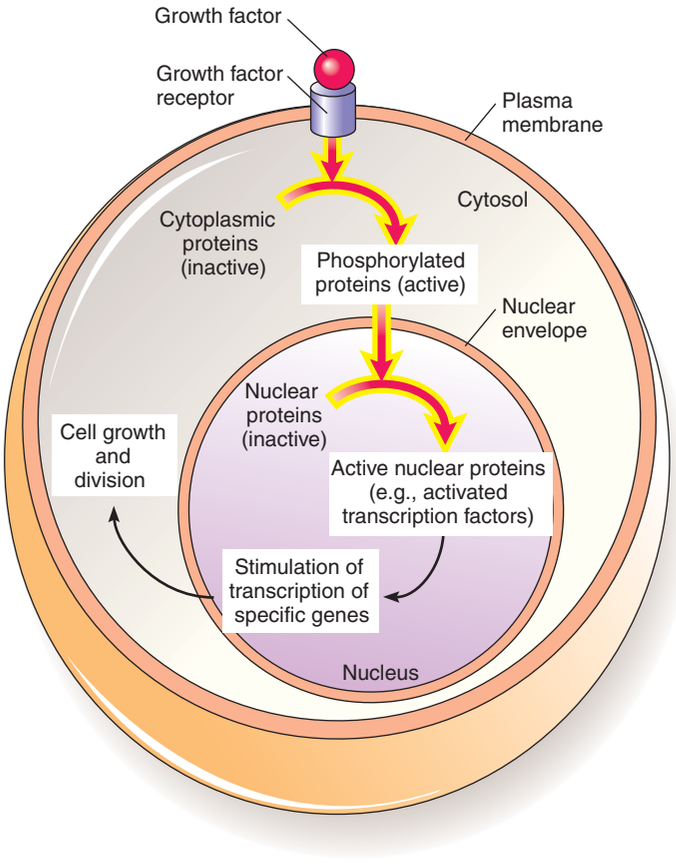

FIGURE **16-19** **A cell growth control cascade.**

In this example, a growth factor stimulates cell growth. The growth factor receptor and some of the other components of the system are coded for by proto-oncogenes. When a proto-oncogene mutates, becoming an oncogene, the cell grows and divides even in the absence of the growth factor.

viding. For example, in some cases a proto-oncogene encoding a growth factor receptor mutates in a way that compromises regulation of the receptor. It is always switched "on," even in the absence of the growth factor that normally controls it.

Not all genes that cause cancer when mutated are proto-oncogenes. About half of all cancers are caused by a mutation in a **tumor suppressor gene.** These genes, also known as *anti-oncogenes,* normally interact with growth-inhibiting factors to block cell division. When mutated they lose their ability to "put on the brakes," and uncontrolled growth ensues.

Currently, more than 100 oncogenes and 15 tumor suppressor genes have been identified. A change in a single proto-oncogene is usually insufficient to cause a cell to become malignant. The development of cancer is usually a multistep process involving both mutations that activate oncogenes and mutations that inactivate tumor suppressor genes. Additional factors, such as the inappropriate activation of the enzyme responsible for the maintenance of telomeres (see Chapter 11) or chromosomal translocation events (see Chapter 15), may also play a role. The Cancer Genome Project, a long-term international initiative based in Great Britain, is currently examining every human gene for cancer-related mutations. As more of these genes are discovered and their interactions unraveled, we will gain a fuller understanding of the control of growth and development. This understanding will improve the diagnosis and treatments of various types of cancer.

Review

- What are oncogenes? Tumor suppressor genes?
- How are oncogenes and tumor suppressor genes related to genes involved in the control of normal growth and development?
- How is a growth factor involved in a growth control cascade?

SUMMARY WITH KEY TERMS

1 Distinguish between cell determination and cell differentiation, and between nuclear equivalence and totipotency.

- **Development,** all the changes that occur in the life of an individual, includes the processes by which the descendants of a single cell specialize and organize into a complex organism.
- An organism contains many types of cells that are specialized both structurally and metabolically to carry out specific functions. These cells are the product of a process of gradual commitment, called **cell determination,** which ultimately leads to the final step in cell specialization, called **cell differentiation.** Differences among various cell types are apparently due to **differential gene expression.**
- There is no evidence that genes are normally lost during most developmental processes. At least some nuclei from differentiated plant and animal cells contain all the genetic material that would be present in the nucleus of a zygote. **Nuclear equivalence** is the concept that, with a few exceptions, all the nuclei of the differentiated **somatic cells** of an organism are identical to each other and to the nucleus of the single cell from which they descended. **Totipotency** is the capability of cells to direct the development of an entire organism.

2 Define *stem cells,* and describe some of the promising areas of research involving stem cells.

- **Stem cells** can divide to produce differentiated descendants, yet retain the ability to divide to maintain the stem cell population. Totipotent stem cells give rise to all cell types, whereas **pluripotent stem cells** give rise to many, but not all, types of cells in an organism.
- Stem cells show promise in treating diseases, such as Parkinson's disease and diabetes mellitus.

3 Point out some of the known exceptions to the principle of nuclear equivalence.

- **Genomic rearrangement** results in physical changes in the structure of a gene.
- **Gene amplification** provides more copies of certain genes for transcription.

SUMMARY WITH KEY TERMS

4 Indicate the features of *Drosophila melanogaster, Caenorhabditis elegans, Mus musculus,* and *Arabidopsis thaliana* that have made these organisms valuable models in developmental genetics.

- Developmental mutations have been identified in the fruit fly, *Drosophila melanogaster,* many of which affect the organism's segmented body plan.
- *Caenorhabditis elegans* is a roundworm with **mosaic development,** a rigid developmental pattern in which the fates of cells are restricted early in development. The lineage of every somatic cell in the adult is known, and each can be traced to a single **founder cell** in the early embryo.
- The laboratory mouse, *Mus musculus,* is extensively used in studies of mammalian development. In contrast to *C. elegans,* the mouse shows **regulative development;** the very early embryo is a self-regulating whole and can develop normally even if it has extra or missing cells. **Transgenic** mice, in which foreign genes have been incorporated, have helped researchers determine how genes are activated and regulated during development.
- Genes affecting development have also been identified in certain plants, including *Arabidopsis* and *Zea mays* (corn). The **ABC model** of interactions among three kinds of genes hypothesizes how floral organs develop in *Arabidopsis.* Mutations in these genes cause one flower part to be substituted for another.

5 Distinguish among maternal effect genes, segmentation genes, and homeotic genes in *Drosophila.*

- The earliest developmental events to operate in the egg are established by **maternal effect genes** in the surrounding maternal tissues, which are active prior to fertilization. Some produce gradients of **morphogens,** chemical agents that affect the differentiation and development of form. Maternal effect genes establish polarity in the embryo.
- **Segmentation genes** generate a repeating pattern of body segments within the embryo. **Gap genes** are segmentation genes that begin organizing the body into anterior, middle, and posterior regions. **Pair-rule genes** and **segment polarity genes** affect all segments instead of small groups of body segments.
- The later-acting **homeotic genes** are responsible for specifying the identity of each segment.

6 Explain the relationship between transcription factors and genes that control development.

- **Transcription factors** are DNA-binding proteins that regulate transcription in eukaryotes. Some genes that code for transcription factors contain a DNA sequence called a **homeobox,** which codes for a protein with a DNA-binding region called a **homeodomain.**
- Some homeobox genes are organized into complexes that appear to be systems of master genes specifying an organism's body plan. Parallels exist between the homeobox complexes of *Drosophila* and those of other animals.

7 Define *induction* and *apoptosis,* and give examples of the roles they play in development.

- **Induction** is developmental interactions with neighboring cells. During development in *C. elegans,* the anchor cell induces cells of the surface to organize to form the vulva, the structure through which the eggs are laid.
- **Apoptosis** is programmed cell death. During human development, the human hand forms as a webbed structure, but the fingers become individualized when the cells between them die.

8 Discuss the relationship between cancer and mutations that affect cell developmental processes.

- The traits of cancer cells are due to cancer-causing **oncogenes.** Oncogenes arise from changes in the expression of normal genes called **proto-oncogenes,** which exist in all cells and are involved in the control of growth and development.
- Known proto-oncogenes include genes that code for various **growth factors** or **growth factor receptors** and genes that respond to stimulation by growth factors, including many transcription factors. When a proto-oncogene is expressed inappropriately (becomes an oncogene), the cell may misinterpret the signal and respond by growing and dividing.
- **Tumor suppressor genes** normally interact with growth-inhibiting factors to block cell division. A mutation in a tumor suppressor gene may inactivate it, leading to cancer.

POST-TEST

1. Morphogenesis occurs through the multistep process of (a) differentiation (b) determination (c) pattern formation (d) totipotency (e) selection
2. The cloning experiments carried out on frogs demonstrated that (a) all differentiated frog cells are totipotent (b) some differentiated frog cells are totipotent (c) all nuclei from differentiated frog cells are totipotent (d) some nuclei from differentiated frog cells are totipotent (e) the mechanism of cell differentiation always requires the loss of certain genes
3. *Drosophila* is a particularly good model for developmental studies because (a) a large number of developmental mutants are available (b) it has a fixed number of somatic cells in the adult (c) its embryos are transparent (d) it is a vertebrate (e) all of the preceding
4. The anterior–posterior axis of a *Drosophila* embryo is first established by certain (a) homeotic genes (b) maternal effect genes (c) segmentation genes (d) chronogenes (e) pair-rule genes
5. You discover a new *Drosophila* mutant in which mouthparts appear where the antennae are normally found. You predict that the mutated gene is most likely a (a) homeotic gene (b) gap gene (c) pair-rule gene (d) maternal effect gene (e) segment polarity gene
6. Most segmentation genes code for (a) transfer RNAs (b) enzymes (c) transcription factors (d) histones (e) transport proteins
7. The developmental pattern of *C. elegans* is said to be mosaic because (a) development is controlled by gradients of morphogens (b) part of the embryo fails to develop if a founder cell is destroyed (c) some individuals are self-fertilizing hermaphrodites (d) all development is controlled by maternal effect genes (e) apoptosis never occurs
8. The formation of the vulva, the structure through which eggs are laid, in *C. elegans* involves (a) maternal effect genes that organize the egg cytoplasm (b) gradients of morphogens in the eggs (c) groups of *Hox* genes that form the *Antennapedia* complex and

POST-TEST *(continued)*

bithorax complex (d) induction of surface cells by the anchor cell (e) mutations in chronogenes, which control developmental timing

9. Which of the following illustrates the regulative nature of early mouse development? (a) the mouse embryo is free-living prior to implantation in the uterus (b) it is possible to produce a transgenic mouse (c) it is possible to produce a mouse in which a specific gene has been knocked out (d) genes related to *Drosophila* homeotic genes have been identified in mice (e) a chimeric mouse can be produced by fusing two mouse embryos
10. When the human gene that codes for insulin is introduced into fertilized mouse eggs that are subsequently allowed to develop, the insulin gene is correctly expressed in the mouse's pancreatic cells. This indicates that (a) the gene that codes for insulin is analogous to the homeotic genes of *Drosophila* (b) the signals for tissue-specific gene expression are highly conserved through evolution (c) like humans, the mouse has polytene chromosomes (d) unlike the rigid developmental pattern of *C. elegans,* the development of mice and humans is highly regulative (e) genomic rearrangements have occurred in the mouse embryo
11. *Arabidopsis* is useful as a model organism for the study of plant development because (a) it is of great economic importance (b) it has large polytene chromosomes (c) many developmental mutants have been isolated (d) it contains a large amount of DNA per cell (e) it has a rigid developmental pattern
12. According to the ABC model of floral organ development in *Arabidopsis,* the A gene is needed to specify sepals, the A and B genes to specify petals, the B and C genes to specify stamens, and the C gene to specify the pistil. If a mutation occurs in one of the B genes, rendering it inactive, the resulting flowers will consist of (a) sepals, petals, stamens, and pistils, (b) sepals, stamens, and pistils (c) petals, stamens, and pistils (d) sepals and pistils (e) petals and stamens
13. Pluripotent stem cells (a) lose genetic material during development (b) give rise to many, but not all, types of cells in an organism (c) organize into recognizable structures through pattern formation (d) cannot grow in tissue culture (e) have been used to clone a sheep and several other mammals
14. The genetic material for Dolly, the first cloned sheep, was a nucleus from (a) an early sheep embryo (b) cultured cancer cells (c) intestinal epithelial cells (d) a mouse–sheep chimera (e) a cultured mammary gland cell
15. Genomic rearrangement is an exception to the principle of (a) nuclear equivalence (b) pattern formation (c) morphogenesis (d) differential gene expression (e) mosaic development
16. Which of the following statements about cancer is *false?* (a) Oncogenes arise from mutations in proto-oncogenes. (b) Tumor suppressor genes normally interact with growth-inhibiting factors to block cell division (c) More than 100 oncogenes and 15 tumor suppressor genes have been identified (d) Oncogenes were first discovered in mouse models for cancer (e) The development of cancer is usually a multistep process involving both oncogenes and mutated tumor suppressor genes
17. Proto-oncogenes code for (a) morphogens (b) antibodies for immune responses (c) growth factor receptors and other components of the growth control cascade (d) enzymes such as reverse transcriptase (e) proteins such as chorion protein

CRITICAL THINKING

1. Why is an understanding of gene regulation in eukaryotes crucial to an understanding of developmental processes?
2. Why is it necessary for scientists to study development in more than one type of organism?
3. Could a gene be involved in the growth of both stem cells and some kinds of cancer? Explain your answer.

Introduction to Darwinian Evolution

The Granger Collection, New York

Charles Darwin. This portrait was made shortly after Darwin returned to England from his voyage around the world.

CHAPTER OUTLINE

- Pre-Darwinian Ideas about Evolution
- Darwin and Evolution
- Evidence for Evolution

The biological diversity represented by the millions of species currently living on our planet may have evolved from a single ancestor during Earth's long history. Thus organisms that are radically different from each other, such as slime molds and crocodiles, are in fact distantly related, linked through numerous intermediate ancestors to a single, common ancestor. The British naturalist Charles Darwin (1809–1882), shown here at age 31, developed a remarkably simple, scientifically testable mechanism to explain this. He argued persuasively that all the species that exist today, as well as the countless extinct species that existed in the past, arose from earlier ones by a process of gradual *divergence* (splitting into separate evolutionary pathways), or evolution.

Evolution is defined as the accumulation of inherited changes within populations over time. A **population** is a group of individuals of one species that live in the same geographic area at the same time. The term *evolution* does not refer to changes that occur in an individual within its lifetime. Instead, it refers to changes in the characteristics of populations over the course of generations. These changes may be so small they are difficult to detect or so great that the population differs markedly from its ancestral population. Eventually, two populations may diverge to such a degree that we refer to them as different species. (The concept of species is developed extensively in Chapter 19. For now, a simple working definition is that a **species** is a group of organisms, with similar structure, function, and behavior, that are capable of interbreeding with one another.) Thus evolution has two main perspectives—the minor evolutionary changes of populations usually viewed over a few generations (*microevolution,* see Chapter 18), and the major evolutionary events usually viewed over a long period, such as formation of different species from common ancestors (*macroevolution*—see Chapter 19).

The concept of evolution is the cornerstone of biology, because it links all fields of the life sciences into a unified body of knowledge. As geneticist Theodosius Dobzhansky put it, "Nothing in biology makes sense except in the light of evolution."[1] Biologists seek to understand both the remarkable variety as well as the fundamental similarities of organisms within the context of evolution. The science of evolution allows biologists to compare common threads among organisms as seemingly different as bacteria, whales, lilies, and tapeworms. Behavioral evolution, evolutionary developmental biology, evolutionary genetics, evolutionary ecology, evolutionary systematics, and molecular evolution are examples of some of the biological disciplines that focus on evolution.

Evolution also has important practical applications. Agriculture must deal with the evolution of pesticide resistance in insects and other pests, and agricultural scientists strive to develop techniques that slow the evolutionary process in pest organisms. Likewise, medicine must respond to the rapid evolutionary potential of disease-causing organisms such as bacteria. (Significant evolutionary change occurs in a very short time period in insects, bacteria, and other organisms with short life spans.) Medical researchers use evolutionary principles to predict which flu strains are evolving more quickly, information the scientists need to make next year's flu vaccine. The conservation management of rare and endangered species makes use of the evolutionary principles of population genetics (see Chapter 18). The rapid evolution of bacteria and fungi in polluted soils is used in the field of **bioremediation,** in which microorganisms are employed to clean up hazardous waste sites. Evolution even has applications beyond biology. For example, certain computer applications make use of algorithms that mimic natural selection in biological systems.

This chapter discusses Darwin and the scientific development of the theory of evolution by natural selection. It also presents several kinds of evidence that support evolution, including fossils, comparative anatomy, biogeography, developmental biology, molecular biology, and experimental studies of ongoing evolutionary change, both in the laboratory and in nature. ■

PRE-DARWINIAN IDEAS ABOUT EVOLUTION

Learning Objective

1 Discuss the historical development of the theory of evolution.

Although Darwin is universally associated with evolution, ideas of evolution predate Darwin by centuries. Aristotle (384–322 B.C.E.) saw much evidence of natural affinities among organisms. This led him to arrange all the organisms he knew in a "scale of nature" that extended from the exceedingly simple to the most complex. Aristotle visualized organisms as being imperfect but "moving toward a more perfect state." Some scientific historians have interpreted this idea as the forerunner of evolutionary theory, but Aristotle was vague on the nature of this "movement toward perfection" and certainly did not propose that natural processes drove the process of evolution. Furthermore, modern evolutionary theory now recognizes that evolution does not move toward more "perfect" states, nor even necessarily toward greater complexity.

Long before Darwin, fossils had been discovered embedded in rocks. Some of these corresponded to parts of familiar species, but others were strangely unlike any known species. Fossils were often found in unexpected contexts. Marine invertebrates (sea animals without backbones) were sometimes discovered in rocks high on mountains. Leonardo da Vinci (1452–1519) was among the first to correctly interpret these unusual finds as the remains of animals that had existed in previous ages but had become extinct.

The French naturalist Jean Baptiste de Lamarck (1744–1829) was the first scientist to propose that organisms undergo change over time as a result of some natural phenomenon rather than divine intervention. According to Lamarck, a changing environment caused an organism to alter its behavior, thereby using some organs or body parts more and others less. Over several generations, a given organ or body part would increase in size if it was used a lot, or shrink and possibly disappear if it was used less. His hypothesis required that organisms pass traits they acquired during their lifetimes to their offspring. For example, Lamarck suggested that the long neck of the giraffe developed when a short-necked ancestor stretched its neck to browse on the leaves of trees. Its offspring inherited the longer neck, which stretched still further as they ate. This process, repeated over many generations, resulted in the long necks of modern giraffes. In his *Philosophie Zoologique,* published in 1809, Lamarck presented this explanation for how organisms evolved. Lamarck also thought all organisms were endowed with a vital force that drove them to change toward greater complexity and "perfection" over time.

Lamarck's proposed mechanism of evolution is quite different from the mechanism later proposed by Darwin. However, Lamarck's hypothesis remained a reasonable explanation for evolution until Mendel's basis of heredity was rediscovered at the beginning of the 20th century. At that time, Lamarck's ideas were largely discredited.

Review

- Why is Aristotle linked to early evolutionary thought?
- What were Jean Baptiste de Lamarck's ideas concerning evolution?

DARWIN AND EVOLUTION

Learning Objectives

2 Define *evolution,* and explain the four premises of evolution by natural selection as proposed by Charles Darwin.

3 Compare the modern synthesis with Darwin's original theory of evolution.

PROCESS OF SCIENCE

Darwin, the son of a prominent physician, was sent at the age of 15 to study medicine at the University of Edinburgh. Finding himself unsuited for medicine, he transferred to Cambridge University to study theology. During that time, he became the protégé of the Rev. John Henslow, who was a professor of botany. Henslow encouraged Darwin's interest in the natural world. Shortly after receiving his degree, Darwin embarked on the H.M.S. *Beagle,* which was taking a five-year exploratory cruise around the world to prepare navigation charts for the British Navy.

The *Beagle* left Plymouth, England, in 1831 and cruised along the east and west coasts of South America (Fig. 17-1). While other members of the crew mapped the coasts and harbors, Darwin spent many weeks ashore studying the animals, plants, fossils, and geological formations of both coastal and inland regions, areas that had not been extensively explored. He collected and cataloged thousands of plant and animal specimens and kept notes of his observations, information that became essential in the development of his theory.

The *Beagle* spent almost two months at the Galapagos Islands, 965 km (600 mi) west of Ecuador, where Darwin continued his observations and collections. He compared the animals and plants of the Galapagos with those of the South American mainland. He was particularly impressed by their similarities and wondered why the organisms of the Galapagos should resemble those from South America more than those from other islands in different parts of the world. Moreover, although there were similarities between Galapagos and South American species, there were also distinct differences. There were even recognizable differences in the reptiles and birds from one island to the next. After he returned home, Darwin pondered these observations and attempted to develop a satisfactory explanation for the distribution of species among the islands.

Darwin drew on several lines of evidence when considering how species might have originated. Despite the work of Lamarck, the general notion in the mid-1800s was that Earth was too young for organisms to have changed significantly since they had first appeared. During the early 19th century, however, geologists advanced the idea that mountains, valleys, and other physical features of Earth's surface did not originate in their present forms. Instead, these features developed slowly over long periods by the geological processes of volcanic activity, uplift, erosion, and glaciation. Darwin took *Principles of Geology,* published by English geologist Charles Lyell in 1830, with him on his voyage and studied it carefully. Lyell provided an important concept for Darwin—that the slow pace of geological processes, which still occur today, indicated that Earth was extremely old.

Other important evidence that influenced Darwin was the fact that breeders and farmers could develop many varieties of domesticated animals in just a few generations (Fig. 17-2). They did so by choosing certain traits and breeding only individuals that exhibited the desired traits, a procedure known as **artificial selection.** Breeders, for example, have produced numerous dog varieties—bloodhounds, Dalmatians, Airedales, border collies, and Pekinese, to name a few—by artificial selection.

Many plant varieties were also produced by artificial selection. For example, cabbage, broccoli, brussels sprouts, cauliflower, collard greens, kale, and kohlrabi are distinct vegetable crops that are all members of the same species, *Brassica oleracea* (Fig. 17-3). Selective breeding of the colewort, or wild cabbage, a leafy plant native to Europe and Asia, produced all seven vegetables. Beginning more than 4000 years ago, some farmers artificially selected wild cabbage plants that formed overlapping leaves. Over time, these leaves became so prominent that the plants, which resembled modern cabbages, became recognized as separate and distinct from their wild cabbage ancestor. Other farmers selected different features of the wild cabbage, giving rise to the other modifications. For example, kohlrabi was pro-

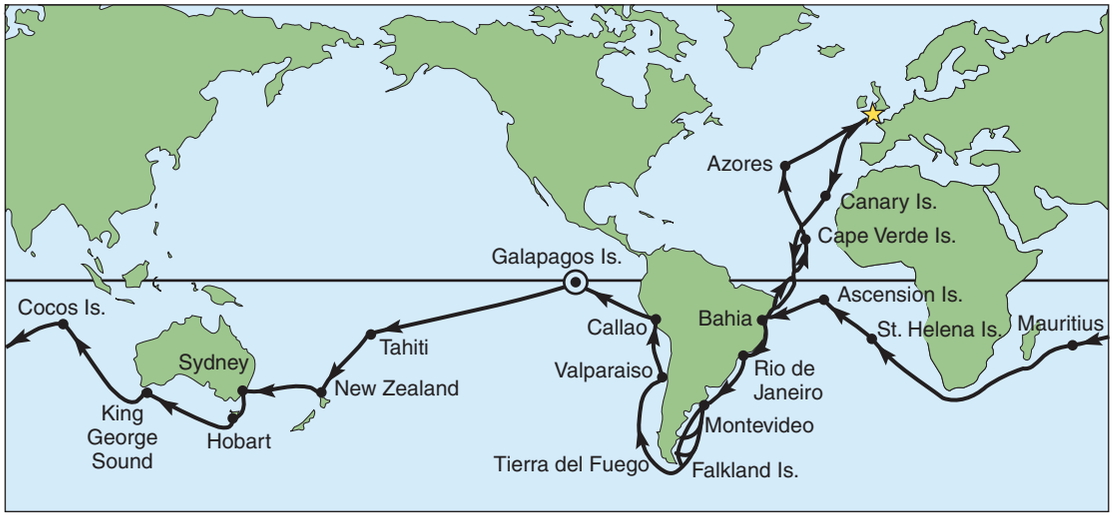

FIGURE **17-1**

The voyage of H.M.S. *Beagle*.

The five-year voyage began in Plymouth, England *(star),* in 1831. Observations made in the Galapagos Islands *(bull's-eye)* off the western coast of South America helped Darwin discover a satisfactory mechanism to explain how a population of organisms could change over time.

Eric Sander

FIGURE **17-2** **Artificial selection in chickens.**
Shown is a chicken that was deliberately bred to resemble Big Bird on *Sesame Street*. Show breeds of chickens exhibit a great deal of variation. Domestic chickens are not a recognizable breed but are hybrids bred for meat or egg production.

duced by selection for an enlarged storage stem, and brussels sprouts by selection for enlarged axillary buds. Thus humans are responsible for the evolution of *B. oleracea* into seven distinct vegetable crops. Darwin was impressed by the changes induced by artificial selection and hypothesized that a similar selective process occurred in nature. Darwin therefore used artificial selection as a model when he developed the concept of natural selection.

The ideas of Thomas Malthus (1766–1834), a British clergyman and economist, were another important influence on Darwin. In *An Essay on the Principle of Population as It Affects the Future Improvement of Society,* published in 1798, Malthus noted that population growth is not always desirable—a view contrary to the beliefs of his day. He observed that populations have the capacity to increase geometrically ($1 \longrightarrow 2 \longrightarrow 4 \longrightarrow 8 \longrightarrow 16$) and thus outstrip the food supply, which only has the capacity to increase arithmetically ($1 \longrightarrow 2 \longrightarrow 3 \longrightarrow 4 \longrightarrow 5$). In the case of humans, Malthus suggested that the conflict between population and food supply generates famine, disease, and war, which serve as inevitable brakes on population growth.

Image not available due to copyright restrictions

Darwin proposed that evolution occurs by natural selection

Malthus's idea that there is a strong and constant check on human population growth strongly influenced Darwin's explanation of evolution. Darwin's years of observing the habits of animals and plants had introduced him to the struggle for existence described by Malthus. It occurred to Darwin that in this struggle inherited variations favorable to survival would tend to be preserved, whereas unfavorable ones would be eliminated. The result would be **adaptation,** an evolutionary modification that improves the chances of survival and reproductive success in a given environment. Eventually, the accumulation of modifications might result in a new species. Time was the only thing required for new species to originate, and the geologists of the era, including Lyell, had supplied evidence that Earth was indeed old enough to provide an adequate period.

Darwin had at last developed a workable explanation of evolution, that of **natural selection,** in which better adapted organisms are more likely to survive and become the parents of the next generation. As a result of natural selection, the population changes over time; the frequency of favorable traits increases in successive generations, whereas less favorable traits become scarce or disappear. Darwin spent the next 20 years formulating his arguments for natural selection, accumulating an immense body of evidence to support his theory, and corresponding with other scientists.

As Darwin was pondering his ideas, Alfred Russel Wallace (1823–1913), a British naturalist who studied the plants and

animals of the Malay Archipelago for eight years, was similarly struck by the diversity of species and the peculiarities of their distribution. He wrote a brief essay on this subject and sent it to Darwin, by then a world-renowned biologist, asking his opinion. Darwin recognized his own theory and realized Wallace had independently arrived at the same conclusion—that evolution occurs by natural selection. Darwin's colleagues persuaded him to present Wallace's manuscript along with an abstract of his own work, which he had prepared and circulated to a few friends several years earlier. Both papers were presented in July 1858 at a London meeting of the Linnaean Society. Darwin's monumental book, *The Origin of Species by Natural Selection; or, The Preservation of Favored Races in the Struggle for Life,* was published in 1859. Wallace's book, *Contributions to the Theory of Natural Selection,* was published in 1870, eight years after he returned from the Malay Archipelago.

Darwin's mechanism of evolution by natural selection consists of observations on four aspects of the natural world: variation, overproduction, limits on population growth, and differential reproductive success.

1. *Variation.* The individuals in a population exhibit variation. Each individual has a unique combination of traits, such as size, color, and ability to tolerate harsh environmental conditions. Some traits improve an individual's chances of survival and reproductive success, whereas others do not. Remember, the variation necessary for evolution by natural selection must be inherited (Fig. 17-4). Although Darwin recognized the importance to evolution of inherited variation, he did not know the mechanism of inheritance.
2. *Overproduction.* The reproductive ability of each species has the potential to cause its population to geometrically increase over time. A female frog lays about 10,000 eggs, and a female cod produces perhaps 40 million eggs! In each case, however, only about two offspring survive to reproduce. Thus in every generation each species has the capacity to produce more offspring than can survive.
3. *Limits on population growth,* or a struggle for existence. There is only so much food, water, light, growing space, and other resources available to a population, so organisms compete with one another for these limited resources. Because there are more individuals than the environment can support, not all survive to reproduce. Other limits on population growth include predators, disease organisms, and unfavorable weather conditions.
4. *Differential reproductive success.* Those individuals that have the most favorable combination of characteristics (those that make individuals better adapted to their environment) are more likely to survive and reproduce. Offspring tend to resemble their parents, because the next generation inherits the parents' genetically based traits. Successful reproduction is the key to natural selection: The best adapted individuals produce the most offspring, whereas individuals that are less well adapted die prematurely or produce fewer or inferior offspring.

Over time, enough changes may accumulate in geographically separated populations (often with slightly different environments) to produce new species. Darwin noted that the Galapagos finches appeared to have evolved in this way. The 13 species are all descended from a single species that found its way from the South American mainland. (The blue-black grassquit, a bird that lives in western South America, may be a close relative of the Galapagos finches.) The different islands of the Galapagos kept the finches isolated from one another, thereby allowing them to diverge into 13 separate species. Of the 13 species, 6 are seed eaters, 6 are insect eaters, and 1 is a woodpecker-type insect eater. The evolution of new species is considered in greater detail in Chapter 19.

BIOS/Peter Arnold, Inc.

FIGURE **17-4** **Genetic variation in emerald tree boas.**
These snakes, all of the same species (*Corallus caninus*), were caught in a small section of forest in French Guiana. Many snake species exhibit considerable variation in their coloration and patterns.

The modern synthesis combines Darwin's theory with genetics

PROCESS OF SCIENCE

One of the premises on which Darwin based his theory of evolution by natural selection is that individuals transmit traits to the next generation. However, Darwin was unable to explain *how* this occurs or *why* individuals vary within a population. Although he was a contemporary of Gregor Mendel (see Chapter 10), who elucidated the basic patterns of inheritance, Darwin was apparently not acquainted with Mendel's work, which was not recognized by the scientific community until the early part of the 20th century.

Beginning in the 1930s and 1940s, biologists experienced a conceptual breakthough when they combined the principles of Mendelian inheritance with Darwin's theory of natural selection. The result was a unified explanation of evolution known as the **modern synthesis,** or the **synthetic theory of evolution.** In this context, *synthesis* refers to combining parts of several previous theories to form a unified whole. Some of the founders of

the modern synthesis were Russian geneticist Theodosius Dobzhansky (1900–1975), British geneticist and statistician Ronald Fisher (1890–1962), British geneticist J.B.S. Haldane (1892–1964), British biologist Julian Huxley (1887–1975), German taxonomist Ernst Mayr (1904–), U.S. paleontologist George Gaylord Simpson (1902–1984), U.S. botanist G. Ledyard Stebbins (1906–2000) and U.S. geneticist Sewell Wright (1889–1988).

Today, the modern synthesis incorporates our expanding knowledge in genetics, systematics, paleontology, developmental biology, behavior, and ecology. It explains Darwin's observation of variation among offspring in terms of **mutation,** or changes in DNA, such as nucleotide substitutions. Mutations provide the genetic variability on which natural selection acts during evolution. The modern synthesis, which emphasizes the genetics of populations as the central focus of evolution, has held up well since it was developed. It has dominated the thinking and research of biologists working in many areas and has resulted in an enormous accumulation of new discoveries that validate evolution by natural selection.

Most biologists not only accept the basic principles of the modern synthesis but also try to better understand the causal processes of evolution. For example, what is the role of chance in evolution? How rapidly do new species evolve? These and other questions have arisen in part from a re-evaluation of the fossil record and in part from new discoveries in molecular aspects of inheritance. Such critical analyses are an integral part of the scientific process because they stimulate additional observation and experimentation, along with re-examination of previous evidence. Science is an ongoing process, and information obtained in the future may require modifications to certain parts of the modern synthesis.

We now consider one of the many evolutionary questions currently being addressed by biologists: the relative effects of chance and natural selection on evolution.

Biologists study the effect of chance on evolution

Biologists have wondered, if we were able to repeat evolution by starting with similar organisms exposed to similar environmental conditions, would we get the same results? That is, would the same kinds of changes evolve, as a result of natural selection? Or would the organisms be quite different, as a result of random events? Several recently reported examples of evolution in action suggest that chance may not be as important as natural selection, at least at the population level.

A fruit fly species (*Drosophila subobscura*) native to Europe inhabits areas from Denmark to Spain. Biologists had noted that the northern flies have larger wings than southern flies (Fig. 17-5). The same fly species was accidentally introduced to North and South America in the late 1970s, in two separate introductions. Ten years after its introduction to the Americas, biologists determined that no statistically significant changes in wing size had occurred in the different regions of North America. However, 20 years after its introduction, the fruit flies in North America exhibited the same type of north–south wing changes as in Europe. (It is not known why larger wings evolve in northern areas and smaller wings in southern climates.)

George Gilchrist

FIGURE **17-5** **Wing size in female fruit flies.**

In Europe, female fruit flies (*Drosophila subobscura*) in northern countries have larger wings than flies in southern countries. Shown are two flies: one from Denmark *(right)* and the other from Spain *(left)*. The same evolutionary pattern emerged in North America after the accidental introduction of *D. subobscura* to the Americas.

A study of the evolution of fish known as *sticklebacks* in three coastal lakes of west Canada yielded intriguingly similar results to the fruit fly study. Molecular evidence indicates that when the lakes first formed several thousand years ago, they were populated with the same ancestral species. (Analysis of the mitochondrial DNA of sticklebacks in the three lakes supports the hypothesis of a common ancestor.) In each lake, the same two species have evolved from the common ancestral fish: One species is large and consumes invertebrates along the bottom of the lake, whereas the other species is smaller and consumes plankton at the lake's surface. Members of the two species within a single lake do not interbreed with one another, but individuals of the larger species from one lake interbreed in captivity with individuals of the larger species from the other lakes. Similarly, smaller individuals from one lake interbreed with smaller individuals from the other lakes.

In these examples, natural selection appears to be a more important agent of evolutionary change than chance. If chance were the most important factor influencing the direction of evolution, then fruit fly evolution would not have proceeded the same way on two different continents, and stickleback evolution would not have proceeded the same way in three different lakes. However, just because we have many examples of the importance of natural selection in evolution, it does not necessarily follow that random events should be discounted as a factor in directing evolutionary change. Proponents of the role of chance think chance is more important in the evolution of major taxonomic groups (macroevolution) than in the evolution of populations (microevolution). It also may be that random events take place but their effects on evolution are simply harder to demonstrate than natural selection.

Review

- What is natural selection?
- Why are only inherited variations important in the evolutionary process?
- What part of Darwin's theory was he unable to explain? How does the modern synthesis fill this gap?

EVIDENCE FOR EVOLUTION

Learning Objectives

4 Summarize the evidence for evolution obtained from the fossil record.
5 Summarize the evidence for evolution derived from comparative anatomy.
6 Define *biogeography,* and summarize how the distribution of organisms supports evolution.
7 Briefly explain how developmental biology provides insights into the evolutionary process.
8 Give an example of how evolutionary hypotheses are tested experimentally.

A vast body of scientific evidence supports evolution, including observations from the fossil record, comparative anatomy, biogeography, developmental biology, and molecular biology. In addition, evolutionary hypotheses are increasingly being tested experimentally.

The fossil record provides strong evidence for evolution

Perhaps the most direct evidence for evolution comes from the discovery, identification, and interpretation of **fossils,** which are the remains or traces typically left in sedimentary rock by previously existing organisms. (The term *fossil* comes from the Latin word *fossilis,* meaning "something dug up.") Sedimentary rock forms by the accumulation and solidification of particles (pebbles, sand, silt, or clay) produced by the weathering of older rocks, such as volcanic rocks. The sediment particles, which are usually deposited on a riverbed, lake bottom, or the ocean floor, accumulate over time and exhibit distinct layers (Fig. 17-6). In an undisturbed rock sequence, the oldest layer is at the bottom, and upper layers are successively younger. The study of sedimentary rock layers, including their composition, arrangement, and correlation (similarity) from one location to another, enables geologists to place events recorded in rocks in their correct sequence.

The fossil record shows a progression from the earliest unicellular organisms to the many unicellular and multicellular organisms living today. The fossil record therefore demonstrates that life has evolved through time. To date, paleontologists (scientists who study extinct species) have described and named about 300,000 fossil species, and more are being discovered all the time.

Image not available due to copyright restrictions

Although most fossils are preserved in sedimentary rock, some more recent remains have been exceptionally well preserved in bogs, tar, amber (ancient tree resin), or ice (Fig. 17-7). For example, the remains of a woolly mammoth deep-frozen in Siberian ice for more than 25,000 years were so well preserved that part of its DNA could be analyzed.

The formation and preservation of a fossil require that an organism be buried under conditions that slow or prevent the decay process. This is most likely to occur if an organism's remains are covered quickly by a sediment of fine soil particles suspended in water. In this way remains of aquatic organisms may be trapped in bogs, mud flats, sandbars, or deltas. Remains of terrestrial organisms that lived on a flood plain may also be covered by water-borne sediments or, if the organism lived in an arid region, by wind-blown sand. Over time, the sediments harden to form sedimentary rock, and minerals usually replace the organism's remains so that many details of its structure, even cellular details, remain.

The fossil record is not a random sample of past life but instead is biased toward aquatic organisms and those living in the few terrestrial habitats conducive to fossil formation. Relatively few fossils of tropical rainforest organisms have been found, for example, because their remains decay extremely rapidly on the forest floor, before fossils can develop. Another reason for bias in the fossil record is that organisms with hard body parts such

The logs were exposed as the mudstone layers in which they were buried weathered. **(c)** A 2-million-year-old insect fossil (a midge) was embedded in amber. **(d)** A cast fossil of ancient echinoderms called *crinoids* formed when the crinoids decomposed, leaving a mold that later filled with dissolved minerals that hardened. **(e)** Dinosaur footprints, each 75 to 90 cm (2.5 to 3 ft) in length, provide clues about the posture, gait, and behavior of these extinct animals.

as bones and shells are more likely to form fossils than are those with soft body parts.

PROCESS OF SCIENCE

Because of the nature of the scientific process, each fossil discovery represents a separate "test" of the theory of evolution. If any of the tests fail, the theory would have to be modified to fit the existing evidence. The verifiable discovery, for example, of fossil remains of modern humans (*Homo sapiens*) in Precambrian rocks, which are more than 570 million years old, would falsify the theory of evolution as currently proposed. However, Precambrian rocks examined to date contain only fossils of simple organisms, such as algae and small, soft-bodied animals, that evolved early in the history of life. The earliest fossils of *H. sapiens* with anatomically modern features do not appear in the fossil record until approximately 100,000 years ago (see Chapter 21).

Fossils provide a record of ancient organisms and some understanding of where and when they lived. Using fossils of organisms from different geological ages, the lines of descent (evolutionary relationships) that gave rise to modern-day organisms can sometimes be inferred. In many instances, fossils provide direct evidence of the origin of new species from preexisting species, including many transitional forms.

Transitional fossils document whale evolution

Over the past century biologists have found evidence suggesting that whales and other cetaceans (an order of marine mammals) evolved from land-dwelling mammals. During the 1980s and 1990s, paleontologists discovered several fossil intermediates in whale evolution that document the whales' transition from land to water. Fossil evidence suggests that one candidate for the ancestor of whales is a now-extinct group of four-legged, land-dwelling mammals called *mesonychians* (Fig. 17-8a). These animals had unusually large heads and teeth that were remarkably similar to those of the earliest whales. About 50 million to 60 million years ago (mya), some descendants of mesonychians had adapted to swimming in shallow seas.

Fossils of *Ambulocetus natans,* a 50-million-year-old whale discovered in Pakistan, have many features of modern whales but also possess hind limbs and feet (Fig. 17-8b). (Modern whales do not have hindlimbs, although *vestigial* pelvic and hindlimb bones persist. Vestigial structures are discussed later in the chapter.) The vertebrae of *Ambulocetus*' lower back were very flexible, allowing the back to move dorsoventrally (up and down) during swimming and diving, as with modern whales. In addition to swimming, this ancient whale moved about on land, perhaps as sea lions do today.

Rodhocetus is a fossil whale found in slightly younger rocks in Pakistan (Fig. 17-8c). The vertebrae of *Rodhocetus* were even more flexible than those found in *Ambulocetus.* The flexible vertebrae allowed *Rodhocetus* a more powerful dorsoventral movement during swimming. *Rodhocetus* may have been totally aquatic.

By 40 mya, the whale transition from land to ocean was almost complete. Egyptian fossils of *Basilosaurus* show a whale with a streamlined body and front flippers for steering, like modern-day whales (Fig. 17-8d). *Basilosaurus* retained vestiges

of its land-dwelling ancestors—a pair of reduced hindlimbs that were disjointed from the backbone and probably not used in locomotion. Reduction in the hindlimbs continued to the present. The modern blue whale has vestigial pelvis and femur bones embedded in its body (Fig. 17-8e).

Various methods determine the age of fossils

Because layers of sedimentary rock occur naturally in the sequence of their deposition, with the more recent layers on top of the older, earlier ones, most fossils are dated by their relative position in sedimentary rock. However, geological events occurring after the rocks were initially formed have occasionally changed the relationships of some rock layers. Geologists identify specific sedimentary rocks not only by their positions in layers but also by features such as mineral content and by the fossilized remains of certain organisms, known as **index fossils,** that characterize a specific layer over large geographical areas. Index fossils are fossils of organisms that existed for a relatively short geological time but were preserved as fossils in large numbers. With this information, geologists can arrange rock layers and the fossils they contain in chronological order and identify comparable layers in widely separated locations.

Radioactive isotopes, also called **radioisotopes,** present in a rock provide a means to accurately measure its age (see Chapter 2). Radioisotopes emit invisible radiations. As a radioisotope emits radiation, its nucleus changes into the nucleus of a different element in a process known as **radioactive decay.** The radioactive nucleus of uranium-235, for example, decays into lead-207.

Each radioisotope has its own characteristic rate of decay. The time required for one half of the atoms of a radioisotope to change into a different atom is known as its **half-life** (Fig. 17-9). Radioisotopes differ significantly in their half-lives. For example, the half-life of iodine-132 is only 2.4 hours, whereas the half-life of uranium-235 is 704 million years. The half-life of a particular radioisotope is constant and does not vary with temperature, pressure, or any other environmental factor.

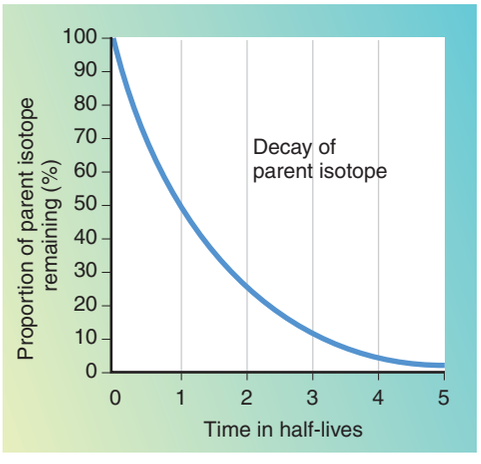

FIGURE **17-9** **Radioisotope decay.**

At time zero, the sample is composed entirely of the radioisotope, and the radioactive clock begins ticking. After one half-life, only 50% of the original radioisotope remains. During each succeeding half-life, half of the remaining radioisotope is converted to decay product(s).

The age of a fossil in sedimentary rock is usually estimated by measuring the relative proportions of the original radioisotope and its decay product in volcanic rock intrusions that penetrate the sediments. For example, the half-life of potassium-40 is 1.3 billion years, meaning that in 1.3 billion years half of the radioactive potassium will have decayed into its decay product, argon-40. The radioactive clock begins ticking when the magma solidifies into volcanic rock. The rock initially contains some potassium but no argon. Because argon is a gas, it escapes from hot rock as soon as it forms, but when potassium decays in rock that has cooled and solidified, the argon accumulates in the crystalline structure of the rock. If the ratio of potassium-40 to argon-40 in the rock being tested is 1:1, the rock is 1.3 billion years old.

Several radioisotopes are commonly used to date fossils. These include potassium-40 (half-life 1.3 billion years), uranium-235 (half-life 704 million years), and carbon-14 (half-life 5730 years). Potassium-40, with its long half-life, is used to date fossils that are many hundreds of millions of years old. Radioisotopes other than carbon-14 are used to date the *rock* in which fossils are found, whereas carbon-14 is used to date the *carbon remains* of anything that was once living, such as wood, bones, and shells. Whenever possible, the age of a fossil is independently verified using two or more different radioisotopes.

Carbon-14, which is continuously produced in the atmosphere from nitrogen-14 (by cosmic radiation), subsequently decays back to nitrogen-14. Because the formation and the decay of carbon-14 occur at constant rates, the ratio of carbon-14 to carbon-12 (a more abundant, stable isotope of carbon) is constant in the atmosphere. Organisms absorb carbon from the atmosphere either directly (by photosynthesis) or indirectly (by consuming photosynthetic organisms). Since each organism absorbs carbon from the atmosphere, its ratio of carbon-14 to carbon-12 is the same as the atmosphere. When an organism dies, however, it no longer absorbs carbon, and the proportion of carbon-14 in its remains declines as carbon-14 decays to nitrogen-14. Because of its relatively short half-life, carbon-14 is useful for dating fossils that are 50,000 years old or less. It is particularly useful for dating archaeological sites.

Comparative anatomy of related species demonstrates similarities in their structures

Comparing the structural details of features found in different but related organisms reveals a basic similarity. Such features that are derived from the same structure in a common ancestor are termed **homologous features;** the condition is known as **homology.** For example, consider the limb bones of mammals. A human arm, a cat forelimb, a whale front flipper, and a bat wing, although quite different in appearance, have strikingly similar arrangements of bones, muscles, and nerves. Figure 17-10 shows a comparison of their skeletal structures. Each has a single

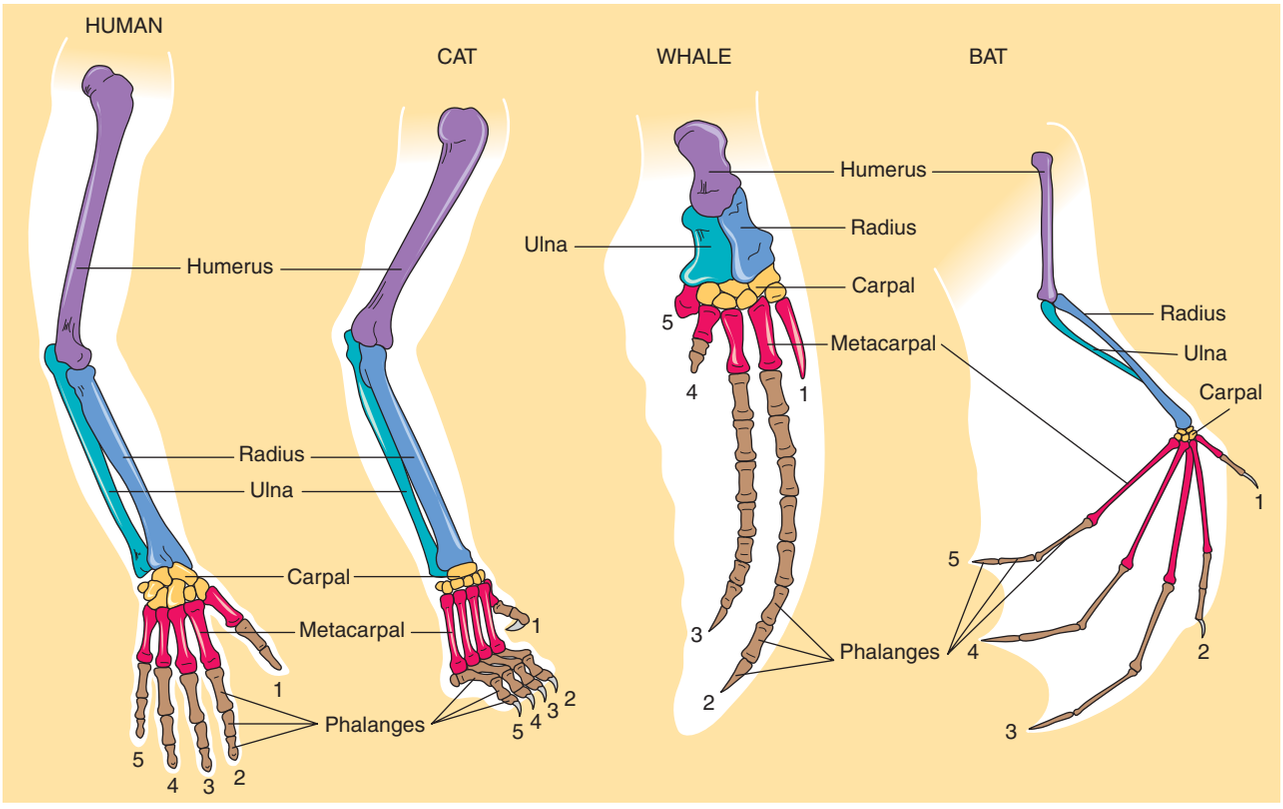

FIGURE **17-10** **Homology in animals.**

The human arm, cat forelimb, whale flipper, and bat wing have a basic underlying similarity of structure because they are derived from a common ancestor. The five digits are numbered in each drawing.

bone (the humerus) in the part of the limb nearest the trunk of the body, followed by the two bones (radius and ulna) of the forearm, a group of bones (carpals) in the wrist, and a variable number of digits (metacarpals and phalanges). This similarity is particularly striking because arms, forelimbs, flippers, and wings are used for different types of locomotion, and there is no overriding mechanical reason for them to be so similar structurally. Similar arrangements of parts of the forelimb are evident in ancestral reptiles and amphibians and even in the first fishes that came out of water onto land hundreds of millions of years ago.

Leaves are an example of homology in plants. In many plant species, leaves have been modified for functions other than photosynthesis. A cactus spine and a pea tendril, although quite different in appearance, are homologous because both are modified leaves (Fig. 17-11). The spine protects the succulent stem tissue of the cactus, whereas the tendril, which winds around a small object once it makes contact, helps support the climbing stem of the pea plant. Such modifications in organs used in different ways are the expected outcome of a common evolutionary origin. The basic structure present in a common ancestor was modified in different ways for different functions as various descendants subsequently evolved.

Not all species with "similar" features have descended from a recent common ancestor, however. Structurally similar features that are not homologous but simply have similar functions that evolved independently in distantly related organisms are said to be **homoplastic features.** Such a condition is called **homoplasy.**[2] For example, the wings of various distantly re-

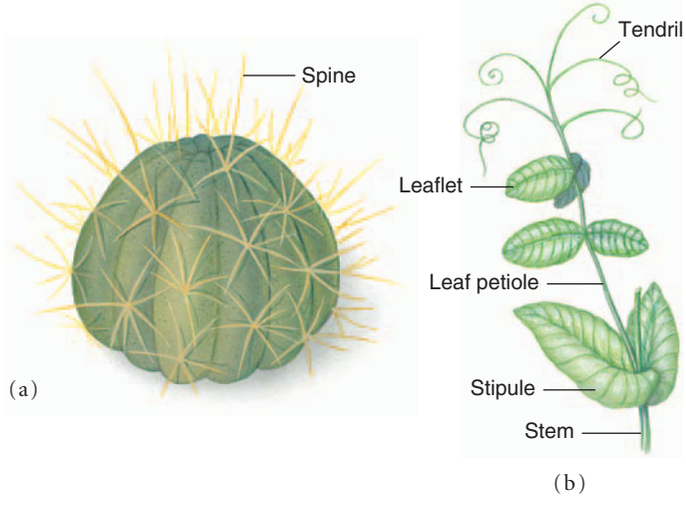

FIGURE **17-11** **Homology in plants.**

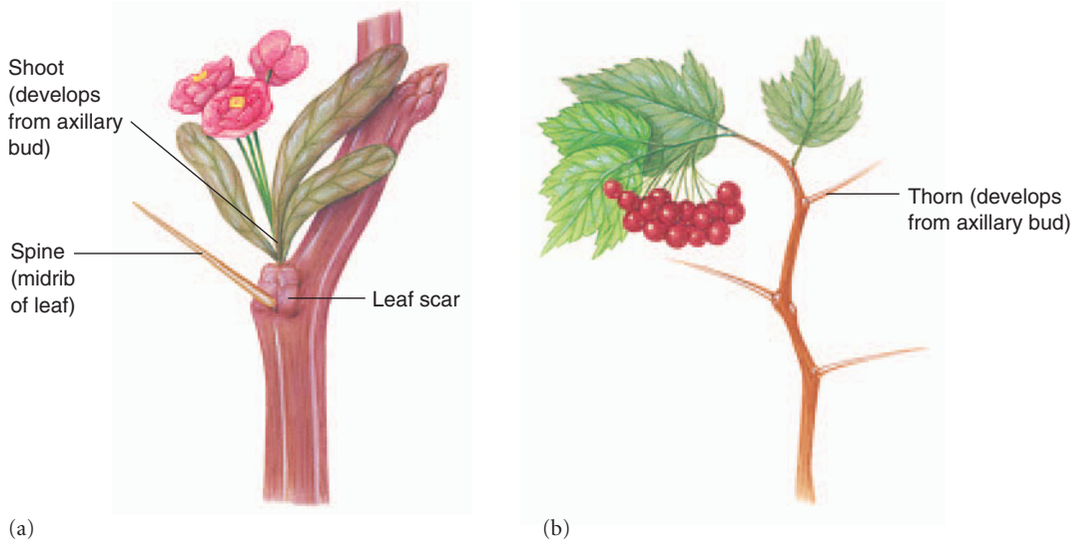
(a) The spines of the fishhook cactus (*Ferocactus wislizenii*) are modified leaves, as are **(b)** the tendrils of the garden pea (*Pisum sativum*). Leaves of the garden pea are compound, and the terminal leaflets are modified into tendrils that are frequently branched.

[2] An older, less precise term that some biologists still use for nonhomologous features with similar functions is *analogy.*

FIGURE **17-12**

Homoplasy.

(a) A spine of Japanese barberry (*Berberis thunbergii*) is a modified leaf. (In this example, the spine is actually the midrib of the original leaf, which has been shed.) **(b)** Thorns of downy hawthorn (*Crataegus mollis*) are modified stems that develop from axillary buds.



lated flying animals, such as insects and birds, resemble each other superficially; they are homoplastic features that evolved over time to meet the common function of flight, although they differ in more fundamental aspects. Bird wings are modified forelimbs supported by bones, whereas insect wings may have evolved from gill-like appendages present in the aquatic ancestors of insects. Spines, which are modified leaves, and thorns, which are modified stems, are an example of homoplasy in plants. Spines and thorns resemble one another superficially but are homoplastic features that evolved independently to solve the common need for protection from herbivores (Fig. 17-12).

Like homology, homoplasy offers crucial evidence of evolution. Homoplastic features are of evolutionary interest because they demonstrate that organisms with separate ancestries may adapt in similar ways to similar environmental demands. Such independent evolution of similar structures in distantly related organisms is known as **convergent evolution.** Aardvarks, anteaters, and pangolins are an excellent example of convergent evolution (Fig. 17-13). They resemble one another in lifestyle and certain structural features. All have strong, sharp claws to dig open ant and termite mounds and elongated snouts with long, sticky tongues to catch these insects. Yet aardvarks, anteaters, and pangolins evolved from three distantly related orders of mammals. (See Chapter 22 for further discussion of homology and homoplasy. Also, see Figure 30-25, which shows several examples of convergent evolution in placental and marsupial mammals.)

Comparative anatomy reveals the existence of **vestigial structures.** Many organisms contain organs or parts of organs that are seemingly nonfunctional and degenerate, often undersized or lacking some essential part. Vestigial structures are remnants of more developed structures that were present and functional in ancestral organisms. In the human body, more than 100 structures are considered vestigial, including the coccyx (fused tailbones), third molars (wisdom teeth), and the muscles that move our ears. Whales and pythons have vestigial hindlimb bones (Fig. 17-14); pigs have vestigial toes that do not touch the ground; wingless birds such as the kiwi have vestigial wing bones; and many blind, burrowing or cave-dwelling animals have nonfunctioning, vestigial eyes.

The occasional presence of a vestigial structure is to be expected as a species adapts to a changing mode of life. Some structures become much less important for survival and may end up as vestiges. When a structure no longer confers a selective advantage, it may become smaller and lose much or all of its function with the passage of time. Because the presence of the vestigial structure is usually not harmful to the organism, however, selective pressure for completely eliminating it is weak, and the vestigial structure is found in many subsequent generations.

The distribution of plants and animals supports evolution

The study of the past and present geographic distribution of organisms is called **biogeography.** The geographic distribution of organisms affects their evolution. Darwin was interested in biogeography, and he considered why the species found on ocean islands tend to resemble species of the nearest mainland, even if the environment is different. He also observed that species on ocean islands do not tend to resemble species on islands with similar environments in other parts of the world. Darwin studied the plants and animals of two sets of arid islands—the Cape Verde Islands, nearly 640 km (400 mi) off western Africa, and the Galapagos Islands, about 960 km (600 mi) west of Ecuador, South America. On each group of islands, the plants and terrestrial animals were indigenous (native), but those of the Cape Verde Islands resembled African species and those of the Galapagos resembled South American species. The similarities of Galapagos species to South American species were particularly striking considering that the Galapagos Islands are dry and rocky and the nearest part of South America is humid and has a lush tropical rain forest. Darwin concluded that species from the neighboring continent migrated or were carried to the islands, where they subsequently adapted to the new environment and, in the process, evolved into new species.

If evolution were not a factor in the distribution of species, we would expect to find a given species everywhere that it could survive. However, the geographic distribution of organisms that actually exists makes sense in the context of evolution. For example, Australia, which has been a separate land mass for millions of years, has distinctive organisms. Australia has populations of egg-laying mammals (monotremes) and pouched mammals (marsupials) not found anywhere else. Two hundred million years ago, Australia and the other continents were joined together in a major land mass. Over the course of millions of years, the Australian continent gradually separated from the others. The monotremes and marsupials in Australia continued to thrive and diversify. The isolation of Australia also prevented placental mammals, which arose elsewhere at a later time, from competing with its monotremes and marsupials. In other areas of the world where placental mammals occurred, most monotremes and marsupials became extinct.

We now consider how Earth's dynamic geology has affected biogeography and evolution.

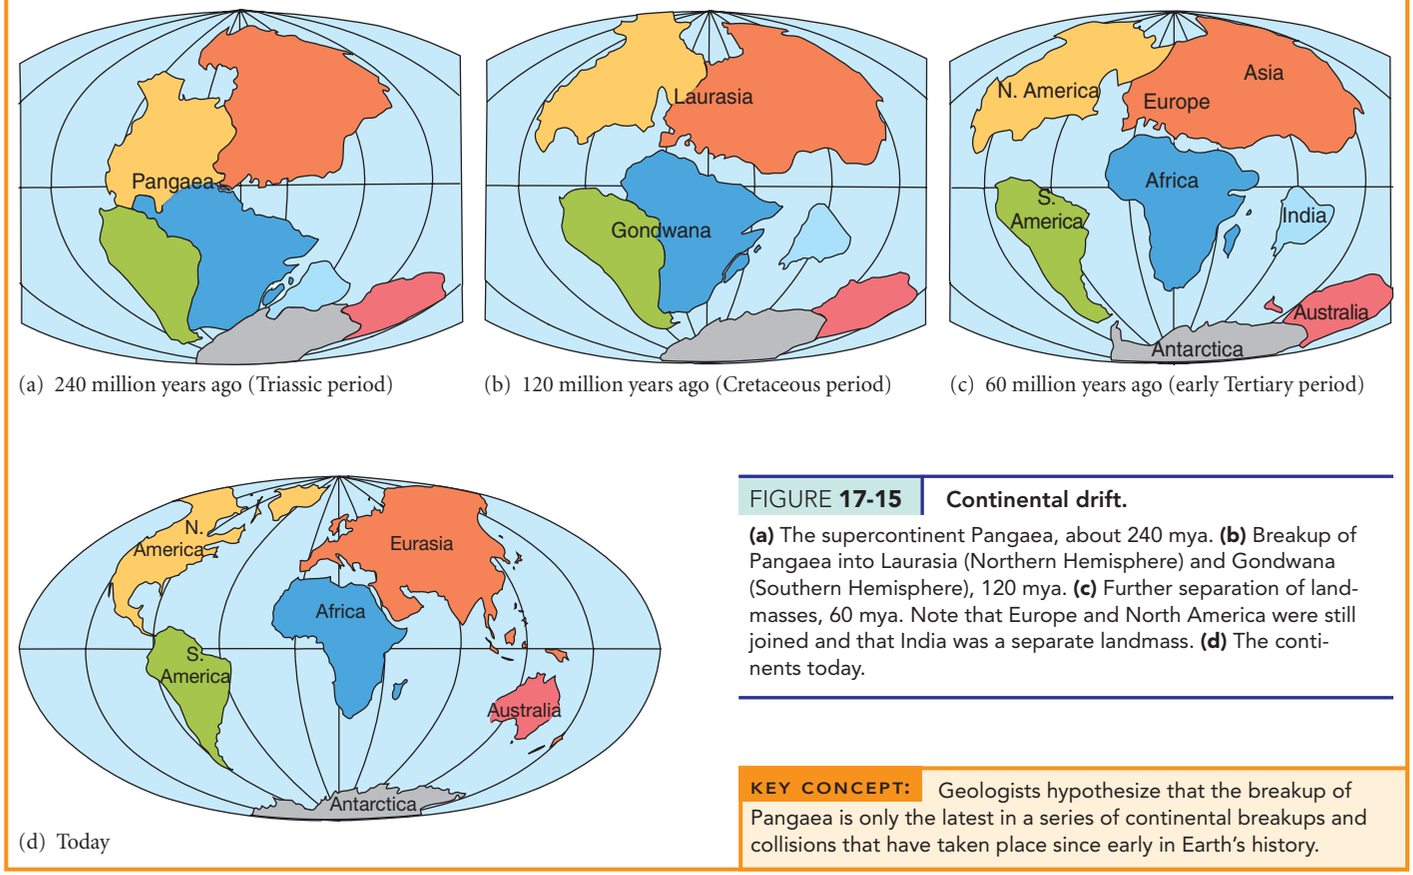
Earth's geological history is related to biogeography and evolution

In 1915 the German scientist Alfred Wegener, who had noted a correspondence between the geographical shapes of South America and Africa, proposed that all the landmasses had at one time been joined into one huge supercontinent, which he called Pangaea (Fig. 17-15a). He further suggested that Pangaea had subsequently broken apart and that the various landmasses had separated in a process known as **continental drift.** Wegener did not know of any mechanism that could have caused continental drift, so his idea, although debated initially, was largely ignored.

In the 1960s, scientific evidence accumulated that provided the explanation for continental drift. Earth's crust is composed of seven large plates (plus a few smaller ones) that float on the mantle, which is the mostly solid layer of Earth lying beneath



(a) 240 million years ago (Triassic period)

(b) 120 million years ago (Cretaceous period)

(c) 60 million years ago (early Tertiary period)

(d) Today

FIGURE **17-15** **Continental drift.**

(a) The supercontinent Pangaea, about 240 mya. **(b)** Breakup of Pangaea into Laurasia (Northern Hemisphere) and Gondwana (Southern Hemisphere), 120 mya. **(c)** Further separation of landmasses, 60 mya. Note that Europe and North America were still joined and that India was a separate landmass. **(d)** The continents today.

KEY CONCEPT: Geologists hypothesize that the breakup of Pangaea is only the latest in a series of continental breakups and collisions that have taken place since early in Earth's history.

the crust and above the core.[3] The landmasses are situated on some of these plates. As the plates move, the continents change their relative positions (Fig. 17-15b, c, and d). The movement of the crustal plates is termed **plate tectonics.**

Any area where two plates meet is a site of intense geological activity. Earthquakes and volcanoes are common in such a region. Both San Francisco, noted for its earthquakes, and the Mount Saint Helens volcano are situated where two plates meet. If landmasses lie on the edges of two adjacent plates, mountains may form. The Himalayas formed when the plate carrying India rammed into the plate carrying Asia. When two plates grind together, one of them is sometimes buried under the other in a process known as *subduction.* When two plates move apart, a ridge of lava forms between them. The Atlantic Ocean is getting larger because of the expanding zone of lava along the Mid-Atlantic Ridge, where two plates are separating.

Knowledge that the continents were at one time connected and have since drifted apart is useful in explaining certain aspects of biogeography (Fig. 17-16). Likewise, continental drift has played a major role in the evolution of different organisms. When Pangaea originally formed during the late Permian period, it brought together terrestrial species that had evolved separately from one another, leading to competition and some extinctions. Marine life was adversely affected, in part because, with the continents joined as one large mass, less coastline existed. (Because coastal areas are shallow, they contain high concentrations of marine species.)

Pangaea separated into several land masses approximately 180 mya. As the continents began to drift apart, populations became geographically isolated in different environmental conditions and began to diverge along separate evolutionary pathways. As a result, the plants, animals, and other organisms of previously connected continents—South America and Africa, for example—differ. Continental drift also caused gradual changes in ocean and atmospheric currents that have profoundly influenced the biogeography and evolution of organisms. (Biogeography is discussed further in Chapter 54.)

Developmental biology helps unravel evolutionary patterns

How snakes became elongated and lost their limbs has long intrigued evolutionary biologists. Comparative anatomy indicates, for example, that pythons have vestigial hindlimb bones embedded in their bodies (see Fig. 17-14). Other snakes have lost their hindlimbs entirely.

Increasingly, developmental biology, particularly at the molecular level, is providing answers to such questions. In many cases, evolutionary changes such as limblessness in snakes, occur as a result of changes in genes that affect the orderly sequence of events that occur during development. In pythons, for exam-

[3] Most of the rock in the upper portion of the mantle is solid, although 1% or 2% is melted. Because of its higher temperature, the solid rock of the mantle is more plastic than the solid rock of the Earth's crust above it.

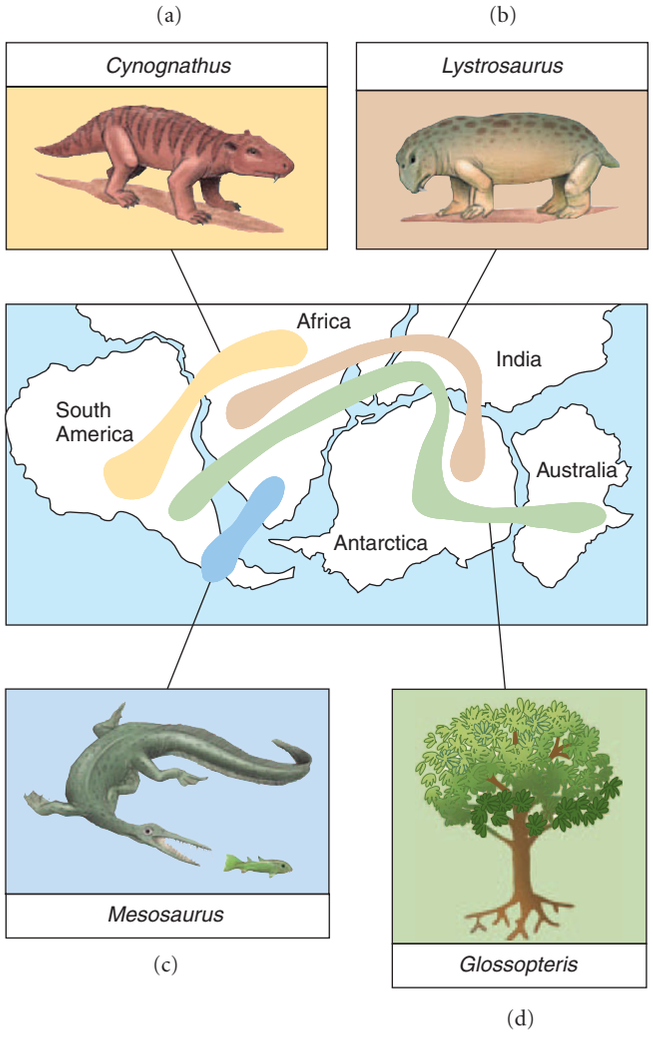


FIGURE **17-16**

Distribution of fossils on continents that were joined during the Permian and Triassic periods (286–213 mya).

(a) *Cynognathus* was a carnivorous reptile found in Triassic rocks in South America and Africa. **(b)** *Lystrosaurus* was a large, herbivorous reptile with beaklike jaws that lived during the Triassic period. Fossils of *Lystrosaurus* have been found in Africa, India, and Antarctica. **(c)** *Mesosaurus* was a small freshwater reptile found in Permian rocks in South America and Africa. **(d)** *Glossopteris* was a seed-bearing tree dating from the Permian period. *Glossopteris* fossils have been found in South America, Africa, India, Antarctica, and Australia. *(Adapted from Colbert, E.H.* Wandering Lands and Animals, *Hutchinson, London, 1973)*

ple, the loss of forelimbs and elongation of the body are linked to mutations in several *Hox* genes that affect the expression of body patterns and limb formation in a wide variety of animals (see Chapter 16 discussion of *Hox* gene clusters). Apparently the hindlimbs do not develop because python embryonic tissue does not respond to internal signals that trigger leg elongation.

Scientific evidence overwhelmingly demonstrates that development in different animals is controlled by the same kinds of genes; these genetic similarities in a wide variety of organisms reflect a shared evolutionary history. For example, all vertebrates have similar patterns of embryological development that indicate they share a common ancestor. All vertebrate embryos have segmented muscles, pharyngeal (gill) pouches, a tubular heart without left and right sides, a system of arteries known as *aortic arches* in the gill region, and many other shared features. All these structures are necessary and functional in the developing fish. The small, segmented muscles of the fish embryo give rise to the segmented muscles used by the adult fish in swimming. The gill pouches break through to the surface as gill slits. The adult fish heart remains undivided and pumps blood forward to the gills that develop in association with the aortic arches.

Because none of these embryonic features persists in the adults of reptiles, birds, or mammals, why are these fishlike structures present in their embryos? Evolution is a conservative process, and natural selection builds on what has come before rather than starting from scratch. The evolution of new features often does not require the evolution of new developmental genes but instead depends on a modification in developmental genes that already exist (see Chapter 19 discussion of preadaptations). Terrestrial vertebrates are thought to have evolved from fishlike ancestors; therefore, they share some of the early stages of development still found in fish today. The accumulation of genetic changes over time in these vertebrates has modified the basic body plan laid out in fish development.

Molecular comparisons among organisms provide evidence for evolution

Similarities and differences in the biochemistry and molecular biology of various organisms provide evidence for evolutionary relationships. Lines of descent based solely on biochemical and molecular characters often resemble lines of descent based on structural and fossil evidence. Molecular evidence for evolution includes the universal genetic code and the conserved sequences of amino acids in proteins and of nucleotides in DNA.

The genetic code is virtually universal

Organisms owe their characteristics to the types of proteins they possess, which in turn are determined by the sequence of nucleotides in their messenger ribonucleic acid (mRNA), as specified by the order of nucleotides in their DNA. Evidence that all life is related comes from the fact that all organisms use a genetic code that is virtually identical.[4] Recall from Chapter 12 that the genetic code specifies a triplet (a sequence of three nucleotides in DNA) that codes for a particular codon (a sequence of three nucleotides in mRNA). The codon then codes for a particular amino acid in a polypeptide chain. For example, "AAA" in DNA codes for "UUU" in mRNA, which codes for the amino acid phenylalanine in organisms as diverse as shrimp, humans, bacteria, and tulips. In fact, "AAA" codes for phenylalanine in all organisms examined to date.

The universality of the genetic code—no other code has been found in any organism—is compelling evidence that all organ-

[4] There is some minor variation in the genetic code. For example, mitochondria have some deviations from the standard code.

isms arose from a common ancestor. The genetic code has been maintained and transmitted through all branches of the evolutionary tree since its origin in some extremely early (and successful) organism.

Proteins and DNA contain a record of evolutionary change

Thousands of comparisons of protein and DNA sequences from various species have been done during the past 25 years or so. In many cases, sequence-based relationships agree with earlier studies, which based evolutionary relationships on similarities in structure among living organisms and on fossil data of extinct organisms.

Investigations of the sequence of amino acids in proteins that play the same roles in many species have revealed both great similarities and certain specific differences. Even organisms that are only remotely related, such as humans, fruit flies, sunflowers, and yeasts, share some proteins, such as cytochrome *c,* which is part of the electron transport chain in aerobic respiration. To survive, all aerobic organisms need a respiratory protein with the same basic structure and function as the cytochrome *c* of their common ancestor. Consequently, not all amino acids that confer the structural and functional features of cytochrome *c* are free to change. Any mutations that changed the amino acid sequence at structurally important sites of the cytochrome *c* molecule would have been harmful, and natural selection would have prevented such mutations from being passed to future generations. However, in the course of the long, independent evolution of different organisms, mutations have resulted in the substitution of many amino acids at less important locations in the cytochrome *c* molecule. The greater the differences in the amino acid sequences of their cytochrome *c* molecules, the longer it has been since two species diverged.

Because a protein's amino acid sequences are coded in DNA, the differences in amino acid sequences indirectly reflect the nature and number of underlying DNA base-pair changes that must have occurred during evolution. Of course, not all DNA codes for proteins (witness introns and transfer RNA genes). **DNA sequencing**—that is, determining the order of nucleotide bases in DNA—of both protein-coding DNA and non–protein-coding DNA is useful in determining evolutionary relationships.

Generally, the more closely species are considered related on the basis of other scientific evidence, the greater the percentage of nucleotide sequences that their DNA molecules have in common. By using the DNA sequence data in Table 17-1, for example, you can conclude that the closest living relative of humans is the chimpanzee (because its DNA has the lowest percentage differences in the sequence examined). Which of the primates in Table 17-1 is the most distantly related to humans? (Primate evolution is discussed in Chapter 21.)

PROCESS OF SCIENCE

In some cases, molecular evidence challenges traditional evolutionary ideas that were based on structural comparisons among living species and/or on studies of fossil skeletons. Consider artiodactyls, an order of even-toed hoofed mammals such as pigs, camels, deer, antelope, cattle, and hippopotamuses. Traditionally, whales, which do not have toes, are not classified as artiodactyls (although early fossil whales had an even number of toes on their appendages).

TABLE **17-1** **Differences in Nucleotide Sequences in DNA as Evidence of Phylogenetic Relationships**

Primate Species Pairs	Percent Divergence in a Selected DNA Sequence
Human–chimpanzee	1.7
Human–gorilla	1.8
Human–orangutan	3.3

Human–rhesus monkey (Old World monkey)	7.0
Human–spider monkey (New World monkey)	10.8
Human–tarsier	24.6

Source: From M., Goodman, et al., "Primate Evolution at the DNA Level and a Classification of Hominoids," *Journal of Molecular Evolution,* Vol. 30, 1990.

Note: Percent divergence refers to how different the base sequences are for the same gene in different organisms. In this example, humans and chimpanzees have a 1.7% difference in their DNA base sequences, which means that 98.3% of the DNA examined is identical. The data shown are for the noncoding sequence of the β-globin gene.

Figure 17-17 depicts a hypothetical phylogenetic tree for whales and selected artiodactyls based on molecular data. Such **phylogenetic trees**—diagrams showing lines of descent—can be derived from differences in a given DNA nucleotide sequence. This diagram suggests whales should be classified as artiodactyls and shows that hippopotamuses are more closely related to whales than any other artiodactyl. The branches representing whales and hippopotamuses probably diverged relatively recently because of the close similarity of DNA sequences in these species. In contrast, camels, which have DNA sequences that are less similar to whales, diverged much earlier. The molecular evidence indicates that whales and hippopotamuses share a recent common ancestor, a hippo-like artiodactyl that split from the rest of the artiodactyl line some 55 mya.

However, available fossil evidence does not currently provide support for the molecular hypothesis; a fossil ancestor common to both whales and hippos has not yet been discovered. (Recall from earlier in the chapter that most paleontologists currently suggest that the mesonychians, which are not ancient artiodactyls, may have been the ancestor of whales.) Scientists hope that future fossil discoveries will help clarify this discrepancy between molecular and fossil data.

DNA sequencing is used to estimate the time of divergence between two closely related species or taxonomic groups

Imagine you know the distance from Miami, Florida, to New York City, and you also know how long it takes to drive that distance. Now imagine you do *not* know the distance from Miami to Chicago, but you do know how long it takes to drive that distance. Based on the knowledge you have, you can infer the distance from Miami to Chicago. Similar reasoning is used to estimate the divergence between closely related taxonomic groups.

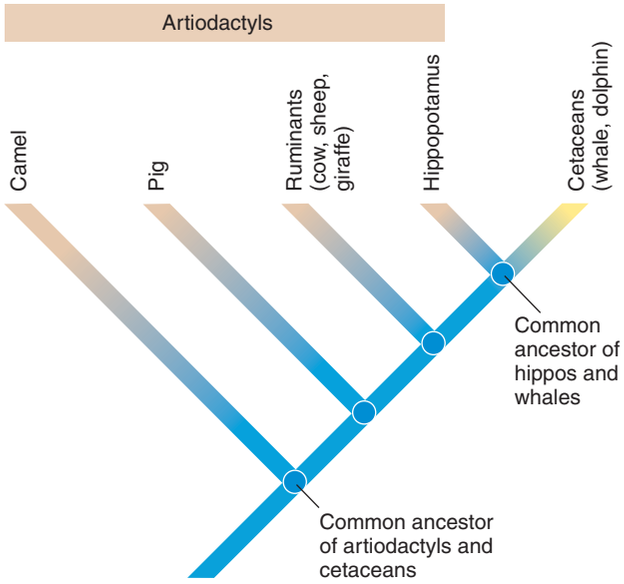

FIGURE 17-17 **Phylogenetic tree of whales and their closest living relatives.**

This branching diagram, called a *cladogram,* shows hypothetical evolutionary relationships. Based on DNA sequence differences among selected mammals, it suggests that artiodactyls are the close relatives of whales, that the hippopotamus is the closest living artiodactyl relative of whales, and that artiodactyls and whales share a common ancestor in the distant past. The nodes (circles) represent branch points where a species splits into two or more lineages. (Ruminants are artiodactyls that have a multichambered stomach and chew regurgitated plant material to make it more digestible.) *(Adapted from M., Nikaido, et al., "Phylogenetic Relationships among Cetartiodactyls Based on Insertions of Short and Long Interspersed Elements: Hippopotamuses Are the Closest Extant Relatives of Whales,"* Proceedings of the National Academy of Sciences, *Vol. 96, 31 Aug. 1999)*

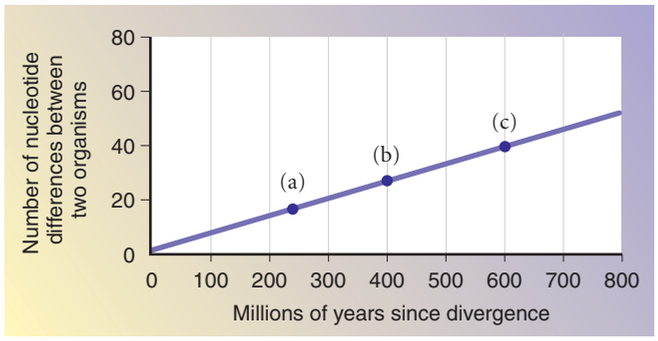

FIGURE 17-18 **Calibration and use of a molecular clock.**

In this hypothetical example, the DNA of a specific gene is sequenced for birds, reptiles, fish, and insects. The number of nucleotide differences between birds and reptiles (a) is placed on a graph at the time at which birds and reptiles are thought to have diverged based on fossil evidence. Likewise, the number of nucleotide differences between reptiles and fish (b) is placed on the graph at the time of branching indicated by the fossil record. A line is drawn through points (a) and (b) and extended, enabling scientists to estimate a much earlier time (c) at which the insect line diverged from the vertebrate line.

Within a given taxonomic group, mutations are assumed to have occurred at a fairly steady rate over millions of years. Thus, if more differences occur in homologous sequences of DNA of one species compared with another, more time elapsed since the two species diverged from a common ancestor.

From the number of alterations in homologous DNA sequences taken from different species, we can develop a **molecular clock** to estimate the time of divergence between two closely related species or higher taxonomic groups. A molecular clock makes use of the average rate at which a particular gene evolves. The clock is calibrated by comparing the number of nucleotide differences between two organisms with the dates of evolutionary branch points that are known from the fossil record. Once a molecular clock is calibrated, past evolutionary events whose timing is not known with certainty are estimated (Fig. 17-18).

Molecular clocks can be used to complement geological estimates of the divergence of species or to assign tentative dates to evolutionary events that lack fossil evidence. Where there is no fossil record of an evolutionary event, molecular clocks are the only way to estimate the timing of that event. Molecular clocks are also used, along with fossil evidence and structural data, to help reconstruct **phylogeny,** which is the evolutionary history of a group of related species (see Chapter 22). By assigning tentative dates to the divergence of species, molecular clocks show the relative order of branch points in phylogeny.

Molecular clocks must be developed and interpreted with care. Mutation rates vary among different genes and among distantly related taxonomic groups, causing molecular clocks to tick at different rates. Some genes, such as the gene for the respiratory protein cytochrome *c,* code for proteins that lose their function if the amino acid sequence changes slightly; these genes evolve slowly. Other genes, such as genes for blood-clotting proteins, code for proteins that are less constrained by changes in amino acid sequence; these genes evolve rapidly. Scientists consider molecular clocks that are based on several genes to be more accurate than clocks based on a single gene.

Although many dates estimated by molecular clocks agree with fossil evidence, some discrepancies between molecular clocks and fossils exist. In most of these cases, the molecular clock's estimates of divergence times of particular organisms are much older than the dates at which the groups are first observed in the fossil record. Resolving these differences will require additional research in both molecular biology and paleontology.

Evolutionary hypotheses are tested experimentally

PROCESS OF SCIENCE

Increasingly, biologists are designing imaginative experiments, often in natural settings, to test evolutionary hypotheses. David Reznick from the University of California at Santa Barbara and John Endler from James Cook University in Australia have studied evolution in guppy populations in Venezuela and in Trinidad, a small island in the southern Caribbean.

Reznick and Endler observed that different streams have different kinds and numbers of fishes that prey on guppies.

Predatory fish that prey on larger guppies are present in all streams at lower elevations; these areas of intense predation pressure are known as *high-predation habitats.* Predators are often excluded from tributaries or upstream areas by rapids and waterfalls. The areas above such barriers are known as *low-predation habitats* because they contain only one species of small predatory fish that occasionally eats smaller guppies.

Differences in predation are correlated with many differences in the guppies, such as male coloration, behavior, and attributes known as *life history traits.* These traits include age and size at sexual maturity, the number of offspring per reproductive event, the size of the offspring, and the frequency of reproduction. For example, guppy adults are larger in streams found at higher elevations and smaller in streams found at lower elevations.

Do predators actually cause these differences to evolve? Reznick and colleagues tested this evolutionary hypothesis by conducting field experiments in Trinidad. Taking advantage of waterfalls that prevent upstream movement of guppies, guppy predators, or both, they moved either guppies or guppy predators over such barriers. For example, guppies from a high-predation habitat were introduced into a low-predation habitat by moving them over a barrier waterfall into a section of stream that was free of guppies and large predators. The only fish species that lived in this section of stream before the introduction was the predator that occasionally preyed on small guppies.

Eleven years later, the researchers captured adult females from the introduction site (low-predation habitat) and the control site below the barrier waterfall (high-predation habitat). They bred these females in their laboratory and compared the life history traits of succeeding generations. The descendants of guppies introduced into the low-predation habitat matured at an older age and larger size than did the descendants of guppies from the control site below the waterfall (Fig. 17-19). They also produced fewer, but larger, offspring. The life histories of the introduced fish had therefore evolved to be similar to those of fish typically found in such low-predation habitats. Similar studies have demonstrated that predators have played an active role in the evolution of other traits, such as average number of offspring produced during the lifetime of an individual female (fecundity), male coloration, and behavior.

These and other experiments demonstrate not only that evolution is real but also that it is occurring now, driven by selective environmental forces, such as predation, that can be experimentally manipulated. Darwin incorrectly assumed evolution is so gradual that humans cannot observe it. As Jonathan Weiner, author of *The Beak of the Finch: A Story of Evolution in Our Time,* puts it, "Darwin did not know the strength of his own theory. He vastly underestimated the power of natural selection. Its action is neither rare nor slow. It leads to evolution daily and hourly, all around us, and we can watch."

FIGURE **17-19** **Experimental evidence of natural selection in guppies.**

Male and female guppies from a stream in which the predators preferred large adult guppies as prey *(brown bars)* were transferred to a stream in which the predators preferred juveniles and small adults. After 11 years, the descendants of these guppies *(pink bars)* were measurably larger in size, compared with their ancestors. *(Data used with permission from D.N. Reznick, et al., "Evaluation of the Rate of Evolution in Natural Populations of Guppies (*Poecilia reticulata*)," Science, Vol. 275, 28 Mar. 1997)*

Review

- How do scientists date fossils?
- How do homologous and homoplastic features provide evidence of evolution?
- Why are fossils of *Mesosaurus,* an extinct reptile that could not swim across open water, found in the southern parts of both Africa and South America?
- How does developmental biology provide evidence of a common ancestry for vertebrates as diverse as reptiles, birds, pigs, and humans?
- How do predator preferences drive the evolution of size in guppies?

BiologyNow™ Assess your understanding of **evidence for evolution** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Discuss the historical development of the theory of evolution.

- Jean Baptiste de Lamarck was the first scientist to propose that organisms undergo change over time as a result of some natural phenomenon rather than divine intervention. Lamarck thought organisms were endowed with a vital force that drove them to change toward greater complexity over time. He thought organisms could pass traits acquired during their lifetimes to their offspring.
- Charles Darwin's observations while voyaging on the H.M.S. *Beagle* was the basis for his theory of evolution. Darwin tried to explain his observations of the similarities between animals and plants of the arid Galapagos Islands and the humid South American mainland.

SUMMARY WITH KEY TERMS *(continued)*

- Darwin was influenced by **artificial selection,** in which breeders develop many varieties of domesticated plants and animals in just a few generations. Darwin applied Thomas Malthus's ideas on the natural increase in human populations to natural populations. Darwin was influenced by the idea that Earth was extremely old, an idea promoted by Charles Lyell and other geologists.

2 Define *evolution,* and explain the four premises of evolution by natural selection as proposed by Charles Darwin.

- **Evolution,** the accumulation of inherited changes within a **population** over time, is the unifying concept of biology. Evolution is the cornerstone of biology because it links all fields of the life sciences into a unified body of knowledge.
- Charles Darwin and Alfred Wallace independently proposed the theory of evolution by **natural selection,** which is based on four observations. First, genetic variation exists among the individuals in a population. Second, the reproductive ability of each species causes its populations to geometrically increase in number over time. Third, organisms compete with one another for the resources needed for life, such as food, living space, water, and light. Fourth, offspring with the most favorable combination of characteristics are most likely to survive and reproduce, passing those genetic characteristics to the next generation.
- Natural selection results in **adaptations,** evolutionary modifications that improve the chances of survival and reproductive success in a particular environment. Over time, enough changes may accumulate in geographically separated populations to produce new species.

3 Compare the modern synthesis with Darwin's original theory of evolution.

- The **modern synthesis,** or **synthetic theory of evolution** combines Darwin's theory of evolution by natural selection with modern genetics to explain how species adapt to their environment.
- **Mutation** provides the genetic variability that natural selection acts on during evolution.

4 Summarize the evidence for evolution obtained from the fossil record.

- Direct evidence of evolution comes from **fossils,** the remains or traces of ancient organisms.
- Layers of sedimentary rock normally occur in their sequence of deposition, with the more recent layers on top of the older, earlier ones. **Index fossils** characterize a specific layer over large geographical areas. **Radioisotopes** present in a rock provide a way to accurately measure the rock's age.

5 Summarize the evidence for evolution derived from comparative anatomy.

- **Homologous features** have basic structural similarities, even though the structures may be used in different ways, because homologous features derive from the same structure in a common ancestor. Homologous features indicate evolutionary affinities among the organisms possessing them.
- **Homoplastic features** have similar functions in quite different, distantly related organisms. Homoplastic features demonstrate **convergent evolution,** in which organisms with separate ancestries adapt in similar ways to comparable environmental demands.
- **Vestigial structures** are nonfunctional or degenerate remnants of structures that were present and functional in ancestral organisms. Structures occasionally become vestigial as species adapt to different modes of life.

6 Define *biogeography,* and summarize how the distribution of organisms supports evolution.

- **Biogeography,** the geographical distribution of organisms, affects their evolution. Areas that have been separated from the rest of the world for a long time have organisms unique to those areas.
- At one time the continents were joined to form a supercontinent. **Continental drift,** which caused the various landmasses to break apart and separate, has played a major role in evolution.

7 Briefly explain how developmental biology provides insights into the evolutionary process.

- Evolutionary changes are often the result of mutations in genes that affect the orderly sequence of events during development. Development in different animals is controlled by the same kinds of genes, which indicates these animals have a shared evolutionary history.
- The accumulation of genetic changes since organisms diverged, or took separate evolutionary pathways, has modified the pattern of development in more complex vertebrate embryos.

8 Give an example of how evolutionary hypotheses are tested experimentally.

- Reznick and Endler have studied the effects of predation intensity on the evolution of guppy populations in the laboratory and in nature. Such experiments are a powerful way for investigators to test the underlying processes of natural selection.

POST-TEST

1. Evolution is based on which of the following concepts? (a) organisms share a common origin (b) over time, organisms have diverged from a common ancestor (c) an animal's body parts can change over its lifetime, and these acquired changes are passed to the next generation (d) a and b are correct (e) a, b, and c are correct
2. Evolution is the accumulation of genetic changes within _____ over time. (a) individuals (b) populations (c) communities (d) a and b (e) a and c
3. Charles Darwin proposed that evolution could be explained by the differential reproductive success of organisms that resulted from their naturally occurring variation. Darwin called this process (a) coevolution (b) convergent evolution (c) natural selection (d) artificial selection (e) homoplasy
4. Which of the following statements is *false?* (a) Darwin was the first to supply convincing evidence for biological evolution (b) Darwin was the first to propose that organisms change over time (c) Wallace independently developed the same theory as Darwin (d) Darwin's theory is based on four observations about the natural world (e) Darwin's studies in the Galapagos strongly influenced his ideas about evolution
5. Which of the following is *not* part of Darwin's mechanism of evolution? (a) differential reproductive success (b) variation in a

POST-TEST *(continued)*

population (c) inheritance of acquired (nongenetic) traits (d) overproduction of offspring (e) struggle for existence

6. The modern synthesis (a) is based on the sequence of fossils in rock layers (b) uses genetics to explain the source of hereditary variation that is essential to natural selection (c) was first proposed by ancient Greek scholars (d) considers the influence of the geographic distribution of organisms on their evolution (e) is reinforced by homologies that are explained by common descent
7. Jewish and Muslim men have been circumcised for many generations, yet this practice has had no effect on the penile foreskin of their offspring. This observation is inconsistent with evolution as envisioned by (a) Lamarck (b) Darwin (c) Wallace (d) Lyell (e) Malthus
8. Which of the following is *least* likely to have occurred after a small population of finches reached the Galapagos Islands from the South American mainland? (a) after many generations, the finches became increasingly different from the original population (b) over time, the finches adapted to their new environment (c) after many generations, the finches were unchanged and unmodified in any way (d) the finches were unable to survive in their new home and died out (e) the finches survived by breeding with other species
9. The fossil record (a) usually occurs in sedimentary rock (b) sometimes appears fragmentary (c) is relatively complete for tropical rainforest organisms but incomplete for aquatic organisms (d) a and b are correct (e) a, b, and c are correct
10. The molecular record found inside cells suggests that evolutionary changes are caused by an accumulation of (a) traits acquired through need (b) alterations in the order of nucleotides in DNA (c) characters acquired during an individual's lifetime (d) hormones (e) environmental changes
11. In _____, the selecting agent is the environment, whereas in _____, the selecting agent is humans. (a) natural selection; convergent evolution (b) mutation; artificial selection (c) homoplasy; homology (d) artificial selection; natural selection (e) natural selection; artificial selection
12. Features that are similar in underlying form in different species because of a common evolutionary origin, are called (a) homoplastic (b) homologous (c) vestigial (d) convergent (e) synthetic
13. Aardvarks, anteaters, and pangolins are only distantly related but are similar in structure and form as a result of (a) homology (b) convergent evolution (c) biogeography (d) vestigial structures (e) artificial selection
14. The species of the Galapagos Islands (a) are similar to those on other islands at the same latitude (b) are similar to those on the South American mainland (c) are identical to those on other islands at the same latitude (d) are identical to those on the South American mainland (e) are similar to those on both the African and South American mainlands

CRITICAL THINKING

1. The use of model organisms such as the mouse for research and biomedical testing of human diseases is based on the assumption that all organisms share a common ancestor. On what evidence is this assumption based?
2. What adaptations must an animal possess to swim in the ocean? Why are such genetically different organisms as porpoises, which are mammals, and sharks, which are fish, so similar in form?
3. The human fetus grows a coat of fine hair (the lanugo) that is shed before or shortly after birth. Fetuses of chimpanzee and other primates also grow coats of hair, but they are not shed. Explain these observations based on what you have learned in this chapter.
4. Charles Darwin once said, "It is not the strongest of the species that survive, nor the most intelligent, but the one most responsive to change." Explain what he meant.
5. Write short paragraphs explaining each of the following statements:
   a. Natural selection chooses from among the individuals in a population those most suited to *current* environmental conditions. It does not guarantee survival under future conditions.
   b. Individuals do not evolve, but populations do.
   c. The organisms that exist today do so because their ancestors had traits that allowed them and their offspring to thrive.
   d. At the molecular level, evolution can take place by the replacement of one nucleotide by another.
   e. Evolution is said to have occurred within a population when measurable genetic changes are detected.

Evolutionary Change in Populations

G.I. Bernard/Animals Animals

Genetic variation in snail shells. Shown are the shell patterns and colors in a single snail species (*Cepaea nemoralis*), native to Scotland. Variation in shell color may have adaptive value in these snails, because some colors predominate in cooler environments, whereas other colors are more common in warmer habitats.

CHAPTER OUTLINE

- **Genotype, Phenotype, and Allele Frequencies**
- **The Hardy-Weinberg Principle**
- **Microevolution**
- **Genetic Variation in Populations**

As you learned in Chapter 17, evolution occurs in populations, not individuals. Although natural selection results from differential survival and reproduction of individuals, individuals do not evolve during their lifetimes. Evolutionary change, which includes modifications in structure, physiology, ecology, and behavior, is inherited from one generation to the next. Although Darwin recognized that evolution occurs in populations, he did not understand how the attributes of organisms are passed to successive generations. One of the most significant advances in biology since Darwin's time has been the demonstration of the genetic basis of evolution. As you will see in this chapter, Gregor Mendel's principles of inheritance (see Chapter 10) underlie Darwinian evolution.

Recall from Chapter 17 that a **population** consists of all individuals of the same species that live in a particular place at the same time. Individuals within a population vary in many recognizable characters. A population of snails, for example, may vary in shell size, weight, or color (see photograph). Some of this variation is due to the environment, and some is due to heredity.

Biologists study variation in a particular character by taking measurements of that character in a population. By comparing the character in parents and offspring, it is possible to estimate the amount of observed variation that is genetic, as represented by the number, frequency, and kinds of alleles in a population. (Recall from Chapter 10 that an **allele** is one of two or more alternate forms of a gene. Alleles occupy corresponding positions, or **loci,** on homologous chromosomes.)

This chapter will help you develop an understanding of the importance of genetic variation as the raw material for evolution and of the basic concepts of **population genetics,** the study of genetic variability within a population and of the forces that act on it. Population genetics represents an extension of Mendelian inheritance. You will learn how to distinguish genetic equilibrium from evolutionary change and to assess the roles of the five factors responsible for evolutionary change: nonrandom mating, mutation, genetic drift, gene flow, and natural selection. ■

GENOTYPE, PHENOTYPE, AND ALLELE FREQUENCIES

Learning Objectives

1 Define what is meant by a population's gene pool.
2 Distinguish among genotype, phenotype, and allele frequencies.

Each population possesses a **gene pool,** which includes all the alleles for all the loci present in the population. Because diploid organisms have a maximum of two different alleles at each genetic locus, a single individual typically has only a small fraction of the alleles present in a population's gene pool. The genetic variation that is evident among individuals in a given population indicates that each individual has a different subset of the alleles in the gene pool.

The evolution of populations is best understood in terms of genotype, phenotype, and allele frequencies. Suppose, for example, that all 1000 individuals of a hypothetical population have their genotypes tested, with the following results:

Genotype	Number	Genotype Frequency
AA	490	0.49
Aa	420	0.42
aa	90	0.09
Total	1000	1.00

Each **genotype frequency** is the proportion of a particular genotype in the population. Genotype frequency is usually expressed as a decimal fraction, and the sum of all genotype frequencies is 1.0 (somewhat like probabilities, which were discussed in Chapter 10). For example, the genotype frequency for the *Aa* genotype is 420 ÷ 1000 = 0.42.

A **phenotype frequency** is the proportion of a particular phenotype in the population. If each genotype corresponds to a specific phenotype, then the phenotype and genotype frequencies are the same. If allele *A* is dominant over allele *a,* however, the phenotype frequencies in our hypothetical population would be the following:

Phenotype	Number	Phenotype Frequency
Dominant	910	0.91
Recessive	90	0.09
Total	1000	1.00

(In this example, the dominant phenotype is the sum of two genotypes, *AA* and *Aa,* and so the number 910 is obtained by adding 490 + 420.)

An **allele frequency** is the proportion of a specific allele (that is, of *A* or *a*) in a particular population. As mentioned earlier, each individual, being diploid, has two alleles at each genetic locus. Because we started with a population of 1000 individuals, we must account for a total of 2000 alleles. The 490 *AA* individuals have 980 *A* alleles, whereas the 420 *Aa* individuals have 420 *A* alleles, making a total of 1400 *A* alleles in the population. The total number of *a* alleles in the population is 420 + 90 + 90 = 600. Now it is easy to calculate allele frequencies:

Allele	Number	Allele Frequency
A	1400	0.7
a	600	0.3
Total	2000	1.0

Review

- Does the term *gene pool* apply to individuals, populations, or both?
- Can the frequencies of all genotypes in a population be determined directly with respect to a locus that has only two alleles, one dominant and the other recessive?
- In a human population of 1000, 840 are tongue rollers (*TT* or *Tt*), and 160 are not tongue rollers *(tt).* What is the frequency of the dominant allele *(T)* in the population?

BiologyNow™ Assess your understanding of **genotype, phenotype, and allele frequencies** by taking the pretest on your BiologyNow CD-ROM.

THE HARDY-WEINBERG PRINCIPLE

Learning Objectives

3 Discuss the significance of the Hardy-Weinberg principle as it relates to evolution, and list the five conditions required for genetic equilibrium.
4 Use the Hardy-Weinberg principle to solve problems involving populations.

In the example just discussed, we observe that only 90 of the 1000 individuals in the population exhibit the recessive phenotype characteristic of the genotype *aa.* The remaining 910 individuals exhibit the dominant phenotype and are either *AA* or *Aa.* You might assume that, after many generations, genetic recombination during sexual reproduction would cause the dominant allele to become more common in the population. You might also assume that the recessive allele would eventually disappear altogether. These were common assumptions of many biologists early in the 20th century. However, these assumptions were incorrect, because the frequencies of alleles and genotypes do not change from generation to generation unless influenced by outside factors (discussed later).

A population whose allele and genotype frequencies do not change from generation to generation is said to be at **genetic equilibrium.** Such a population, with no net change in allele or genotype frequencies over time, is not undergoing evolutionary change. A population that is at genetic equilibrium is not evolving with respect to the locus being studied. However, if allele frequencies change over successive generations, evolution is occurring.

The explanation for the stability of successive generations in populations at genetic equilibrium was provided independently by Godfrey Hardy, an English mathematician, and Wilhelm Weinberg, a German physician, in 1908. They pointed out that the expected frequencies of various genotypes in a population can be described mathematically. The resulting **Hardy-Weinberg principle** shows that if the population is large, the process of inheritance does not by itself cause changes in allele frequencies.

It also explains why dominant alleles are not necessarily more common than recessive ones. The Hardy-Weinberg principle represents an ideal situation that seldom occurs in the natural world. However, it is useful because it provides a model to help us understand the real world. Knowledge of the Hardy-Weinberg principle is essential to understanding the mechanisms of evolutionary change in sexually reproducing populations.

We now expand our original example to illustrate the Hardy-Weinberg principle. Keep in mind as we go through these calculations that in most cases we only know the phenotype frequencies. When alleles are dominant and recessive, it is usually impossible to visually distinguish heterozygous individuals from homozygous dominant individuals. The Hardy-Weinberg principle lets us use phenotype frequencies to calculate the expected genotype frequencies and allele frequencies, assuming we have a clear understanding of the genetic basis for the character under study.

As mentioned earlier, the frequency of either allele, *A* or *a*, is represented by a number that ranges from 0 to 1. An allele that is totally absent from the population has a frequency of zero. If all the alleles of a given locus are the same in the population, then the frequency of that allele is 1.

Because only two alleles, *A* and *a*, exist at the locus in our example, the sum of their frequencies must equal 1. If we let p represent the frequency of the dominant *(A)* allele in the population, and q the frequency of the recessive *(a)* allele, then we can summarize their relationship with a simple binomial equation, $p + q = 1$. When we know the value of either p or q, we can calculate the value of the other: $p = 1 - q$ and $q = 1 - p$.

Squaring both sides of $p + q = 1$ results in $(p + q)^2 = 1$. This equation can be expanded to describe the relationship of the allele frequencies to the genotypes in the population. When it is expanded, we obtain the frequency of the offspring genotypes:

$$\underset{\text{Frequency of } AA}{p^2} + \underset{\text{Frequency of } Aa}{2pq} + \underset{\text{Frequency of } aa}{q^2} = \underset{\text{All individuals in the population}}{1}$$

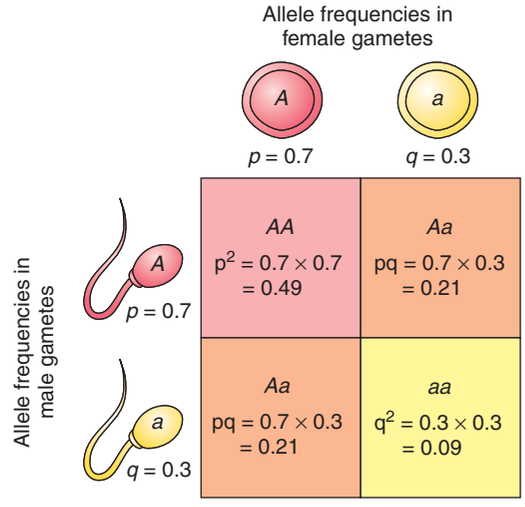
We always begin Hardy-Weinberg calculations by determining the frequency of the homozygous recessive genotype. From the fact that we had 90 homozygous recessive individuals in our population of 1000, we infer that the frequency of the *aa* genotype, q^2, is 90/1000, or 0.09. Because q^2 equals 0.09, q (the frequency of the recessive *a* allele) is equal to the square root of 0.09, or 0.3. From the relationship between p and q, we conclude that the frequency of the dominant *A* allele, p, equals $1 - q = 1 - 0.3 = 0.7$.

Given this information, we can calculate the frequency of homozygous dominant *(AA)* individuals: $p^2 = 0.7 \times 0.7 = 0.49$ (Fig. 18-1). The expected frequency of heterozygous individuals *(Aa)* would be $2pq = 2 \times 0.7 \times 0.3 = 0.42$. Thus, approximately 490 individuals are expected to be homozygous dominant, and 420 are expected to be heterozygous. Note that the sum of homozygous dominant and heterozygous individuals equals 910, the number of individuals showing the dominant phenotype we started with.

Any population in which the distribution of genotypes conforms to the relation $p^2 + 2pq + q^2 = 1$, whatever the absolute values for p and q may be, is at genetic equilibrium. The Hardy-Weinberg principle allows biologists to calculate allele frequencies in a given population if we know the genotype frequencies, and vice versa. These values provide a basis of comparison with a population's allele or genotype frequencies in succeeding generations. During that time, if the allele or genotype frequencies deviate from the values predicted by the Hardy-Weinberg principle, then the population is evolving.

Genotypes	*AA*	*Aa*	*aa*
Frequency of genotypes in population	0.49	0.42 (0.21 + 0.21)	0.09
Frequency of alleles in gametes	*A* = 0.49 + 0.21 = 0.7		*a* = 0.21 + 0.09 = 0.3

(a) Genotype and allele frequencies



(b) Segregation of alleles and random fertilization

ACTIVE FIGURE 18-1 **Hardy-Weinberg principle**

(a) How to calculate frequencies of the alleles *A* and *a* in the gametes. **(b)** When eggs and sperm containing *A* or *a* alleles unite randomly, the frequency of each of the possible genotypes *(AA, Aa, aa)* among the offspring is calculated by multiplying the frequencies of the alleles *A* and *a* in eggs and sperm.

BiologyNow™ Interact with the **Hardy-Weinberg principle** by clicking on this figure on your BiologyNow CD-ROM.

Genetic equilibrium occurs if certain conditions are met

The Hardy-Weinberg principle of genetic equilibrium tells us what to expect when a sexually reproducing population is not evolving. The relative proportions of alleles and genotypes in successive generations will always be the same, provided the following five conditions are met:

1. Random mating. In unrestricted random mating, each individual in a population has an equal chance of mating with

any individual of the opposite sex. In our example, the individuals represented by the genotypes *AA*, *Aa*, and *aa* must mate with one another at random and must not select their mates on the basis of genotype or any other factors that result in nonrandom mating.

2. No net mutations. There must be no mutations that convert *A* into *a* or vice versa. That is, the frequencies of *A* and *a* in the population must not change because of mutations.
3. Large population size. Allele frequencies in a small population are more likely to change by random fluctuations (that is, by genetic drift, which is discussed later) than are allele frequencies in a large population.
4. No migration. There can be no exchange of alleles with other populations that might have different allele frequencies. In other words, there can be no migration[1] of individuals into or out of a population.
5. No natural selection. If natural selection is occurring, certain phenotypes (and their corresponding genotypes) are favored over others. Consequently, the allele frequencies will change, and the population will evolve.

Human MN blood groups are a valuable illustration of the Hardy-Weinberg principle

Humans have dozens of antigens on the surfaces of their blood cells. (An *antigen* is a molecule, usually a protein or carbohydrate, that is recognized as foreign by cells of another organism's immune system.) One group of antigens, designated the MN blood group, stimulates the production of antibodies when injected into rabbits or guinea pigs. However, humans do not produce antibodies for M and N, so the MN blood group is not medically important, for example, when giving blood transfusions. (Recall the discussion of the medically important ABO alleles in Chapter 10.) The MN blood group is of interest to population geneticists because the alleles for the MN blood group, usually designated *M* and *N*, are codominant (genotype *MM* produces antigen M only, genotype *NN* produces antigen N only, and the heterozygous genotype *MN* produces both antigens.) This allows all three possible genotype frequencies to be observed directly and compared with calculated frequencies. The following data are typical of the MN blood group in people in the United States:

Genotype	Observed
MM	320
MN	480
NN	200
Total	1000

Because 1000 diploid individuals are in the sample, there are a total of 2000 alleles. The frequency of *M* alleles in the population $= p = (2 \times 320 + 480) \div 2000 = 0.56$. The frequency of *N* alleles in the population $= q = (2 \times 200 + 480) \div 2000 = 0.44$. As a quick check, the sum of the frequencies should equal 1. Does it?

If this population is in genetic equilibrium, then the expected *MM* genotype frequency $= p^2 = (0.56)^2 = 0.31$. The expected *MN* genotype frequency $= 2pq = 2 \times 0.56 \times 0.44 = 0.49$. The expected *NN* genotype frequency $= q^2 = (0.44)^2 = 0.19$. As a quick check, the sum of the three genotype frequencies should equal 1. Does it? You can use the calculated genotype frequencies to determine how many individuals in a population of 1000 should have the expected genotype frequencies. By comparing the expected numbers with the actual results observed, you see how closely the population is to genetic equilibrium. Simply multiply each genotype frequency by 1000:

Genotype	Observed	Expected
MM	320	313.6
MN	480	492.8
NN	200	193.6
Total	1000	1000.0

The expected numbers closely match the observed numbers, indicating that the *MN* blood groups in the human population are almost at genetic equilibrium. This is not surprising, because the lack of medical significance suggests that the *MN* characteristic is not subject to natural selection and that it does not produce a visible phenotype that might affect random mating.

Review

- In a population at genetic equilibrium, the frequency of the homozygous recessive genotype *(tt)* is 0.16. What are the allele frequencies of *T* and *t*, and what are the expected frequencies of the *TT* and *Tt* genotypes?
- In a population at genetic equilibrium, the frequency of the dominant phenotype is 0.96. What are the frequencies of the dominant *(A)* and recessive *(a)* alleles, and what are the expected frequencies of the *AA*, *Aa*, and *aa* genotypes?
- The genotype frequencies of a population are determined to be 0.6 *BB*, 0.0 *Bb*, and 0.4 *bb*. Is it likely that this population meets all the conditions required for genetic equilibrium?

MICROEVOLUTION

Learning Objectives

5 Define *microevolution*.
6 Discuss how each of the following microevolutionary forces alters allele frequencies in populations: nonrandom mating, mutation, genetic drift, gene flow, and natural selection.
7 Distinguish among stabilizing selection, directional selection, and disruptive selection, and give an example of each.

Evolution represents a departure from the Hardy-Weinberg principle of genetic equilibrium. The degree of departure between the observed allele or genotype frequencies and those expected by

[1] Note that evolutionary biologists use the term *migration*, not in its ordinary sense of periodic or seasonal movement of individuals from one location to another, but instead to refer to a movement of individuals that results in a transfer of alleles from one population to another.

the Hardy-Weinberg principle indicates the amount of evolutionary change. This type of evolution—generation-to-generation changes in allele or genotype frequencies *within* a population—is sometimes referred to as **microevolution,** because it often involves relatively small or minor changes, usually over a few generations. Changes in the allele frequencies of a population result from five microevolutionary processes: nonrandom mating, mutation, genetic drift, gene flow, and natural selection. These microevolutionary processes are the opposite of the conditions that must be met if a population is in genetic equilibrium. When one or more of these processes acts on a population, allele or genotype frequencies change from one generation to the next.

Text not available due to copyright restrictions

Nonrandom mating changes genotype frequencies

When individuals select mates on the basis of phenotype (thereby selecting the corresponding genotype), they bring about evolutionary change in the population. Two examples of nonrandom mating are inbreeding and assortative mating.

In many populations, individuals mate more often with close neighbors than with more distant members of the population. As a result, neighbors tend to be more closely related—that is, genetically similar—to one another. The mating of genetically similar individuals that are more closely related than if they had been chosen at random from the entire population is known as **inbreeding.** Although inbreeding does not change the overall allele frequency, the frequency of homozygous genotypes increases with each successive generation of inbreeding. The most extreme example of inbreeding is self-fertilization, which is particularly common in certain plants.

Inbreeding does not appear to be detrimental in some populations, but in others it causes **inbreeding depression,** in which inbred individuals have lower fitness than those not inbred. **Fitness** is the relative ability of a given genotype to make a genetic contribution to subsequent generations; fitness is usually measured as the average number of surviving offspring of one genotype compared to the average number of surviving offspring of competing genotypes. Inbreeding depression, as evidenced by fertility declines and high juvenile mortality, is thought to be caused by the expression of harmful recessive alleles as homozygosity increases with inbreeding.

Several studies in the 1990s provided direct evidence of the deleterious consequences of inbreeding in nature. For example, white-footed mice (*Peromyscus leucopus*) were taken from a field and used to develop both inbred and non-inbred populations in the laboratory. When these laboratory-bred populations were returned to nature, their survivorship was estimated from release–recapture data. The non-inbred mice had a statistically significant higher rate of survival (Fig. 18-2). It is not known why the inbred mice had a lower survival rate. Some possibilities include higher disease susceptibility, poorer ability to evade predators, less ability to find food, and less ability to win fights with other white-footed mice.

Assortative mating, in which individuals select mates by their phenotypes, is another example of nonrandom mating. For example, biologists selected two phenotypes—high bristle number and low bristle number—in a fruit fly (*Drosophila melanogaster*) population. Although they made no effort to control mating, they observed that the flies preferentially mated with those of similar phenotypes. Females with high bristle number tended to mate with males with high bristle number, and females with low bristle number tended to mate with males with low bristle number. Such selection of mates with the same phenotype is known as *positive assortative mating* (as opposed to the less common phenomenon, *negative assortative mating,* in which mates with opposite phenotypes are selected).

Positive assortative mating is practiced in many human societies, in which men and women tend to marry individuals like themselves in such characteristics as height or intelligence. Like inbreeding, assortative mating usually increases homozygosity at the expense of heterozygosity in the population and does not change the overall allele frequencies in the population. However, assortative mating changes genotype frequencies only at the loci involved in mate choice, whereas inbreeding affects genotype frequencies in the entire genome.

Mutation increases variation within a population

Variation is introduced into a population through **mutation,** which is an unpredictable change in deoxyribonucleic acid (DNA). As discussed in Chapter 12, mutations, which are the source of all new alleles, result from (1) a change in the nucleotide base pairs of a gene, (2) a rearrangement of genes within chromosomes so that their interactions produce different effects, or (3) a change in chromosome structure. Mutations occur unpredictably and spontaneously. The rate of mutation appears

relatively constant for a particular locus, but may vary by several orders of magnitude among genes within a single species and among different species.

Not all mutations pass from one generation to the next. Those occurring in somatic (body) cells are not inherited. When an individual with such a mutation dies, the mutation is lost. Some mutations, however, occur in reproductive cells. These mutations may or may not overtly affect the offspring, because most of the DNA in a cell is "silent" and does not code for specific polypeptides or proteins that are responsible for physical characteristics. Even if a mutation occurs in the DNA that codes for a polypeptide, it may still have little effect on the structure or function of that polypeptide (we discuss such *neutral variation* later in the chapter). However, when a polypeptide is sufficiently altered to change its function, the mutation is usually harmful. By acting against seriously abnormal phenotypes, natural selection eliminates or reduces to low frequencies the most harmful mutations. Mutations with small phenotypic effects, even if slightly harmful, have a better chance of being incorporated into the population, where at some later time, under different environmental conditions, they may produce phenotypes that are useful or adaptive.

Mutations do not determine the *direction* of evolutionary change. Consider a population living in an increasingly dry environment. A mutation producing a new allele that helps an individual adapt to dry conditions is no more likely to occur than one for adapting to wet conditions or one with no relationship to the changing environment. The production of new mutations simply increases the genetic variability that is acted on by natural selection and, therefore, increases the potential for new adaptations.

Mutation by itself causes small deviations in allele frequencies from those predicted by the Hardy-Weinberg principle. Although allele frequencies may be changed by mutation, these changes are typically several orders of magnitude smaller than changes caused by other evolutionary forces, such as genetic drift. As an evolutionary force, mutation is usually negligible, but it is important as the ultimate source of variation for evolution.

In genetic drift, random events change allele frequencies

The size of a population has important effects on allele frequencies because random events, or chance, tend to cause changes of relatively greater magnitude in a small population. If a population consists of only a few individuals, an allele present at a low frequency in the population could be completely lost by chance. Such an event would be unlikely in a large population. For example, consider two populations, one with 10,000 individuals and one with 10 individuals. If an uncommon allele occurs at a frequency of 10%, or 0.1, in both populations, then 1900 individuals in the large population have the allele.[2] That same frequency, 0.1, in the smaller population means that only about two individuals have the allele.[3] From this exercise, it is easy to see that there is a greater likelihood of losing the rare allele from the smaller population than from the larger one. Predators, for example, might happen to kill one or two individuals possessing the uncommon allele in the smaller population purely by chance, so these individuals would leave no offspring.

The production of random evolutionary changes in small breeding populations is known as **genetic drift.** Genetic drift results in changes in allele frequencies in a population from one generation to another. One allele may be eliminated from the population purely by chance, regardless of whether that allele is beneficial, harmful, or of no particular advantage or disadvantage. Thus, genetic drift decreases genetic variation *within* a population, although it tends to increase genetic differences *among* different populations.

When bottlenecks occur, genetic drift becomes a major evolutionary force

Because of fluctuations in the environment, such as depletion in food supply or an outbreak of disease, a population may rapidly and markedly decrease from time to time. The population is said to go through a **bottleneck** during which genetic drift can occur in the small population of survivors. As the population again increases in size, many allele frequencies may be quite different from those in the population preceding the decline.

Scientists hypothesize that genetic variation in the cheetah (see Figs. 50-9 and 50-20d) was considerably reduced by a bottleneck at the end of the last Ice Age, some 10,000 years ago. Cheetahs nearly became extinct, perhaps from overhunting by humans. The few surviving cheetahs had greatly reduced genetic variability, and as a result, the cheetah population today is so genetically uniform that unrelated cheetahs can accept skin grafts from one another. (Normally, only identical twins accept skin grafts so readily.)

The founder effect occurs when a few "founders" establish a new colony

When one or a few individuals from a large population establish, or found, a colony (as when a few birds separate from the rest of the flock and fly to a new area), they bring with them only a small fraction of the genetic variation present in the original population. As a result, the only alleles among their descendants will be those of the colonizers. Typically, the allele frequencies in the newly founded population are quite different from those of the parent population. The genetic drift that results when a small number of individuals from a large population found a new colony is called the **founder effect.**

The Finnish people may illustrate the founder effect (Fig. 18-3). Geneticists who sampled DNA from Finns and from the European population at large found that Finns exhibit considerably less genetic variation than other Europeans. This evidence supports the hypothesis that Finns are descended from a small group of people who settled about 4000 years ago in that area that is now Finland and, because of the geography, remained separate from other European societies for centuries.

The founder effect is sometimes of medical importance. For example, by chance one of the approximately 200 founders of

[2] $2pq + q^2 = 2(0.9)(0.1) + (0.1)^2 = 0.18 + 0.01 = 0.19; 0.19 \times 10{,}000 = 1900.$

[3] $0.19 \times 10 = 1.9.$

the Amish population of Pennsylvania carried a recessive allele that is responsible for a form of dwarfism, Ellis-van Creveld syndrome, when homozygous. Although this allele is rare in the general population (frequency about 0.001), today it is relatively common in the Amish population (frequency about 0.07).

Gene flow generally increases variation within a population

Individuals of a species tend to be distributed in local populations that are genetically isolated to some degree from other populations. For example, the bullfrogs of one pond form a population separated from those in an adjacent pond. Some exchanges occur by migration between ponds, but the frogs in one pond are much more likely to mate with those in the same pond. Because each population is isolated to some extent from other populations, they have distinct genetic traits and gene pools.

The migration of breeding individuals between populations causes a corresponding movement of alleles, or **gene flow,** that has significant evolutionary consequences. As alleles flow from one population to another, they usually increase the amount of genetic variability within the recipient population. If sufficient gene flow occurs between two populations, they become more similar genetically. Because gene flow reduces the amount of variation between two populations, it tends to counteract the effects of natural selection and genetic drift, both of which often cause populations to become increasingly distinct.

If migration by members of a population is considerable, and if populations differ in their allele frequencies, then significant genetic changes occur in local populations. For example, by 10,000 years ago modern humans occupied almost all of Earth's major land areas except a few islands. Because the population density was low in most locations, the small, isolated human populations underwent random genetic drift and natural selection. More recently (during the past 300 years or so), major migrations have increased gene flow, significantly altering allele frequencies within previously isolated human populations.

Natural selection changes allele frequencies in a way that increases adaptation

Natural selection is the mechanism of evolution first proposed by Darwin in which members of a population that are more successfully adapted to the environment are more likely to survive and reproduce (see Chapter 17). Over successive generations, the proportion of favorable alleles increases in the population. In contrast with other microevolutionary processes (nonrandom mating, mutation, genetic drift, and gene flow), natural selection leads to adaptive evolutionary change. Natural selection not only explains why organisms are well adapted to the environments in which they live but also helps account for the remarkable diversity of life. Natural selection enables populations to change, thereby adapting to different environments and different ways of life.

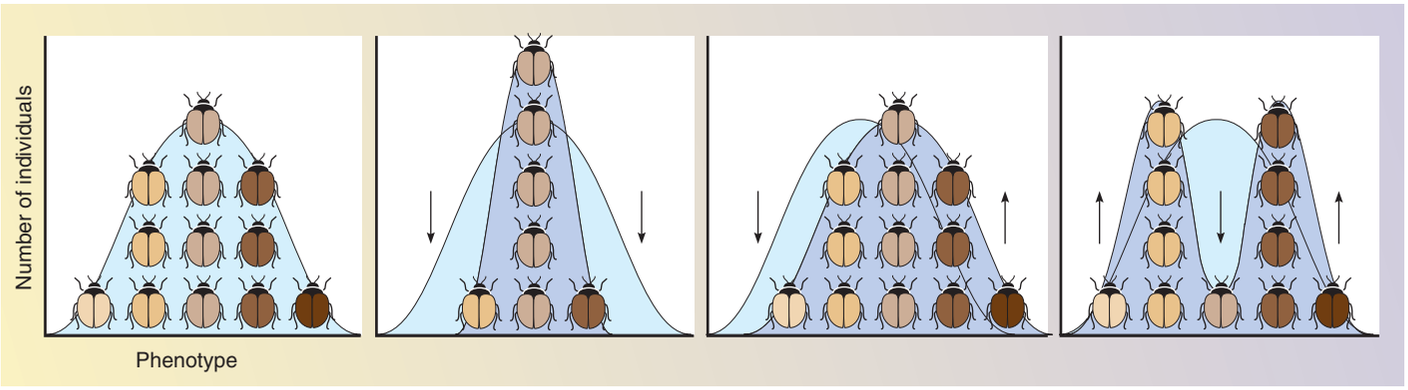
Natural selection is the differential reproduction of individuals with different traits, or phenotypes (and therefore different genotypes), in response to the environment. Natural selection preserves individuals with favorable phenotypes and eliminates those with unfavorable phenotypes. Individuals that survive and produce fertile offspring have a selective advantage.

The mechanism of natural selection does not develop a "perfect" organism. Rather, it weeds out those individuals whose phenotypes are less adapted to environmental challenges, while allowing better adapted individuals to survive and pass their alleles to their offspring. By reducing the frequency of alleles that result in the expression of less favorable traits, the probability is increased that favorable alleles responsible for an adaptation will come together in the offspring.

Natural selection operates on an organism's phenotype

Natural selection does not act directly on an organism's genotype. Instead, it acts on the phenotype, which is, at least in part, an expression of the genotype. The phenotype represents an interaction between the environment and all the alleles in the organism's genotype. It is rare that alleles of a single locus determine the phenotype, as Mendel originally observed in garden peas. Much more common is the interaction of alleles of several loci for the expression of a single phenotype (see Chapter 10). Many plant and animal characteristics are under this type of polygenic control.

When characters (characteristics) are under polygenic control (as is human height), a range of phenotypes occurs, with most of the population located in the median range and fewer at either extreme. This is a normal distribution or standard bell curve (Fig. 18-4a; see also Fig. 10-22). Three kinds of selection cause changes in the normal distribution of phenotypes in a population: stabilizing, directional, and disruptive selection. Although we consider each process separately, in nature their influences generally overlap.



(a) No selection (b) Stabilizing selection (c) Directional selection (d) Disruptive selection

ACTIVE FIGURE **18-4** **Modes of selection.**

The blue screen represents the distribution of individuals by phenotype (in this example, color variation) in the original population. The purple screen represents the distribution by phenotype in the evolved population. The arrows represent the pressure of natural selection on the phenotypes. **(a)** A character that is under polygenic control (in this example, wing colors in a hypothetical population of beetles) exhibits a normal distribution of phenotypes in the absence of selection. **(b)** As a result of stabilizing selection, which trims off extreme phenotypes, variation about the mean is reduced. **(c)** Directional selection shifts the curve in one direction, changing the average value of the character. **(d)** Disruptive selection, which trims off intermediate phenotypes, results in two or more peaks.

BiologyNow™ Watch **natural selection** in action by clicking on this figure on your BiologyNow CD-ROM.

Stabilizing selection The process of natural selection associated with a population well adapted to its environment is known as **stabilizing selection.** Most populations are probably influenced by stabilizing forces most of the time. Stabilizing selection selects against phenotypic extremes. In other words, individuals with an average, or intermediate, phenotype are favored.

Because stabilizing selection tends to decrease variation by favoring individuals near the mean of the normal distribution at the expense of those at either extreme, the bell curve narrows (Fig. 18-4b). Although stabilizing selection decreases the amount of variation in a population, variation is rarely eliminated by this process, because other microevolutionary processes act against a decrease in variation. For example, mutation is slowly but continually adding to the genetic variation within a population.

One of the most widely studied cases of stabilizing selection involves human birth weight, which is under polygenic control and is also influenced by environmental factors. Extensive data from hospitals have shown that infants born with intermediate weights are most likely to survive (Fig. 18-5). Infants at either extreme (too small or too large) have higher rates of mortality. When newborn infants are too small, their body systems are immature, and when they are too large, they have difficult deliveries because they cannot pass as easily through the cervix and vagina. Stabilizing selection operates to reduce variability in birth weight so it is close to the weight with the minimum mortality rate.

Directional selection If an environment changes over time, **directional selection** may favor phenotypes at one of the extremes of the normal distribution (Fig. 18-4c). Over successive generations, one phenotype gradually replaces another. So, for example, if greater size is advantageous in a new environment, larger individuals will become increasingly common in the population. Directional selection only occurs, however, if alleles favored under the new circumstances are already present in the population.

Darwin's Galapagos finches provide an excellent example of directional selection. Since 1973, Peter Grant and Rosemary Grant of Princeton University have studied the Galapagos

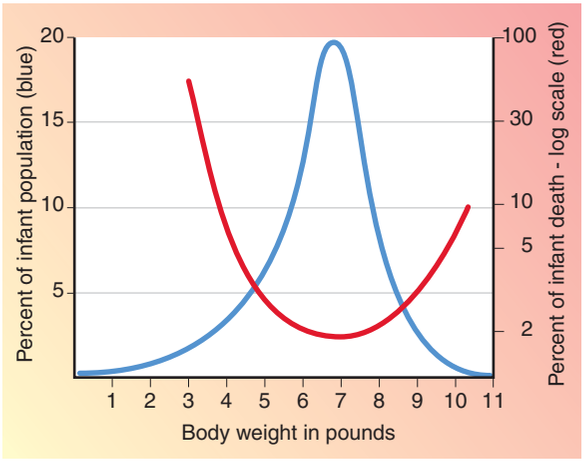


FIGURE **18-5** **Stabilizing selection.**

The blue curve shows the distribution of birth weights in a sample of 13,730 infants. The red curve shows mortality (death) at each birth weight. Infants with very low or very high birth weights have higher death rates than infants of average weight. The optimum birth weight, that is, the one with the lowest mortality, is close to the average birth weight (about 7 pounds). *(Adapted from, L.L. Cavalli-Sforza and W.F. Bodmer,* The Genetics of Human Populations, *W.H. Freeman and Company, San Francisco, 1971)*

TABLE **18-1** Population Changes in *Geospiza fortis* Before and After the 1976–1977 Drought

Character	Average Before Drought (634)*	Average After Drought (135)*	Difference
Weight (g)	16.06	17.13	+1.07
Wing length (mm)	67.88	68.87	+0.99
Tarsus (leg, just above the foot) length (mm)	19.08	19.29	+0.21

finches. The Grants did a meticulous analysis of finch eating habits and beak sizes on Isla Daphne Major during three extended droughts (1977–1978, 1980, and 1982), one of which was followed by an extremely wet El Niño event (1983). During the droughts, the number of insects and small seeds declined, and large, heavy seeds became the finches' primary food source. Many finches died during this time, and most of the survivors were larger birds whose beaks were larger and deeper. In a few generations, these larger birds became more common in the population (Table 18-1). After the wet season, however, smaller seeds became the primary food source, and smaller finches with average-sized beaks were favored. In this example, natural selection is directional: During the drought, natural selection operated in favor of the larger phenotype, whereas after the wet period selection occurred in the opposite direction, favoring the smaller phenotype. The guppy populations studied in Venezuela and Trinidad (see Chapter 17) are another example of directional selection.

Disruptive selection Sometimes extreme changes in the environment may favor two or more different phenotypes at the expense of the mean. That is, more than one phenotype may be favored in the new environment. **Disruptive selection** is a special type of directional selection in which there is a trend in several directions rather than just one (Fig. 18-4d). It results in a divergence, or splitting apart, of distinct groups of individuals within a population. Disruptive selection, which is relatively rare, selects against the average, or intermediate, phenotype.

Limited food supply during a severe drought caused a population of finches on another island in the Galapagos to experience disruptive selection. The finch population initially exhibited a variety of beak sizes and shapes. Because the only foods available on this island during the drought were wood-boring insects and seeds from cactus fruits, natural selection favored birds with beaks suitable for obtaining these types of food. Finches with longer beaks survived because they could open cactus fruits, and those with wider beaks survived because they could strip off tree bark to expose insects. However, finches with intermediate beaks could not use either food source efficiently, and had a lower survival rate.

Natural selection induces change in the types and frequencies of alleles in populations only if there is pre-existing inherited variation. Genetic variation is the raw material for evolutionary change, because it provides the diversity on which natural selection acts. Without genetic variation, evolution cannot occur. In the next section we explore the genetic basis for variation that is acted on by natural selection.

Review

- Which microevolutionary force leads to adaptive changes in allele frequencies?
- Why is mutation important to evolution if it is the microevolutionary force that generally has the smallest effect on allele frequencies?
- Which microevolutionary forces are most associated with an increase in variation within a population? Among populations?
- Which microevolutionary force typically changes genotype frequencies without changing allele frequencies? Explain.

GENETIC VARIATION IN POPULATIONS

Learning Objective

8 Describe the nature and extent of genetic variation, including genetic polymorphism, balanced polymorphism, neutral variation, and geographic variation.

Populations contain abundant genetic variation that was originally introduced by mutation. Sexual reproduction, with its associated crossing-over, independent assortment of chromosomes during meiosis, and random union of gametes, also contributes to genetic variation. The sexual process allows the variability introduced by mutation to be combined in new ways, which may be expressed as new phenotypes.

Genetic polymorphism exists among alleles and the proteins for which they code

One way of evaluating genetic variation in a population is to examine **genetic polymorphism,** which is the presence in a population of two or more alleles for a given locus. Genetic polymor-

phism is extensive in populations, although many of the alleles are present at low frequencies. Much of genetic polymorphism is not evident, because it does not produce distinct phenotypes.

One way biologists estimate the total amount of genetic polymorphism in populations is by comparing the different forms of a particular protein. Each form consists of a slightly different amino acid sequence that is coded for by a different allele. For example, tissue extracts containing a particular enzyme may be analyzed by gel electrophoresis for different individuals. In gel electrophoresis, the enzymes are placed in slots on an agarose gel, and an electric current is applied, causing each enzyme to migrate across the gel (see Fig. 14-8). Slight variations in amino acid sequences in the different forms of a particular enzyme cause each to migrate at a different rate, which can be detected using special stains or radioactive labels. Table 18-2 shows the degree of polymorphism in selected plant and animal groups based on gel electrophoresis of several enzymes. Note that genetic polymorphism tends to be greater in plants than in animals.

Determining the sequence of nucleotides in DNA from individuals in a population provides a *direct* estimate of genetic polymorphism. DNA sequencing is shown in Figures 14-9 and 14-10. DNA sequencing of specific alleles in an increasing number of organisms, including humans, indicates that genetic polymorphism is extensive in most populations.

Weir (eds.), *Plant Population Genetics, Breeding, and Genetic Resources,* Sunderland, MA, Sinauer Associates, 1990. Animal data adapted from D. Hartl, *Principles of Population Genetics,* Sunderland, MA, Sinauer Associates, 1980, and P.W. Hedrick, *Genetics of Populations,* Boston, Science Books International, 1983.

Balanced polymorphism exists for long periods

Balanced polymorphism is a special type of genetic polymorphism in which two or more alleles persist in a population over many generations as a result of natural selection. Heterozygote advantage and frequency-dependent selection are mechanisms that preserve balanced polymorphism.

Genetic variation may be maintained by heterozygote advantage

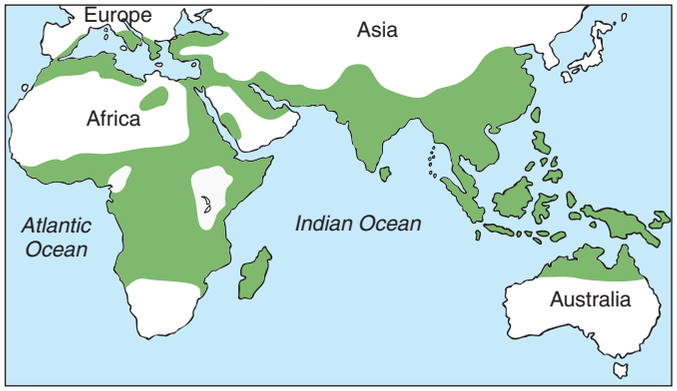
We have seen that natural selection often eliminates unfavorable alleles from a population, whereas favorable alleles are retained. However, natural selection sometimes helps maintain genetic diversity in a population, including alleles that are unfavorable in the homozygous state. This happens, for example, when the heterozygote, *Aa,* has a higher degree of fitness than either homozygote, *AA* or *aa.* This phenomenon, known as **heterozygote advantage,** is demonstrated in humans by the selective advantage of heterozygous carriers of the sickle cell allele.

The mutant allele (Hb^S) for sickle cell anemia produces an altered hemoglobin that deforms or sickles the red blood cells, making them more likely to form dangerous blockages in capillaries and to be destroyed in the liver, spleen, or bone marrow (see Chapter 15). People who are homozygous for the sickle cell allele (Hb^SHb^S) usually die at an early age if medical treatment is not available.

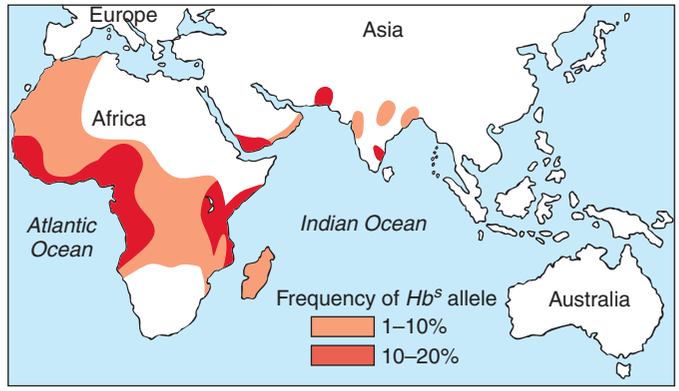
Heterozygous individuals carry alleles for both normal (Hb^A) and sickle cell hemoglobin. The heterozygous condition (Hb^AHb^S) makes a person more resistant to a type of severe malaria (caused by the parasite *Plasmodium falciparum*) than people who are homozygous for the normal hemoglobin allele (Hb^AHb^A). In a heterozygous individual, each allele produces its own specific kind of hemoglobin, and the red blood cells contain the two kinds in roughly equivalent amounts. Not only do such cells sickle much less readily than cells containing only the Hb^S allele, but also they are more resistant to infection by the malaria-causing parasite, which lives in red blood cells, than are the red blood cells containing only normal hemoglobin.

Where malaria is a problem, each of the two types of homozygous individuals is at a disadvantage. Those homozygous for the sickle cell allele are likely to die of sickle cell anemia, whereas those homozygous for the normal allele may die of malaria. The heterozygote is therefore more fit than either homozygote. In parts of Africa, the Middle East, and southern Asia where falciparum malaria is prevalent, heterozygous individuals survive in greater numbers than either homozygote (Fig. 18-6). The Hb^S allele is maintained at a high frequency in the population, even though the homozygous recessive condition is almost always lethal.

What happens to the frequency of Hb^S alleles in Africans and others who possess it when they migrate to the United States and other nonmalarial countries? As might be expected, the frequency of the Hb^S allele gradually declines in such populations, possibly because it confers a selective disadvantage by causing sickle cell anemia in homozygous individuals but no longer confers a selective advantage by preventing malaria in heterozygous individuals. The Hb^S allele never disappears from the pop-



(a) *P. falciparum* malaria



(b) Sickle cell anemia

FIGURE **18-6** **Heterozygote advantage.**

The geographic distribution of **(a)** falciparum malaria *(green)* is compared with that of **(b)** sickle cell anemia *(red and orange).* The greater fitness of heterozygous individuals in malarial regions supports the hypothesis of heterozygote advantage, which can be seen by the large area of codistribution. *(Adapted from A.C. Allison, "Protection Afforded by Sickle-Cell Traits against Subtertian Malarial Infection."* British Medical Journal, *Vol. 1, 1954)*

ulation, however, because it is "hidden" from selection in heterozygous individuals and because it is reintroduced into the population by gene flow from the African population.

Genetic variation may be maintained by frequency-dependent selection

Thus far in our discussion of natural selection, we have assumed the fitness of particular phenotypes (and their corresponding genotypes) is independent of their frequency in the population. However, in cases of **frequency-dependent selection** the fitness of a particular phenotype depends on how frequently it appears in the population. Often a phenotype has a greater selective value when rare than when common in the population. Such phenotypes lose their selective advantage as they become more common.

Frequency-dependent selection often acts to maintain genetic variation in populations of prey species. In this case, the predator catches and consumes the more common phenotype but may ignore the rarer phenotypes. Consequently, the less common phenotype produces more offspring and therefore makes a greater relative contribution to the next generation.

Frequency-dependent selection is demonstrated in scale-eating fish (cichlids of the species *Perissodus microlepsis*) from Lake Tanganyika in Africa. The scale-eating fish, which obtain food by biting scales off other fish, have either left-pointing or right-pointing mouths. A single locus with two alleles determines this characteristic; the allele for right-pointing mouth is dominant over the allele for left-pointing mouth. These fish attack their prey from behind, and from a single direction, depending on mouth morphology. Those with left-pointing mouths always attack the right flanks of their prey, whereas those with right-pointing mouths always attack the left flanks (Fig. 18-7a).

The prey species are more successful at evading attacks from the more common form of scale-eating fish. For example, if the cichlids with right-pointing mouths are more common than those with left-pointing mouths, the prey are attacked more often on their left flanks. They therefore become more wary against such attacks, conferring a selective advantage to the less common cichlids with left-pointing mouths. The cichlids with left-

Images not available due to copyright restrictions

pointing mouths would be more successful at obtaining food and would therefore have more offspring. Over time, the frequency of fish with left-pointing mouths would increase in the population, until their abundance causes frequency-dependent selection to work against them and confer an advantage on the now less-common fish with right-pointing mouths. Thus frequency-dependent selection maintains both populations of fish at approximately equal numbers (Fig. 18-7b).

Neutral variation may give no selective advantage or disadvantage

Some of the genetic variation observed in a population may confer no apparent selective advantage or disadvantage in a particular environment. For example, random changes in DNA that do not alter protein structure usually do not affect the phenotype. Variation that does not alter the ability of an individual to survive and reproduce and is, therefore, not adaptive is called **neutral variation.**

The extent of neutral variation in organisms is difficult to determine. It is relatively easy to demonstrate that an allele is beneficial or harmful if its effect is observable. But the variation in alleles that involves only slight differences in the proteins they code for may or may not be neutral. These alleles may be influencing the organism in subtle ways that are difficult to measure or assess. Also, an allele that is neutral in one environment may be beneficial or harmful in another.

Populations in different geographic areas often exhibit genetic adaptations to local environments

In addition to the genetic variation among individuals within a population, genetic differences often exist among different populations within the same species, a phenomenon known as *geographic variation.* One type of geographic variation is a **cline,** which is a gradual change in a species' phenotype and genotype frequencies through a series of geographically separate populations as a result of an environmental gradient. A cline exhibits variation in the expression of such attributes as color, size, shape, physiology, or behavior. Clines are common among species with continuous ranges over large geographic areas. For example, the body sizes of many widely distributed birds and mammals increase gradually as the latitude increases, presumably because larger animals are better able to withstand the colder temperatures of winter.

The common yarrow (*Achillea millefolium*), a wildflower that grows in a variety of North American habitats from lowlands to mountain highlands, exhibits clinal variation in height in response to different climates at different elevations. Although

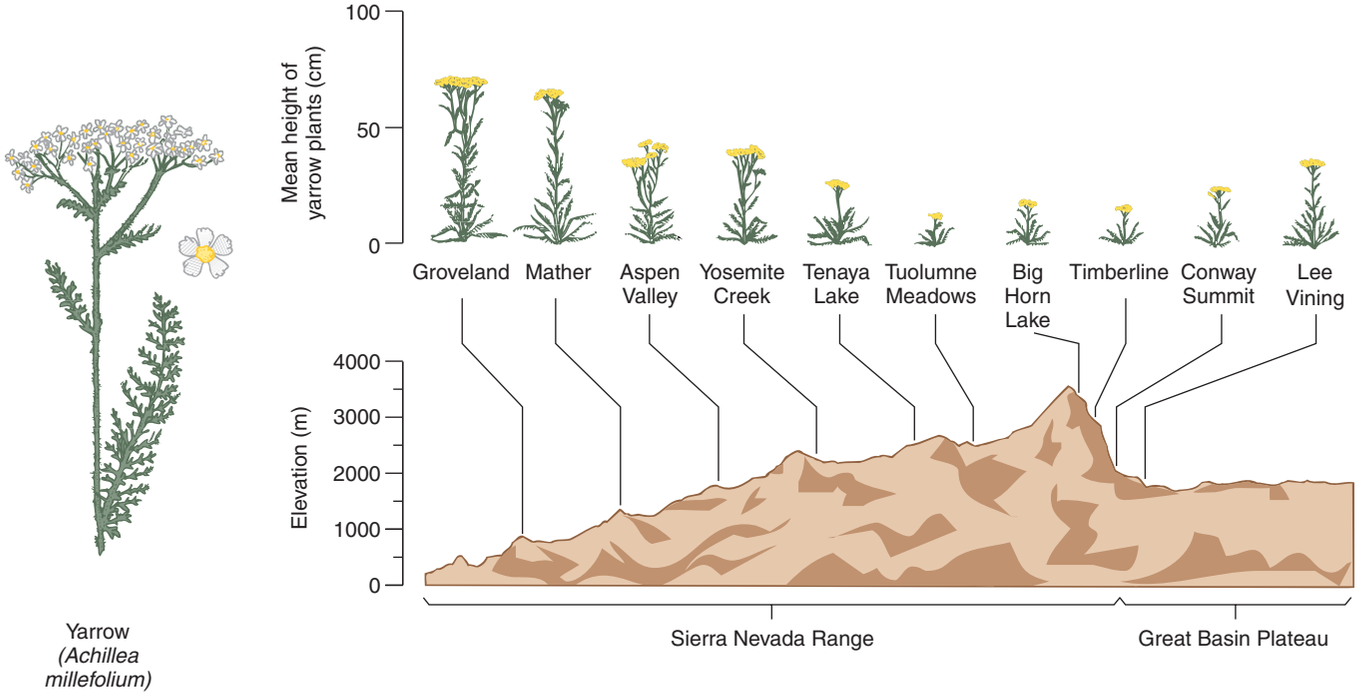


FIGURE **18-8** **Clinal variation in yarrow (*Achillea millefolium*).**

Seeds from widely dispersed populations in the Sierra Nevada of California and Nevada were collected and grown for several generations under identical conditions in the same test garden at Stanford, California. The plants retained their distinctive heights, revealing genetic differences related to the elevation where the seeds were collected. *(After J. Clausen, D.D. Keck, and W.M. Hiesey, "Experimental Studies on the Nature of Species: III. Environmental Responses of Climatic Races of* Achillea*," Carnegie Institute Washington Publication, Vol. 58, 1948)*

substantial variation exists among individuals within each population, individuals in populations at higher elevations are, on average, shorter than those at lower elevations. The genetic basis of these clinal differences was experimentally demonstrated in a set of classical experiments in which series of populations from different geographic areas were grown in the same environment (Fig. 18-8). Despite being exposed to identical environmental conditions, each experimental population exhibited the traits characteristic of the elevation from which it was collected.

Review

- How does the sickle cell allele illustrate heterozygote advantage?
- How does frequency-dependent selection affect genetic variation within a population over time?
- How can researchers test the hypothesis that clinal variation in a particular population has a genetic basis?

BiologyNow™ Assess your understanding of **genetic variation in populations** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Define what is meant by a population's gene pool.

- All the individuals that live in a particular place at the same time make up a **population.** Each population has a **gene pool,** which includes all the **alleles** for all the **loci** present in the population. **Population genetics** is the study of genetic variability within a population and of the forces that act on it.

2 Distinguish among genotype, phenotype, and allele frequencies.

- A **genotype frequency** is the proportion of a particular genotype in the population.
- A **phenotype frequency** is the proportion of a particular phenotype in the population.
- An **allele frequency** is the proportion of a specific allele of a given genetic locus in the population.

3 Discuss the significance of the Hardy-Weinberg principle as it relates to evolution, and list the five conditions required for genetic equilibrium.

- The **Hardy-Weinberg principle** states that allele and genotype frequencies do not change from generation to generation (no evolution is occurring) in a population at **genetic equilibrium.**
- The Hardy-Weinberg principle applies only if mating is random in the population, there are no net mutations that change the allele frequencies, the population is large, individuals do not migrate between populations, and natural selection does not occur.

4 Use the Hardy-Weinberg principle to solve problems involving populations.

- In the Hardy-Weinberg equation, p = the frequency of the dominant allele, q = the frequency of the recessive allele: $p + q = 1$.
- The genotype frequencies of a population are described by the relationship $p^2 + 2pq + q^2 = 1$, where p^2 is the frequency of the homozygous dominant genotype, $2pq$ the frequency of the heterozygous genotype, and q^2 the frequency of the homozygous recessive genotype.

5 Define *microevolution.*

- **Microevolution** is a change in allele or genotype frequencies within a population over successive generations.

6 Discuss how each of the following microevolutionary forces alters allele frequencies in populations: nonrandom mating, mutation, genetic drift, gene flow, and natural selection.

- In nonrandom mating, individuals select mates on the basis of phenotype, indirectly selecting the corresponding genotype(s). **Inbreeding** is the mating of genetically similar individuals that are more closely related than if they had been chosen at random from the entire population. Inbreeding in some populations causes **inbreeding depression,** in which inbred individuals have lower **fitness** than non-inbred individuals. In **assortative mating** individuals select mates by their phenotypes. Both inbreeding and assortative mating increase the frequency of homozygous genotypes.
- **Mutations,** unpredictable changes in DNA, are the source of new alleles. Mutations increase the genetic variability acted on by natural selection.
- **Genetic drift** is a random change in the allele frequencies of a small population. Genetic drift decreases genetic variation within a population, and the changes caused by genetic drift are usually not adaptive. A sudden decrease in population size caused by adverse environmental factors is known as a **bottleneck.** The **founder effect** is genetic drift that occurs when a small population colonizes a new area.
- **Gene flow,** a movement of alleles caused by the migration of individuals between populations, causes changes in allele frequencies.
- **Natural selection** causes changes in allele frequencies that lead to adaptation. Natural selection operates on an organism's phenotype, but it changes the genetic composition of a population in a favorable direction for a particular environment.

7 Distinguish among stabilizing selection, directional selection, and disruptive selection, and give an example of each.

- **Stabilizing selection** favors the mean at the expense of phenotypic extremes.
- **Directional selection** favors one phenotypic extreme over another, causing a shift in the phenotypic mean.
- **Disruptive selection** favors two or more phenotypic extremes.

8 Describe the nature and extent of genetic variation, including genetic polymorphism, balanced polymorphism, neutral variation, and geographic variation.

- **Genetic polymorphism** is the presence in a population of two or more alleles for a given locus.
- **Balanced polymorphism** is a special type of genetic polymorphism in which two or more alleles persist in a population over many generations as a result of natural selection. **Heterozygote advantage** occurs when the heterozygote exhibits greater fitness than either homozygote. In **frequency-dependent selection,** a genotype's selective value varies with its frequency of occurrence.
- **Neutral variation** is genetic variation that confers no detectable selective advantage.
- Geographic variation is genetic variation that exists among different populations within the same species. A **cline** is a gradual change in a species' phenotype and genotype frequencies through a series of geographically separate populations.

POST-TEST

1. The genetic description of an individual is its genotype, whereas the genetic description of a population is its (a) phenotype (b) gene pool (c) genetic drift (d) founder effect (e) changes in allele frequencies
2. In a diploid species, each individual possesses (a) one allele for each locus (b) two alleles for each locus (c) three or more alleles for each locus (d) all the alleles found in the gene pool (e) half of the alleles found in the gene pool
3. The MN blood group is of interest to population geneticists because (a) people with genotype *MN* cannot receive blood transfusions from either *MM* or *NN* people (b) the *MM, MN,* and *NN* genotype frequencies can be observed directly and compared with calculated expected frequencies (c) the *M* allele is dominant to the *N* allele (d) people with the *MN* genotype exhibit frequency-dependent selection (e) people with the *MN* genotype exhibit heterozygote advantage
4. If all copies of a given locus have the same allele throughout the population, then the allele frequency is (a) 0 (b) 0.1 (c) 0.5 (d) 1.0 (e) 10.0
5. If a population's allele and genotype frequencies remain constant from generation to generation (a) the population is undergoing evolutionary change (b) the population is said to be at genetic equilibrium (c) microevolution has taken place (d) directional selection is occurring, but only for a few generations (e) genetic drift is a significant evolutionary force
6. Comparing the different forms of a particular protein in a population provides biologists with an estimate of (a) genetic drift (b) genetic polymorphism (c) gene flow (d) heterozygote advantage (e) frequency-dependent selection
7. The continued presence of the allele that causes sickle cell anemia in areas where falciparum malaria is prevalent demonstrates which of the following phenomena? (a) inbreeding depression (b) frequency-dependent selection (c) heterozygote advantage (d) genetic drift (e) a genetic bottleneck
8. Frequency-dependent selection maintains _____ in a population. (a) assortative mating (b) genetic drift (c) gene flow (d) genetic variation (e) stabilizing selection
9. According to the Hardy-Weinberg principle, (a) allele frequencies are not dependent on dominance or recessiveness but remain essentially unchanged from generation to generation (b) the sum of allele frequencies for a given locus is always greater than 1 (c) if a locus has a single allele, its frequency must be zero (d) allele frequencies change from generation to generation (e) the process of inheritance, by itself, causes changes in allele frequencies
10. What is the correct equation for the Hardy-Weinberg principle?
    (a) $p^2 + pq + 2q^2 = 1$ (b) $p^2 + 2pq + 2q^2 = 1$
    (c) $2p^2 + 2pq + 2q^2 + 1$ (d) $p^2 + pq + q^2 = 1$
    (e) $p^2 + 2pq + q^2 = 1$
11. The Hardy-Weinberg principle is applicable if (a) population size is small (b) migration only occurs at the beginning of the breeding season (c) mutations occur at a constant rate (d) matings occur exclusively between individuals of the same genotype (e) natural selection does not occur
12. Which of the following is *not* an evolutionary agent that causes change in allele frequencies? (a) mutation (b) natural selection (c) genetic drift (d) random mating (e) gene flow from migration
13. Mutation (a) leads to adaptive evolutionary change (b) adds to the genetic variation of a population (c) is the result of genetic drift (d) almost always benefits the organism (e) a and b are correct
14. Which of the following is *not* true of natural selection? (a) Natural selection acts to preserve favorable traits and eliminate unfavorable traits. (b) The offspring of individuals that are better adapted to the environment will make up a larger proportion of the next generation. (c) Natural selection directs the course of evolution by preserving the traits acquired during an individual's lifetime. (d) Natural selection acts on a population's genetic variability, which arises through mutation. (e) Natural selection may result in changes in allele frequencies in a population.
15. In _____, individuals with a phenotype near the phenotypic mean of the population are favored over those with phenotypic extremes. (a) microevolution (b) stabilizing selection (c) directional selection (d) disruptive selection (e) genetic equilibrium

CRITICAL THINKING

1. Why are mutations almost always neutral or harmful?
2. Explain this apparent paradox: People discuss evolution in terms of *genotype* fitness (the selective advantage that a particular genotype confers on an individual), yet natural selection acts on an organism's *phenotype.*
3. Recall that the allele for right-pointing mouth in cichlids *(A)* is dominant over that for left-pointing mouth *(a)*. Use the Hardy-Weinberg principle to calculate the allele frequencies that would correspond to equal frequencies of the two phenotypes. Which allele has the higher frequency? Why? How are these scale-eating fish an example of balanced polymorphism?

Speciation and Macroevolution

Gary Retherford/Photo Researchers, Inc.

Interbreeding between different species. Shown is a "zebrass," a sterile hybrid formed by a cross between a zebra and a donkey that retains features of both parental species. Although such matings may occur under artificial conditions, such as the wildlife ranch in Texas where this cross took place, zebras and donkeys do not interbreed in the wild.

CHAPTER OUTLINE

- Reproductive Isolation
- Speciation
- The Rate of Evolutionary Change
- Macroevolution

A Brazilian rain forest contains thousands of different species of insects, amphibians, reptiles, birds, and mammals. The Great Barrier Reef off the coast of Australia has thousands of species of sponges, corals, mollusks, crustaceans, sea stars, and fishes. We don't know exactly how many species exist today, but biologists estimate there may be something on the order of 10 million to 100 million![1] About 1.8 million of these species have been scientifically named and described. These include 250,000 plant species, 42,000 vertebrate animals, and some 750,000 insects. How did all these species evolve?

In Chapters 17 and 18, we examined natural selection and how populations evolve. We now focus on how species and higher taxonomic categories evolve. The taxonomic groups above the level of species are artificial constructs that humans use to indicate degrees of relatedness among organisms. As described in Chapter 1, scientists group closely related species into the same genus (pl., *genera*), similar genera into the same family, similar families into the same order, similar orders into the same class, and similar classes into the same phylum (pl., *phyla*).

The concept of distinct kinds of organisms, known as **species** (from Latin, meaning "kind") is not new. However, every definition of species has some sort of limitation. Linnaeus, the 18th-century biologist—who founded modern **taxonomy,** the science of naming, describing, and classifying organisms—classified plants and other organisms into separate species based on their structural differences (see Chapter 22). This method, known as the *morphological species concept,* is still used to help characterize species, but structure alone is not adequate to explain what constitutes a species.

Population genetics did much to clarify the concept of species. According to the **biological species concept,** first expressed by evolutionary biologist Ernst Mayr in 1942, a species consists of one or more populations whose members interbreed in nature to produce fertile offspring and do not interbreed with—that is, are reproductively isolated from—members of different

[1] M. L. Reaka-Kudla, D. E. Wilson, and E. O. Wilson, eds., *Biodiversity II* (Washington, D.C.: Joseph Henry Press, 1997).

species. In other words, each species has a *gene pool* separate from that of other species, and reproductive barriers restrict each species from interbreeding with other species.

One problem with the biological species concept is that it applies only to sexually reproducing organisms. Organisms that reproduce asexually do not interbreed, so they cannot be considered in terms of reproductive isolation. These organisms and extinct organisms are classified on the basis of structural and biochemical characteristics. Another potential problem with the biological species concept is that although individuals assigned to different species do not normally interbreed, they may *sometimes* successfully interbreed (see photograph).

Some biologists prefer the evolutionary species concept instead of the biological species concept. In the **evolutionary species concept,** also called the *phylogenetic species concept,* to be declared a separate species a population must have undergone evolution long enough for statistically significant differences in diagnostic traits to emerge. This approach has the advantage of being testable. However, many biologists do not want to abandon the biological species concept, in part because the evolutionary species concept cannot be applied if the evolutionary history of a taxonomic group has not been carefully studied, and most groups have not been rigorously analyzed. Also, if the evolutionary species concept were universally embraced, that would probably double the number of named species. This increase would occur because many closely related populations that are classified as subspecies or varieties under the biological species concept would fit the requirements of separate species under the evolutionary species concept. Thus the exact definition of a species remains fuzzy. Unless we clearly state otherwise, when we mention *species* in this text we mean the biological species concept.

This chapter discusses reproductive barriers that isolate species from one another, the possible evolutionary mechanisms that explain how the millions of species that live today or lived in the past originated from ancestral species, and the rates of evolutionary change. We then examine macroevolution. ■

REPRODUCTIVE ISOLATION

Learning Objective

1 Explain the significance of reproductive isolating mechanisms, and distinguish among the different prezygotic and postzygotic barriers.

Various **reproductive isolating mechanisms** prevent interbreeding between two different species whose *ranges* (areas where each lives) overlap. These mechanisms preserve the genetic integrity of each species, because gene flow between the two species is prevented. Most species have two or more mechanisms that block a chance occurrence of individuals from two closely related species overcoming a single reproductive isolating mechanism. Most occur before mating or fertilization occurs *(prezygotic)*, whereas others work after fertilization has taken place *(postzygotic)*.

Prezygotic barriers interfere with fertilization

Prezygotic barriers are reproductive isolating mechanisms that prevent fertilization from taking place. Because male and female gametes never come into contact, an *interspecific zygote*—that is, a fertilized egg formed by the union of an egg from one species and a sperm from another species—is never produced. Prezygotic barriers include temporal isolation, habitat isolation, behavioral isolation, mechanical isolation, and gametic isolation.

Sometimes genetic exchange between two groups is prevented because they reproduce at different times of the day, season, or year. Such examples demonstrate **temporal isolation.** For example, two very similar species of fruit flies, *Drosophila pseudoobscura* and *Drosophila persimilis,* have ranges that overlap to a great extent, but they do not interbreed. *D. pseudoobscura* is sexually active only in the afternoon, and *D. persimilis* only in the morning. Similarly, two frog species have overlapping ranges in eastern Canada and the United States. The wood frog (*Rana sylvatica*) usually mates in late March or early April, when the water temperature is about 7.2°C (45°F), whereas the northern leopard frog (*Rana pipiens*) usually mates in mid-April, when the water temperature is 12.8°C (55°F) (Fig. 19-1).

Although two closely related species may be found in the same geographic area, they usually live and breed in different habitats in that area. This provides **habitat isolation** between the two species. For example, the five species of small birds known as flycatchers are nearly identical in appearance and have overlapping ranges in the eastern part of North America. They exhibit habitat isolation because, during the breeding season, each species stays in a particular habitat within its range, so potential mates from different species do not meet. The least flycatcher (*Empidonax minimus*) frequents open woods, farms, and orchards, whereas the acadian flycatcher (*E. virescens*) is found in deciduous forests, particularly in beech trees, and swampy woods. The alder flycatcher (*E. alnorum*) prefers wet thickets of alders, the yellow-bellied flycatcher (*E. flaviventris*) nests in conifer woods, and the willow flycatcher (*E. traillii*) frequents brushy pastures and willow thickets.

Many animal species exchange a distinctive series of signals before mating. Such courtship behaviors illustrate **behavioral isolation** (also known as **sexual isolation**). Bowerbirds, for example, exhibit species-specific courtship patterns. The male satin bowerbird of Australia constructs an elaborate bower of twigs, adding decorative blue parrot feathers and white flowers at the entrance (Fig. 19-2). When a female approaches the bower, the male dances about her, holding a particularly eye-catching decoration in his beak. While dancing, he puffs his feathers, extends his wings, and sings a courtship song that consists of a variety of sounds, including loud buzzes and laughlike hoots. These specific courtship behaviors keep similar bird species reproductively isolated from the satin bowerbird. If a male and female of two different species begin courtship, it stops when one member does

ACTIVE FIGURE **19-1** **Temporal isolation in wood and leopard frogs.**

(a) The wood frog (*Rana sylvatica*) mates in early spring, often before the ice has completely melted in the ponds. **(b)** The leopard frog (*R. pipiens*) typically mates a few weeks later. **(c)** Graph of peak mating activity in wood and leopard frogs. In nature, wood and leopard frogs do not interbreed, although they have done so in the laboratory.

BiologyNow™ Explore **reproductive isolation in another species** by clicking on this figure on your BiologyNow CD ROM.

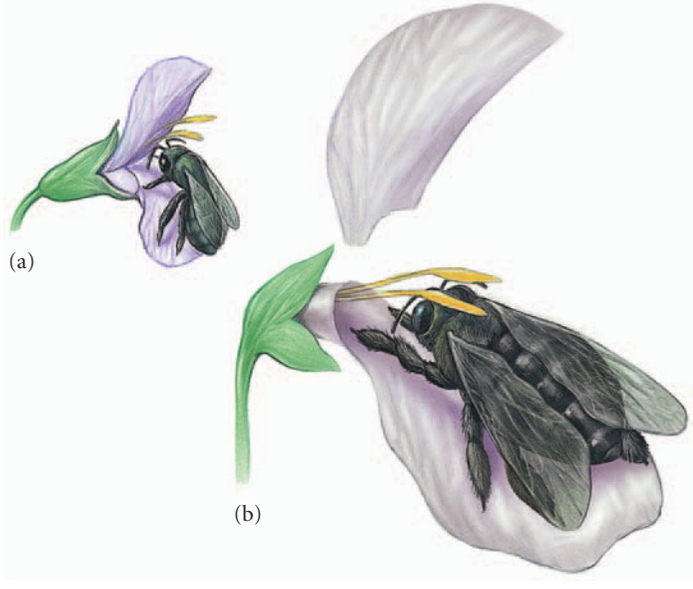
not recognize or respond to the signals of the other. Another example of behavioral isolation involves the wood frogs and northern leopard frogs (just discussed as an example of temporal isolation). Males of these two species have very specific vocalizations to attract females of their species for breeding. These vocalizations reinforce each species' reproductive isolation.

Sometimes members of different species court and even attempt copulation, but the incompatible structures of their genital organs prevent successful mating. Structural differences that inhibit mating between species produce **mechanical isolation.** For example, many flowering plant species have physical differences in their flower parts that help them maintain their reproductive isolation from one another. In such plants, the flower parts are adapted for specific insect pollinators. Two species of sage, for example, have overlapping ranges in southern California. Black sage (*Salvia mellifera*), which is pollinated by small bees, has a floral structure different from that of white sage (*Salvia apiana*), which is pollinated by large carpenter bees (Fig. 19-3). Interestingly, black sage and white sage are also prevented from mating by a temporal barrier: black sage flowers in early spring, and white sage flowers in late spring and early summer. Presumably, mechanical isolation prevents insects from cross-pollinating the two species should they happen to flower at the same time.

R. Brown/VIREO

FIGURE **19-2** **Behavioral isolation in bowerbirds.**

Each bowerbird species has highly specialized courtship patterns that prevent its mating with another species. The male satin bowerbird (*Ptilonorhynchus violacens*) constructs an enclosed place, or bower, of twigs to attract a female. (The bower is the dark "tunnel" on the left.) Note the white flowers and blue decorations, including human-made objects such as bottle caps, that he has arranged at the entrance to his bower.



(a)

(b)

FIGURE **19-3** **Mechanical isolation in black sage and white sage.**

Their differences in floral structures allow black sage and white sage to be pollinated by different insects. Because the two species exploit different pollinators, they cannot interbreed. **(a)** The petal of the black sage functions as a landing platform for small bees. Larger bees cannot fit on this platform. **(b)** The larger landing platform and longer stamens of white sage allow pollination by larger California carpenter bees (a different species). If smaller bees land on white sage, their bodies do not brush against the stamens. (In the figure, the upper part of the white sage flower has been removed.)

If mating takes place between two species, their gametes may still not combine. Molecular and chemical differences between species cause **gametic isolation,** in which the egg and sperm of different species are incompatible. In aquatic animals that release their eggs and sperm into the surrounding water simultaneously, interspecific fertilization is extremely rare. The surface of the egg contains specific proteins that bind only to complementary molecules on the surface of sperm cells of the same species (see Chapter 49). A similar type of molecular recognition often occurs between pollen grains and the stigma (receptive surface of the female part of the flower) so that pollen does not germinate on the stigma of a different plant species.

Postzygotic barriers prevent gene flow when fertilization occurs

Fertilization sometimes occurs between gametes of two closely related species despite the existence of prezygotic barriers. When this happens, **postzygotic barriers** that increase the likelihood of reproductive failure come into play. Generally, the embryo of an interspecific hybrid spontaneously aborts. Embryonic development is a complex process requiring the precise interaction and coordination of many genes. Apparently the genes from parents belonging to different species do not interact properly in regulating the mechanisms for normal development. In this case, reproductive isolation occurs by **hybrid inviability.** For example, nearly all the hybrids die in the embryonic stage when the eggs of a bullfrog are fertilized artificially with sperm from a leopard frog. Similarly, in crosses between different species of irises the embryos die before reaching maturity.

If an interspecific hybrid does live, it may not reproduce. There are several reasons for this. Hybrid animals may exhibit courtship behaviors incompatible with those of either parental species, and as a result they will not mate. More often, **hybrid sterility** occurs when problems during meiosis cause the gametes of an interspecific hybrid to be abnormal. Hybrid sterility is particularly common if the two parental species have different chromosome numbers. For example, a mule is the offspring of a female horse ($2n = 64$) and a male donkey ($2n = 62$) (Fig. 19-4). This type of union almost always results in sterile offspring ($2n = 63$), because synapsis (the pairing of homologous chromosomes during meiosis) and segregation cannot occur properly. The zebrass shown in the chapter introduction also exhibits hybrid sterility because of different chromosome numbers. Donkeys have 62 chromosomes, and zebras, depending on the species, have 32, 44, or 46 chromosomes.

Occasionally, a mating between two F_1 hybrids produces a second hybrid generation (F_2). The F_2 hybrid may exhibit **hybrid breakdown,** the inability of a hybrid to reproduce because of some defect. For example, hybrid breakdown in the F_2 generation of a cross between two sunflower species was 80%. In other words, 80% of the F_2 generation were defective in some way and could not reproduce successfully. Hybrid breakdown also occurs in the F_3 and later generations.

Table 19-1 summarizes the various prezygotic and postzygotic barriers that prevent interbreeding between two species.

Biologists are discovering the genetic basis of isolating mechanisms

Progress has been made in identifying some of the genes involved in reproductive isolation. For example, scientists have determined the genetic basis for prezygotic isolation in species of abalone, large mollusks found along the Pacific coast of North America. In abalone, the fertilization of eggs by sperm requires lysin, a sperm protein that attaches to a lysin receptor protein located on the egg envelope. After attachment, the lysin produces a hole in the egg envelope that permits the sperm to penetrate the egg. Scientists cloned the lysin receptor gene and demonstrated that this gene varies among abalone species. Differences in the lysin receptor protein in various abalone species determine sperm compatibility with the egg. Sperm of one abalone species do not attach to a lysin receptor protein of an egg of a different abalone species.

John Eastcott/Yva Momatiuk/Animals Animals

FIGURE **19-4** **Hybrid sterility in mules.**

Mules are interspecific hybrids formed by mating a female horse with a male donkey. Although the mule *(center)* exhibits valuable characteristics of each of its parents, it is sterile.

TABLE **19-1** **Reproductive Isolating Mechanisms**

Mechanism	How It Works
Prezygotic Barriers	Prevent fertilization
Temporal isolation	Similar species reproduce at different times
Habitat isolation	Similar species reproduce in different habitats
Behavioral isolation	Similar species have distinctive courtship behaviors
Mechanical isolation	Similar species have structural differences in their reproductive organs
Gametic isolation	Gametes of similar species are chemically incompatible
Postzygotic Barriers	Reduce viability or fertility of hybrid
Hybrid inviability	Interspecific hybrid dies at early stage of embryonic development
Hybrid sterility	Interspecific hybrid survives to adulthood but is unable to reproduce successfully
Hybrid breakdown	Offspring of interspecific hybrid are unable to reproduce successfully

Review

- What barriers prevent wood frogs and leopard frogs from interbreeding in nature?
- How is temporal isolation different from behavioral isolation?
- How is mechanical isolation different from gametic isolation?
- Of which type of postzygotic barrier is the mule an example?

BiologyNow™ Assess your understanding of **reproductive isolation** by taking the pretest on your BiologyNow CD-ROM.

SPECIATION

Learning Objectives

2 Explain the mechanism of allopatric speciation, and give an example.

3 Explain the mechanisms of sympatric speciation, and give both plant and animal examples.

We are now ready to consider how entirely new species may arise from previously existing ones. The evolution of a new species is called **speciation.** The formation of two species from a single species occurs when a population becomes reproductively isolated from other populations of the species, and the gene pools of the two separated populations begin to diverge in genetic composition. When a population is sufficiently different from its ancestral species that no genetic exchange occurs between them, we say speciation has occurred. Speciation occurs in two ways: allopatric speciation and sympatric speciation.

Long physical isolation and different selective pressures result in allopatric speciation

Speciation that occurs when one population becomes geographically separated from the rest of the species and subsequently evolves by natural selection and/or genetic drift is known as **allopatric speciation** (from the Greek *allo,* "different," and *patri,* "native land"). Recall from Chapter 17 that *natural selection* occurs as individuals that possess favorable adaptations to the environment survive and become parents of the next generation. *Genetic drift* is a random change in allele frequency resulting from the effects of chance on the survival and reproductive success of individuals in a small breeding population (see Chapter 18). Both natural selection and genetic drift result in changes in allele frequencies in a population, but only in natural selection is the change in allele frequency adaptive.

Allopatric speciation is the most common method of speciation, and the evolution of new animal species has been almost exclusively by allopatric speciation. The geographic isolation required for allopatric speciation may occur in several ways. Earth's surface is in a constant state of change. Such change includes rivers shifting their courses; glaciers migrating; mountain ranges forming; land bridges developing that separate previously united aquatic populations; and large lakes diminishing into several smaller, geographically separated pools.

What might be an imposing geographic barrier to one species may be of no consequence to another. Birds and cattails, for example, do not become isolated when a lake subsides into smaller pools; birds easily fly from one pool to another, and cattails disperse their pollen and fruits by air currents. Fish, in contrast, usually cannot cross the land barriers between the pools and so become reproductively isolated.

In the Death Valley region of California and Nevada, large interconnected lakes formed during wetter climates of the last Ice Age. These lakes were populated by one or several species of pupfish. Over time, the climate became drier, and the large lakes dried up, leaving isolated pools. Presumably, each pool contained a small population of pupfish that gradually diverged from the common ancestral species by genetic drift and natural selection in response to the high temperatures, high salt concentrations, and low oxygen levels characteristic of desert springs. Today, there are 20 or so distinct species, subspecies, and populations in the area of Death Valley, California, and Ash Meadows, Nevada. Many, such as the Devil's Hole pupfish (*Cyprinodon diabolis*) and the Owens pupfish (*Cyprinodon radiosus*), are restricted to one or two isolated springs (Fig. 19-5).

Allopatric speciation also occurs when a small population migrates or is dispersed (such as by a chance storm) and colonizes a new area away from the range of the original species. This colony is geographically isolated from its parental species, and the small *microevolutionary* changes that accumulate in the isolated gene pool over many generations may eventually be sufficient to form a new species. Because islands provide the geographic isolation required for allopatric speciation, they offer excellent opportunities to study this evolutionary mechanism. A few individuals of a few species probably colonized the Galapagos Islands and the Hawaiian Islands, for example. The hundreds of unique species presently found on each island presumably descended from these original colonizers (Fig. 19-6).

Speciation is more likely to occur if the original isolated population is small. Recall that genetic drift, including the founder

FIGURE **19-5** **Allopatric speciation of pupfish (*Cyprinodon*).**

Shown is one of the more than 20 pupfish species that apparently evolved when larger lakes in southern Nevada dried up about 10,000 years ago, leaving behind small, isolated desert pools fed by springs. The pupfish's short, stubby body is characteristic of fish that live in springs; fish that live in larger bodies of water are more streamlined.

Victoria McCormick/Animals Animals

FIGURE **19-6** **Allopatric speciation of the Hawaiian goose (the nene).**

Nene (pronounced "nay–nay"; *Branta sandvicensis*) are geese originally found only on volcanic mountains on the geographically isolated islands of Hawaii and Maui, which are some 4200 km (2600 mi) from the nearest continent. Compared with other geese, the feet of Hawaiian geese are not completely webbed, their toenails are longer and stronger, and their foot pads are thicker; these adaptations enable Hawaiian geese to walk easily on lava flows. Nene are thought to have evolved from a small population of geese that originated in North America. Photographed in Hawaii Volcanoes National Park, Hawaii.

effect, is more consequential in small populations (see Chapter 18). Genetic drift tends to result in rapid changes in allele frequencies in the small, isolated population. The different selective pressures of the new environment to which the population is exposed further accentuate the divergence caused by genetic drift.

The Kaibab squirrel may be an example of allopatric speciation in progress

About 10,000 years ago, when the American Southwest was less arid, the forests in the area supported a tree squirrel with conspicuous tufts of hair sprouting from its ears. A small tree squirrel population living on the Kaibab Plateau of the Grand Canyon became geographically isolated when the climate changed, causing areas to the north, west, and east to become desert. Just a few miles to the south lived the rest of the squirrels, known as Abert squirrels, but the two groups were separated by the Grand Canyon. With changes over time in both its appearance and its ecology, the Kaibab squirrel is on its way to becoming a new species.

During its many years of geographic isolation, the small population of Kaibab squirrels has diverged from the widely distributed Abert squirrels in several ways. Perhaps most evident are changes in fur color. The Kaibab squirrel now has a white tail and a gray belly, in contrast to the gray tail and white belly of the Abert squirrel (Fig. 19-7). Biologists think these striking changes arose in Kaibab squirrels as a result of genetic drift.

Some scientists consider the Kaibab squirrel and the Abert squirrel as distinct populations of the same species (*Sciurus aberti*). Because the Kaibab and Abert squirrels are reproductively isolated from each other, however, some scientists have classified the Kaibab squirrel as a different species (*Sciurus kaibabensis*).

Porto Santo rabbits may be an example of extremely rapid allopatric speciation

Allopatric speciation has the potential to occur quite rapidly. Early in the 15th century, a small population of rabbits was released on Porto Santo, a small island off the coast of Portugal. Because there were no other rabbits or competitors and no predators on the island, the rabbits thrived. By the 19th century, these rabbits were markedly different from their European ancestors. They were only half as large (weighing slightly more than 500 g, or 1.1 lb), with a different color pattern and a more nocturnal lifestyle. Most significantly, attempts to mate Porto Santo rabbits with mainland European rabbits failed. Many biologists concluded that, within 400 years, an extremely brief period in evolutionary history, a new species of rabbit had evolved.

Not all biologists agree that the Porto Santo rabbit is a new species. The objection stems from a more recent breeding experiment and is based on biologists' lack of a consensus about the definition of a species. In the experiment, foster mothers of the wild Mediterranean rabbit raised newborn Porto Santo rabbits. When they reached adulthood, these Porto Santo rabbits

mated successfully with Mediterranean rabbits to produce healthy, fertile offspring. To some biologists, this experiment clearly demonstrated that Porto Santo rabbits are not a separate species but, instead, are an example of speciation in progress, much like the Kaibab squirrels just discussed. Other biologists think the Porto Santo rabbit is a separate species, because it does not interbreed with other rabbits under natural conditions. They point out that the breeding experiment was successful only after the baby Porto Santo rabbits were raised under artificial conditions that probably modified their natural behavior.

Two populations diverge in the same physical location by sympatric speciation

Although geographic isolation is an important factor in many cases of evolution, it is not an absolute requirement. In **sympatric speciation** (from the Greek *sym,* "together," and *patri,* "native land"), a new species evolves within the same geographic region as the parental species. The divergence of two populations in the same geographic range occurs when reproductive isolating mechanisms evolve at the *start* of the speciation process. Sympatric speciation is especially common in plants. The role of sympatric speciation in animal evolution is probably much less important than allopatric speciation; until recently, sympatric speciation in animals has been difficult to demonstrate in nature.

Sympatric speciation occurs in at least two ways: a change in **ploidy** (the number of chromosome sets making up an organism's genome) and a change in ecology. We now examine each of these mechanisms.

Allopolyploidy is an important mechanism of sympatric speciation in plants

As a result of reproductive isolating mechanisms discussed earlier, the union of two gametes from different species rarely forms viable offspring; if offspring are produced, they are usually sterile. Before gametes form, meiosis reduces the chromosome number (see Chapter 9). For the chromosomes to be parceled correctly into the gametes, homologous chromosome pairs must come together (a process called *synapsis*) during prophase I. This cannot usually occur in interspecific hybrid offspring, because not all the chromosomes are homologous. However, if the chromosome number doubles *before* meiosis, then homologous chromosomes undergo synapsis. Although not common, this spontaneous doubling of chromosomes has been documented in a variety of plants and a few animals. It produces nuclei with multiple sets of chromosomes.

Polyploidy, the possession of more than two sets of chromosomes, is a major factor in plant evolution. Reproductive isolation occurs in a single generation when a polyploid species with multiple sets of chromosomes arises from diploid parents. There are two kinds of polyploidy: autopolyploidy and allopolyploidy. An **autopolyploid** contains multiple sets of chromosomes from a single species, and an **allopolyploid** contains multiple sets of chromosomes from two or more species. We discuss only allopolyploidy, because it is much more common in nature.

Allopolyploidy occurs in conjunction with **hybridization,** which is sexual reproduction between individuals from closely related species. Allopolyploidy produces a fertile interspecific hybrid because the polyploid condition provides the homologous chromosome pairs necessary for synapsis during meiosis. As a result, gametes may be viable (Fig. 19-8). An allopolyploid, that is, an interspecific hybrid produced by allopolyploidy, reproduces with itself (self-fertilization) or with a similar individual. However, allopolyploids are reproductively isolated from both parents, because their gametes have a different number of chromosomes from those of either parent.

If a population of allopolyploids (that is, a new species) becomes established, selective pressures cause one of three outcomes. First, the new species may not compete successfully against species that are already established, so it becomes extinct. Second, the allopolyploid individuals may assume a new role in the environment and so coexist with both parental species. Third, the new species may successfully compete with either or both of its parental species. If it has a combination of traits that confers greater fitness than one or both parental species for all or part of the original range of the parent(s), the hybrid species may replace the parent(s).

Although allopolyploidy is extremely rare in animals, it is significant in the evolution of flowering plant species. As many as 80% of all flowering plant species are polyploids, and most of these are allopolyploids. Moreover, allopolyploidy provides a mechanism for extremely rapid speciation. A single generation is all that is needed to form a new, reproductively isolated species. Allopolyploidy may explain the rapid appearance of many flowering plant species in the fossil record and their remarkable diversity (about 235,000 species) today.

The kew primrose (*Primula kewensis*) is an example of sympatric speciation that was documented at the Royal Botanic Gardens at Kew, England, in 1898 (Fig. 19-9). The interspecific hybrid of two primrose species, *Primula floribunda* ($2n = 18$) and *Primula verticillata* ($2n = 18$), *P. kewensis* had a chromosome number of 18 but was sterile. Then, at three different times, it was reported to have spontaneously formed a fertile branch, which was an allopolyploid ($2n = 36$) that produced viable seeds of *P. kewensis.*

The mechanism of sympatric speciation has been experimentally verified for many plant species. One example is a group of species, collectively called *hemp nettles,* that occurs in temperate parts of Europe and Asia. One hemp nettle, *Galeopsis tetrahit* ($2n = 32$), is a naturally occurring allopolyploid hypothesized to have formed by the hybridization of two species, *Galeopsis pubescens* ($2n = 16$) and *Galeopsis speciosa* ($2n = 16$). This process occurred in nature but was experimentally reproduced. *Galeopsis pubescens* and *G. speciosa* were crossed to produce F_1 hybrids, most of which were sterile. Nevertheless, both F_2 and F_3 generations were produced. The F_3 generation included a polyploid plant with $2n = 32$ that self-fertilized to yield fertile F_4 offspring that could not mate with either of the parental species. These allopolyploid plants had the same appearance and chromosome number as the naturally occurring *G. tetrahit.* When the experimentally produced plants were crossed with the naturally occurring *G. tetrahit,* a fertile F_1 generation was formed. Thus, the experiment duplicated the speciation process that occurred in nature.

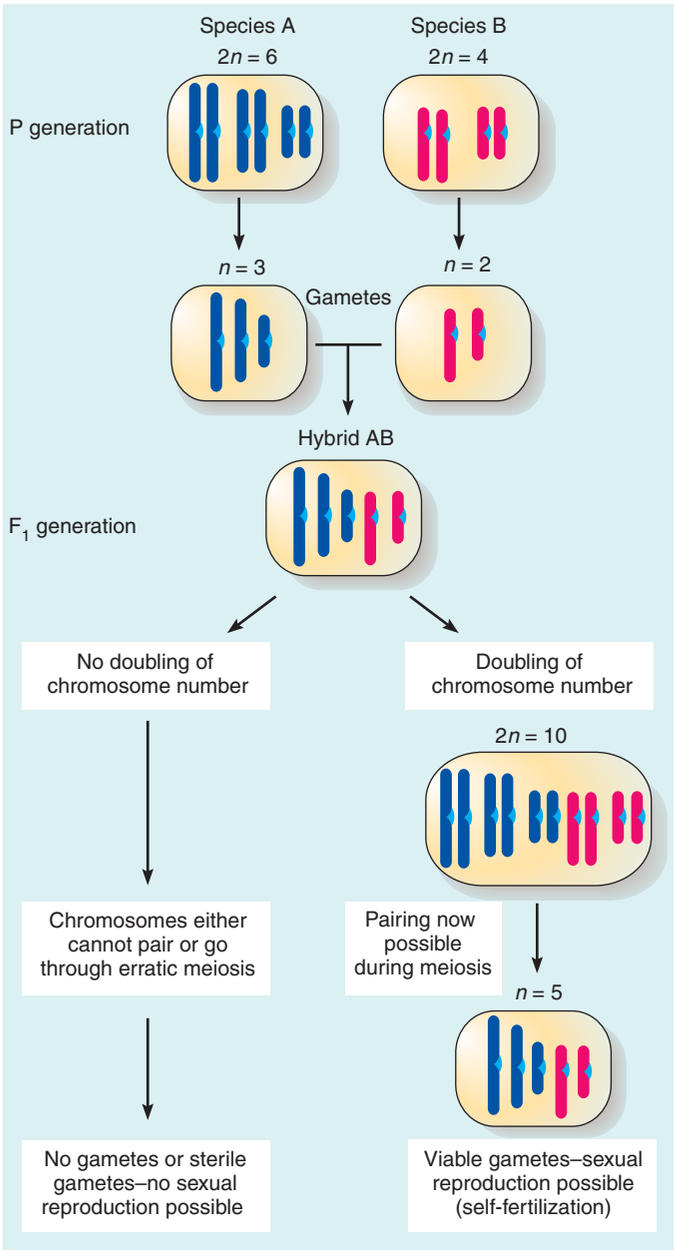

FIGURE **19-8** **Sympatric speciation by allopolyploidy in plants.**

When two species (designated the P generation) successfully interbreed, the interspecific hybrid offspring (the F_1 generation) are almost always sterile *(bottom left)*. If the chromosomes double, proper synapsis and segregation of the chromosomes occur, and viable gametes are produced *(bottom right)*. (Unduplicated chromosomes are shown for clarity.)

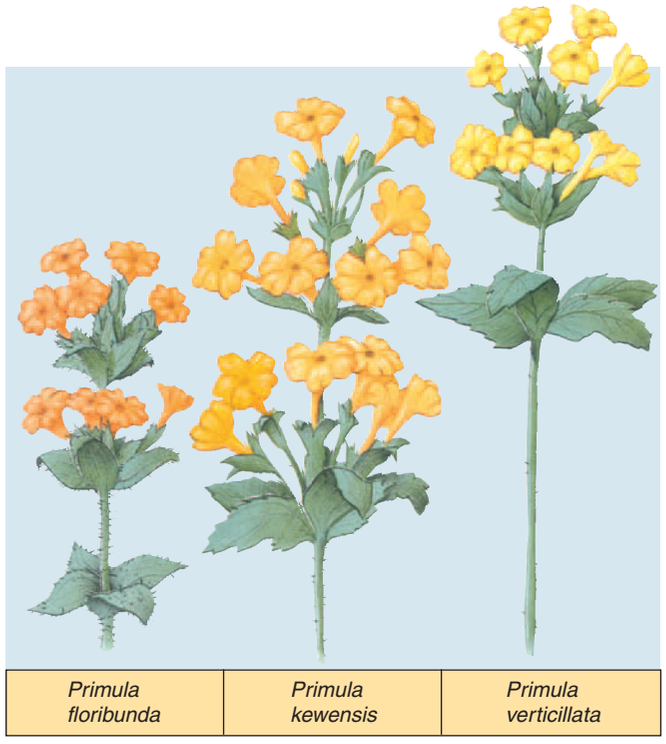

FIGURE **19-9** **Sympatric speciation of a primrose.**

An allopolyploid primrose, *Primula kewensis,* arose in 1898 as an allopolyploid derived from the interspecific hybridization of *P. floribunda* and *P. verticillata*. Today *P. kewensis* is a popular houseplant.

Changing ecology causes sympatric speciation in animals

Biologists have observed the occurrence of sympatric speciation in animals, but its significance—how often it occurs and under what conditions—is still debated. Many examples of sympatric speciation in animals involve parasitic insects and rely on genetic mechanisms other than polyploidy. For example, in the 1860s in the Hudson River Valley of New York, a population of fruit maggot flies (*Rhagoletis pomonella*) parasitic on the small red fruits of native hawthorn trees was documented to have switched to a new host, domestic apples, which had been introduced from Europe. Although the sister populations (hawthorn maggot flies and apple maggot flies) continue to occupy the same geographic area, no gene flow occurs between them because they eat, mate, and lay their eggs on different hosts (Fig. 19-10). In other words, because the hawthorn and apple maggot flies have diverged and are reproductively isolated from each other, they have effectively become separate species. Most entomologists, however, still recognize hawthorn and apple maggot flies as a single species, because their appearance is virtually identical.

In situations like the fruit maggot flies, a mutation arises in an individual and spreads through a small group of insects by sexual reproduction. The particular mutation leads to *disruptive selection* (see Chapter 18), in which both the old and new phenotypes are favored. This occurs because the original population is still favored when it parasitizes the original host, and the mutants are favored by a new ecological opportunity—in this case, to parasitize a different host species. Additional mutations may occur that cause the sister populations to diverge even further.

Biologists have studied the speciation of colorful fishes known as *cichlids* (pronounced "sick-lids") in several East African lakes. The different species of cichlids in a given lake have remarkably

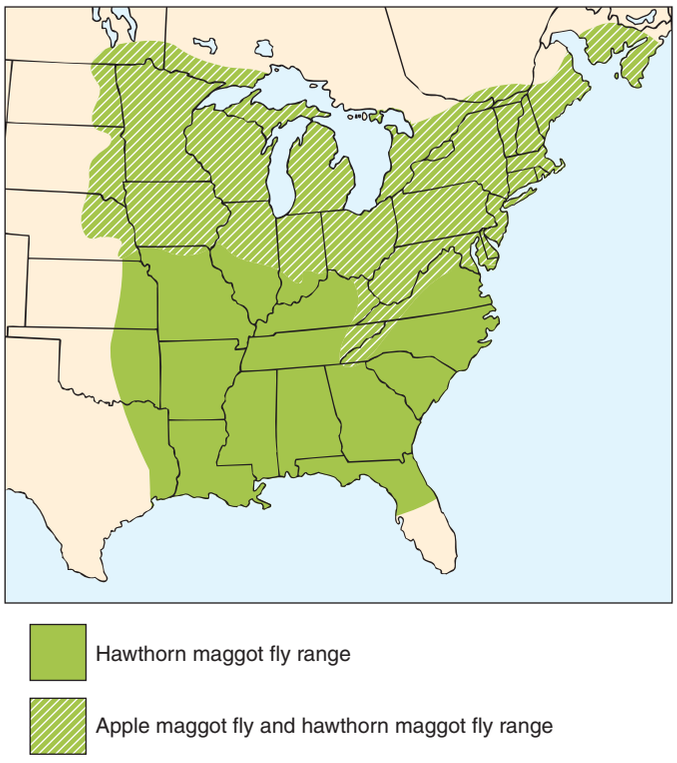

FIGURE **19-10** **Ranges of apple and hawthorn maggot flies.**

Apple and hawthorn maggot flies are sympatric throughout the northern half of the hawthorn maggot fly's range. (*Adapted from G. L. Bush, "Sympatric Host Race Formation and Speciation in Frugivorous Flies of the Genus* Rhagoletis *[Diptera, Tephritidae]," Evolution, Vol. 23, No. 2, Jun. 1969*)

different eating habits, which are reflected in the shapes of their jaws and teeth. Some graze on algae, some consume dead organic material at the bottom of the lake, and others are predatory and eat plankton (microscopic aquatic organisms), insect larvae, the scales off fish, or even other cichlid species. In some cichlids food preferences are related to size (smaller cichlids consume plankton), which in turn is related to mating preference (small, plankton-eating cichlids mate only with other small, plankton-eating cichlids).

In other cichlids related species do not differ in size but only in color. Each species has its own distinct male coloration, which matches the preferences of females of that species in choosing mates (Fig. 19-11). Charles Darwin called choosing a mate based on its color or some other characteristic **sexual selection.** He recognized that females' preferences for certain males, if it was based on *inherited* variation, could result in certain male variants becoming more common over time. Darwin suggested that sexual selection, like natural selection, could eventually result in the evolution of new species. (Sexual selection is discussed in greater detail in Chapter 50.)

Recent DNA sequence data indicate the cichlid species within a single lake are more closely related to one another than to fishes in nearby lakes or rivers. These molecular data suggest that cichlid species evolved sympatrically, or at least within the confines of a lake, rather than by repeated colonizations by fish populations in nearby rivers.

How rapidly did sympatric speciation occur in cichlids? In 1996 scientists published seismic and drill core data suggesting that the more than 500 endemic (that is, found nowhere else) cichlid species in Lake Victoria evolved in a remarkably short time—less than 12,400 years. This inference is based on evidence that Lake Victoria dried up completely during the late Pleistocene (from about 17,000 to 12,400 years ago), when much of north and equatorial Africa was arid. It appears the cichlids evolved after the climate became wetter and Lake Victoria refilled. If future data substantiate this conclusion, it means the evolution of Lake Victoria's cichlids is the fastest known for such a large number of vertebrate species.

Reproductive isolation breaks down in hybrid zones

When two populations have significantly diverged as a result of geographic separation, there is no easy way to determine if the

FIGURE **19-11** **Color variation in Lake Victoria cichlids.**

(a) *Pundamilia pundamilia* males have bluish-silver bodies. **(b)** *Pundamilia nyererei* males have red backs. **(c)** *Pundamilia* "red head" males have a red "chest." (The "red head" species has not yet been scientifically named.) Some evidence suggests that changes in male coloration may be the first step in speciation of Lake Victoria cichlids. Later, other traits, including ecological characteristics, diverge. Female cichlids generally have cryptic coloration; their drab colors help them blend into their surroundings.

speciation process is complete (recall the disagreement about whether Porto Santo rabbits are a separate species or a *subspecies,* which is a taxonomic subdivision of a species). If such populations, subspecies, or species come into contact, they may hybridize where they meet, forming a **hybrid zone,** or area of overlap in which interbreeding occurs. Hybrid zones are typically narrow, presumably because the hybrids are not well adapted for either parental environment, and the hybrid population is typically very small compared with the parental populations.

On the Great Plains of North America, red-shafted and yellow-shafted flickers (types of woodpeckers) meet and interbreed. The red-shafted flicker, named for the male's red underwings and tail, is found in the western part of North America, from the Great Plains to the Pacific Ocean. Yellow-shafted flicker males, which have yellow underwings and tails, range east of the Rockies. Hybrid flickers, which form a stable hybrid zone from Texas to southern Alaska, are varied in appearance, although many have orange underwings and tails.

PROCESS OF SCIENCE

Biologists do not agree about whether the red-shafted and yellow-shafted flickers are separate species or geographic subspecies. According to the biological species concept, if red-shafted and yellow-shafted flickers are two species, they should maintain their reproductive isolation. However, the flicker hybrid zone has not expanded, that is, the two types of flickers have maintained their distinctiveness and have not rejoined into a single, freely interbreeding population.

The study of hybrid zones has made important contributions to what is known about speciation. As in other fields of science, disagreements and differences of opinion are an important part of the scientific process because they stimulate new ideas, hypotheses, and experimental tests that expand our base of scientific knowledge.

Review

- What are five geographic barriers that might lead to allopatric speciation?
- How do hybridization and polyploidy cause a new plant species to form in as little as one generation?
- What is the likely mechanism of speciation for pupfish? For cichlids?

THE RATE OF EVOLUTIONARY CHANGE

Learning Objective

4 Take either side in a debate on the pace of evolution, by representing the opposing views of gradualism and punctuated equilibrium.

We have seen that speciation is hard for us to directly observe as it occurs. Does the fossil record provide clues about how rapidly new species arise? Biologists have long recognized that the fossil record lacks many transitional forms; the starting points (ancestral species) and the end points (new species) are present, but the intermediate stages in the evolution from one species to another are often lacking. This observation has traditionally been explained by the incompleteness of the fossil record. Biologists have attempted to fill in the missing parts with new fossil discoveries, much as a writer might fill in the middle of a novel when the beginning and end are already there.

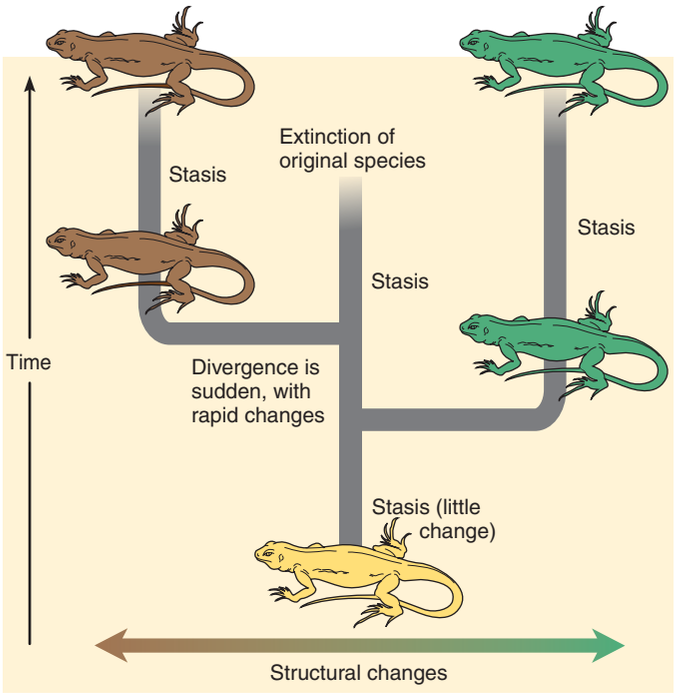
Two different models—punctuated equilibrium and gradualism—have been developed to explain evolution as observed in the fossil record (Fig. 19-12). The **punctuated equilibrium** model was proposed by paleontologists who question whether the fossil record really is as incomplete as it initially appeared. First advanced by paleontologists Stephen Jay Gould and Niles Eldredge in 1972, the punctuated equilibrium model suggests that the fossil record accurately reflects evolution as it actually occurs. That is, in the history of a species long periods of **stasis** (little or no evolutionary change) are punctuated, or interrupted, by short periods of rapid speciation that are perhaps triggered by changes in the environment, that is, periods of great evolutionary stress. Thus speciation normally proceeds in "spurts." These relatively short periods of active evolution (such as 100,000 years) are followed by long periods (such as 2 million years) of stability.

With punctuated equilibrium, speciation occurs in a relatively short period. Keep in mind, however, that a "short" amount of time for speciation may be thousands of years. Such a span is short when compared with the several million years of a species' existence. Biologists who support the idea of punctuated equilibrium emphasize that sympatric speciation and even allopatric speciation occur in such relatively short periods. Punctuated equilibrium accounts for the abrupt appearance of a new species in the fossil record, with little or no evidence of intermediate forms. Proponents hypothesize that few transitional forms appear in the fossil record, because few transitional forms occurred during speciation.

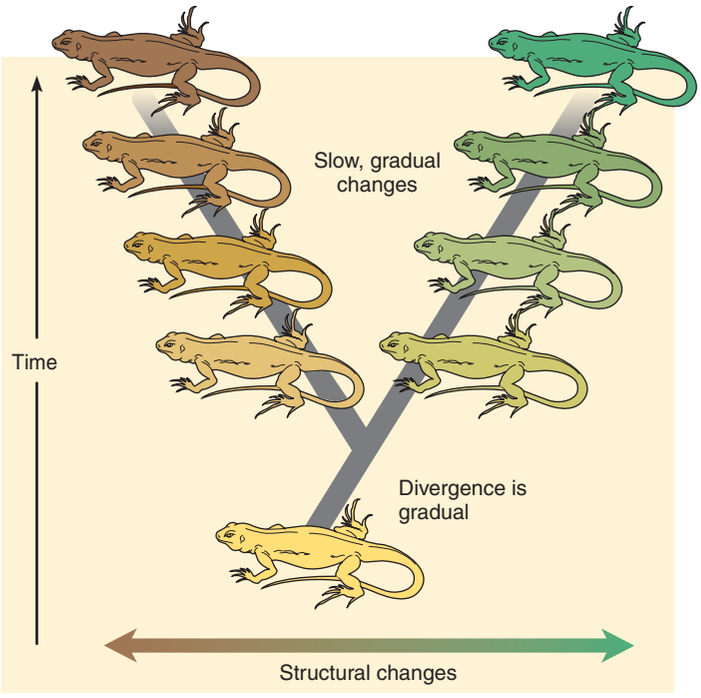
In contrast, the traditional view of evolution espouses the **gradualism** model, in which evolution proceeds continuously over long periods. Gradualism is rarely observed in the fossil record, because the record is incomplete. (Recall from Chapter 17 that precise conditions are required for fossil formation. Most organisms decompose when they die, leaving no trace of their existence.) Occasionally a complete fossil record of transitional forms is discovered and cited as a strong case for gradualism. The gradualism model maintains that populations slowly diverge from one another by the gradual accumulation of adaptive characteristics within each population. These adaptive characteristics accumulate as a result of different selective pressures encountered in different environments.

PROCESS OF SCIENCE

The abundant fossil evidence of long periods with no change in a species has been used to argue against the gradualism model of evolution. Gradualists, however, maintain that any periods of stasis evident in the fossil record are the result of *stabilizing selection* (see Chapter 18). They also emphasize that stasis in fossils is deceptive, because fossils do not reveal all aspects of evolution. Although fossils display changes in external structure and skeletal structure, other genetic changes—in physiol-



(a) Punctuated equilibrium



(b) Gradualism

FIGURE **19-12** **Punctuated equilibrium and gradualism.**
In this figure, structural changes in the lizards are represented by changes in skin color. **(a)** In punctuated equilibrium, long periods of stasis are interrupted by short periods of rapid speciation. **(b)** In gradualism, a slow, steady change in species occurs over time.

ogy, internal structure, and behavior—all of which also represent evolution, are not evident. Gradualists recognize rapid evolution only when strong *directional selection* occurs.

Many biologists embrace both models to explain the fossil record; they also contend that the pace of evolution may be abrupt in certain instances and gradual in others and that neither punctuated equilibrium nor gradualism exclusively characterizes the changes associated with evolution. Other biologists do not view the distinction between punctuated equilibrium and gradualism as real. They suggest that genetic changes occur gradually and at a roughly constant pace and that the majority of these mutations do not cause speciation. When the mutations that do cause speciation occur, they are dramatic and produce a pattern consistent with the punctuated equilibrium model.

Review

- If you were in a debate, how would you support the gradualism model?
- How would you support the punctuated equilibrium model?
- Are the gradualism and punctuated equilibrium models mutually exclusive? Explain your answer.

MACROEVOLUTION

Learning Objectives

5 Define *macroevolution.*
6 Discuss macroevolution in the context of novel features, including preadaptations, allometric growth, and paedomorphosis.
7 Discuss the macroevolutionary significance of adaptive radiation and extinction.

Macroevolution is large-scale phenotypic changes in populations that warrant their placement in taxonomic groups at the species level and higher—that is, new species, genera, families, orders, classes, and even phyla, kingdoms, and domains. One concern of macroevolution is to explain evolutionary novelties, which are large phenotypic changes such as the appearance of jointed limbs during the evolution of arthropods (crustaceans, insects, and spiders). These phenotypic changes are so great that the new species possessing them are assigned to different genera or higher taxonomic categories. Studies of macroevolution also seek to discover and explain major changes in species diversity through time, such as occur during *adaptive radiation,* when many species appear, and *mass extinction,* when many species disappear. Thus evolutionary novelties, adaptive radiation, and mass extinction are important aspects of macroevolution.

Evolutionary novelties originate through modifications of pre-existing structures

New designs arise from structures already in existence. A change in the basic pattern of an organism produces something unique, such as wings on insects, flowers on plants, and feathered wings

on birds. Usually these evolutionary novelties are variations of some pre-existing structures, called **preadaptations,** that originally fulfilled one role but subsequently changed in a way that was adaptive for a different role. Feathers, which evolved from reptilian scales and may have originally provided thermal insulation in primitive birds and some dinosaurs (see Chapter 20), represent a preadaptation for flight. With gradual modification, feathers evolved to function in flight as well as to fulfill their original thermoregulatory role. (Interestingly, a few feather-footed birds exist; this phenotype is the result of a change in gene regulation that alters scales, normally found on bird feet, into feathers.)

How do such evolutionary novelties originate? Many are probably due to changes during **development,** which is the orderly sequence of events that occurs as an organism grows and matures. *Regulatory genes* exert control over hundreds of other genes during development, and very slight genetic changes in regulatory genes could ultimately cause major structural changes in the organism (see Chapters 16 and 17).

For example, during development most organisms exhibit varied rates of growth for different parts of the body, known as **allometric growth** (from the Greek *allo,* "different," and *metr,* "measure"). The size of the head in human newborns is large in proportion to the rest of the body. As a human grows and matures, its torso, hands, and legs grow more rapidly than the head. Allometric growth is found in many organisms, including the male fiddler crab with its single, oversized claw, and the ocean sunfish with its enlarged tail (Fig. 19-13). If growth rates are altered even slightly, drastic changes in the shape of an organism may result, changes that may or may not be adaptive. For example, allometric growth may help explain the extremely small and relatively useless forelegs of the dinosaur *Tyrannosaurus rex,* compared with those of its ancestors.

Sometimes novel evolutionary changes occur when a species undergoes changes in the *timing* of development, in comparison with its ancestor. Consider, for example, the changes that would occur if juvenile characteristics were retained in the adult stage, a phenomenon known as **paedomorphosis** (from the Greek *paed,* "child," and *morph,* "form"). Adults of some salamander species have external gills and tail fins, features found only in the larval (immature) stages of other salamanders.

Retention of external gills and tail fins throughout life obviously alters the salamander's behavioral and ecological characteristics (Fig. 19-14). Perhaps such salamanders succeeded because they had a selective advantage over "normal" adult salamanders, that is, by remaining aquatic they did not have to compete for food with the terrestrial adult forms of related species. The paedomorphic forms also escaped the typical predators of terrestrial salamanders (although they had other predators in their aquatic environment). Studies suggest that paedomorphosis in salamanders is probably the result of mutations in genes that block the production of hormones that stimulate metamorphic changes. When paedomorphic salamanders receive hormone injections, they develop into adults lacking external gills and tail fins.

Adaptive radiation is the diversification of an ancestral species into many species

Adaptive radiation is the evolutionary diversification of many related species from one or a few ancestral species in a relatively short period. The concept of adaptive zones was developed to help explain why adaptive radiations take place. **Adaptive zones** are new ecological opportunities that were not exploited by an ancestral organism. At the species level, an adaptive zone is essentially identical to one or more similar *ecological niches* (the

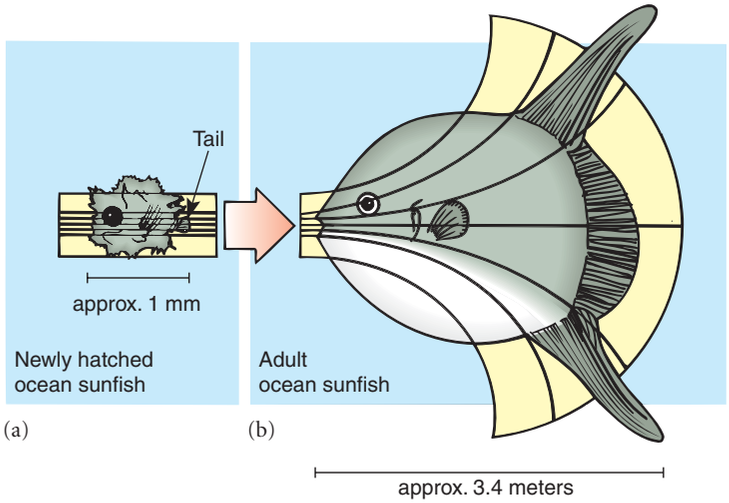

Image not available due to copyright restrictions

FIGURE **19-13** **Allometric growth in the ocean sunfish.**

The tail end of an ocean sunfish (*Mola mola*) grows faster than the head end, resulting in the unique shape of the adult. **(a)** A newly hatched ocean sunfish, only 1 mm long, has an extremely small tail. **(b)** This allometric transformation is visualized by drawing rectangular coordinate lines through a picture of the juvenile fish and then changing the coordinate lines mathematically.

functional roles of species within a community; see Chapter 52). Examples of adaptive zones include nocturnal flying to catch small insects, grazing on grass while migrating across a savanna, and swimming at the ocean's surface to filter out plankton. When many adaptive zones are empty, as they were in Lake Victoria when it refilled some 12,000 years ago (discussed earlier in the chapter), colonizing species such as the cichlids may rapidly diversify and exploit them.

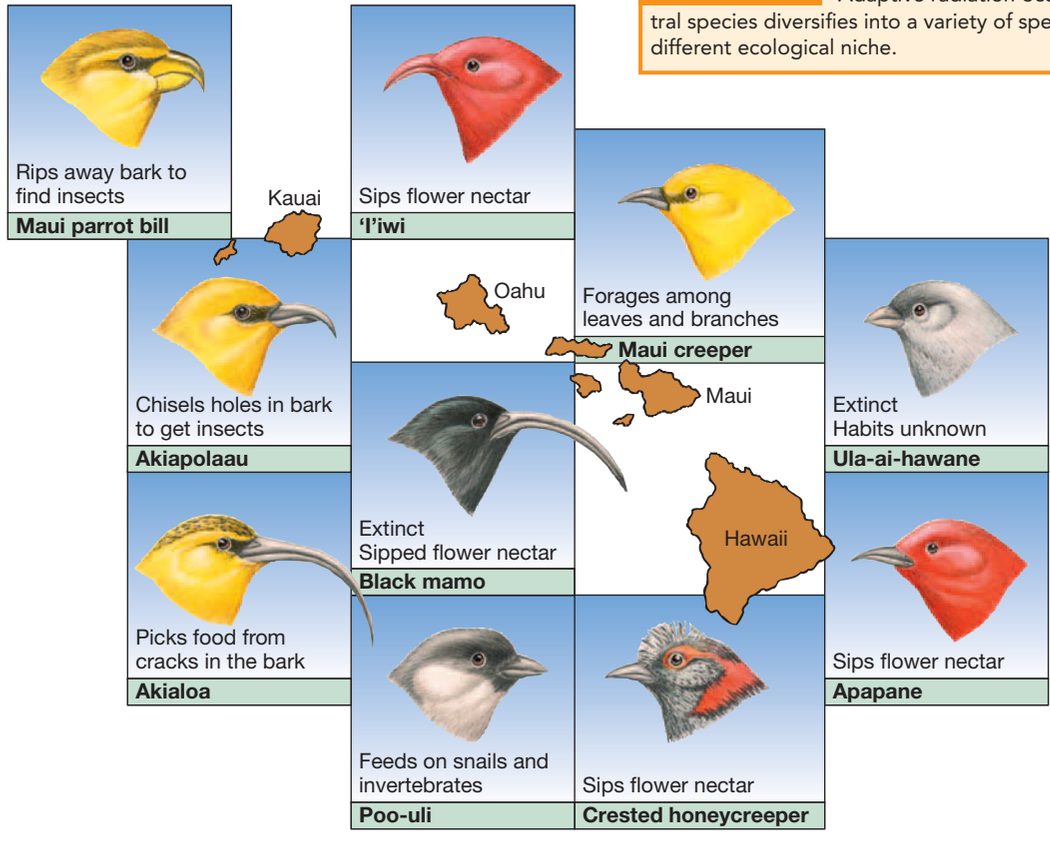
Because islands have fewer species than do mainland areas of similar size, latitude, and topography, vacant adaptive zones are more common on islands than on continents. Consider the Hawaiian honeycreepers, a group of related birds found on the Hawaiian Islands. When the honeycreeper ancestors reached Hawaii, few other birds were present. The succeeding generations of honeycreepers quickly diversified into many new species and, in the process, occupied the many available adaptive zones that on the mainland are occupied by finches, honeyeaters, treecreepers, and woodpeckers. The diversity of their bills is a particularly good illustration of adaptive radiation (Fig. 19-15). Some honeycreeper bills are curved to extract nectar out of

Image not available due to copyright restrictions

FIGURE **19-15** **Adaptive radiation in Hawaiian honeycreepers.**

Compare the various beak shapes and methods of obtaining food. Many honeycreeper species are now extinct or nearing extinction as a result of human activities, including the destruction of habitat and the introduction of predators such as rats, dogs, and pigs.

KEY CONCEPT: Adaptive radiation occurs when a single ancestral species diversifies into a variety of species, each adapted to a different ecological niche.



tubular flowers, whereas others are short and thick for ripping away bark in search of insects.

Another example of vacant adaptive zones involves the Hawaiian silverswords, 28 species of closely related plants found only on the Hawaiian Islands. When the silversword ancestor, a California plant related to daisies, reached the Hawaiian Islands, many diverse environments, such as cool, arid mountains; exposed lava flows; dry woodlands; shady, moist forests; and wet bogs were present and more or less unoccupied. The succeeding generations of silverswords quickly diversified in structure and physiology, occupying the many adaptive zones available to them. The diversity in their leaves, which changed during the course of natural selection as different populations adapted to various levels of light and moisture, is a particularly good illustration of adaptive radiation (Fig. 19-16). Leaves of silverswords that are adapted to shady moist forests are large, for example, whereas those of silverswords living in arid areas are small. The leaves of silverswords living on exposed volcanic slopes are covered with dense silvery hairs that may reflect some of the intense ultraviolet radiation off the plant.

Adaptive radiation appears more common during periods of major environmental change, but it is difficult to determine if these changes actually induce adaptive radiation. Possibly major environmental change indirectly affects adaptive radiation by increasing the extinction rate. Extinction produces empty adaptive zones, which provide new opportunities for species that remain. Mammals, for example, had existed as small nocturnal insectivores (insect eaters) for millions of years before undergoing adaptive radiation leading to the modern mammalian orders. This radiation was presumably triggered by the extinction of the dinosaurs. Mammals diversified and exploited a variety of adaptive zones relatively soon after the dinosaurs' demise. Flying bats, running gazelles, burrowing moles, and swimming whales all originated from the small, insect-eating, ancestral mammals.

Extinction is an important aspect of evolution

Extinction, the end of a lineage, occurs when the last individual of a species dies. The loss is permanent, for once a species is extinct it never reappears. Extinctions have occurred continually since the origin of life; by one estimate, only 1 species is alive today for every 2000 that have become extinct. Extinction is the eventual fate of all species, in the same way that death is the eventual fate of all individual organisms.

Although extinction has a negative short-term impact on the number of species, it facilitates evolution over a period of thousands to millions of years. As mentioned previously, when species become extinct their adaptive zones become vacant.

(a)

(b)

(c)

FIGURE **19-16** **Adaptive radiation in Hawaiian silverswords.**

The 28 silversword species, which are classified in three closely related genera, live in a variety of habitats. **(a)** The Haleakala silversword (*Argyroxyphium sandwicense* ssp. *macrocephalum*) is found only in the cinders on the upper slope of Haleakala Crater on the island of Maui. This plant is adapted to low precipitation and high levels of ultraviolet radiation. **(b)** This silversword species (*Wilkesia gymnoxiphium*), which superficially resembles a yucca, is found only along the slopes of Waimea Canyon on the island of Kauai. **(c)** *Daubautia scabra* is a small, herbaceous silversword found in moist to wet environments on several Hawaiian islands. (The fern fronds in the background give an idea of the small size of *D. scabra*.)

Consequently, surviving species are presented with new evolutionary opportunities and may diverge, filling in some of the unoccupied zones. In other words, the extinct species may eventually be replaced by new species.

During the long history of life, extinction appears to have occurred at two different rates. The continuous, low-level extinction of species is sometimes called **background extinction.** In contrast, five or possibly six times during Earth's history, **mass extinctions** of numerous species and higher taxonomic groups have taken place in both terrestrial and marine environments. The most recent mass extinction, which occurred about 65 million years ago (mya), killed off many marine organisms, terrestrial plants, and vertebrates, including the last of the dinosaurs (Fig. 19-17). The time span over which a mass extinction occurred may have been several million years, but that is relatively short compared with the 3.5 billion years or so of Earth's history of life. Each period of mass extinction has been followed by a period of adaptive radiation of some of the surviving groups.

The causes of past episodes of mass extinction are not well understood. Both environmental and biological factors seem to have been involved. Major changes in climate could have adversely affected those plants and animals that lacked the genetic flexibility to adapt. Marine organisms, in particular, are adapted to a steady, unchanging climate. If Earth's temperature were to increase or decrease by just a few degrees overall, many marine species would probably perish.

It is also possible that past mass extinctions were due to changes in the environment induced by catastrophes. If a large comet or small asteroid collided with Earth, the dust ejected into the atmosphere on impact could have blocked much of the sunlight. In addition to disrupting the food chain by killing many plants (and therefore terrestrial animals), this event would have lowered Earth's temperature, leading to the death of many marine organisms. Evidence that the extinction of dinosaurs was caused by an extraterrestrial object's collision with Earth continues to accumulate (see Chapter 20).

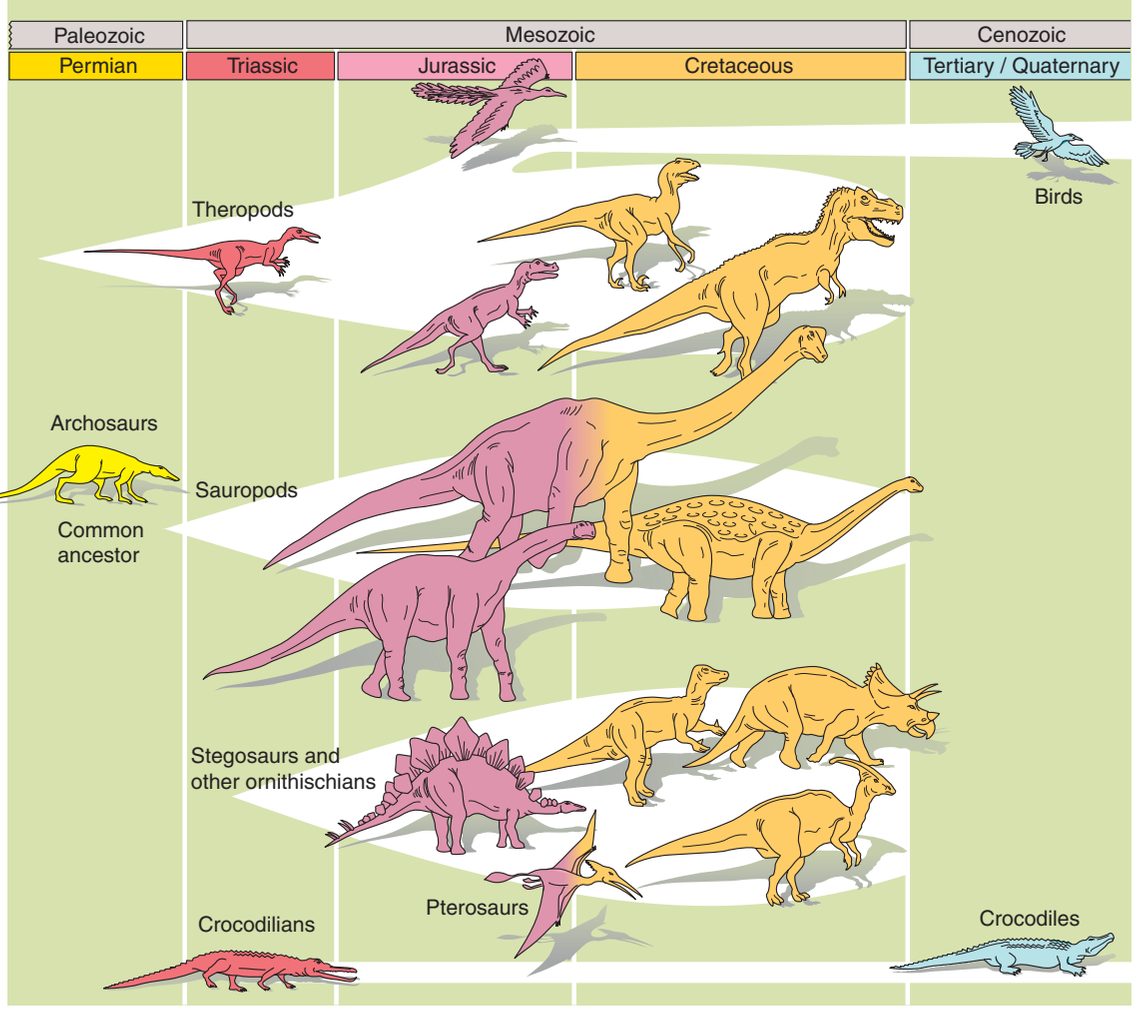


FIGURE **19-17** **Mass extinction of the archosaurs.**

At the end of the Cretaceous period, approximately 65 mya, a mass extinction of many organisms, including the remaining dinosaurs, occurred. (Dinosaurs had already been declining in diversity throughout the latter part of the Cretaceous period.) Most of the archosaurs, one of five main groups of reptiles, became extinct. The only lines to survive were crocodiles and birds, both of which are archosauran descendants.

Biological factors also trigger extinction. Competition among species may lead to the extinction of species that cannot compete effectively. The human species, in particular, has had a profound impact on the rate of extinction. The habitats of many animal and plant species have been altered or destroyed by humans, and habitat destruction can result in a species' extinction. Some biologists think we have entered the greatest mass extinction episode in Earth's history. (Extinction is discussed further in Chapter 55.)

Is microevolution related to speciation and macroevolution?

The concepts presented in Chapters 17 and 18 represent the **modern synthesis,** or *synthetic theory of evolution,* in which mutation provides the genetic variation on which natural selection acts. The modern synthesis combines Darwin's theory with important aspects of genetics. Many aspects of the modern synthesis have been tested and verified at the population and subspecies levels. Many biologists contend that microevolutionary processes (natural selection, mutation, genetic drift, and gene flow) account for the genetic variation within species and for the origin of new species. These biologists also hypothesize that microevolutionary processes explain macroevolutionary patterns.

A considerable body of data from many fields supports the modern synthesis as it relates to speciation and macroevolution. Consider, for example, the evolution of amphibians from fish, which was a major macroevolutionary event in the history of vertebrates. Study of the few known fossil intermediates shows that the transition from aquatic fish to terrestrial amphibian occurred as evolutionary novelties, such as changes in the limbs and skull roof, were added. These novelties accumulated as a succession of small changes over a period of 9 million to 14 million years. This time scale is sufficient to have allowed natural selection and other microevolutionary processes to produce the novel characters.

Although few biologists doubt the role of natural selection and microevolution in generating specific adaptations, some question the *extent* of microevolution's role in the overall pattern of life's history. These biologists ask whether speciation and macroevolution have been dominated by microevolutionary processes or by external, chance events, such as an impact by an asteroid. Chance events do not "care" about adaptive superiority but instead lead to the random extinction or survival of species. In the case of an asteroid impact, for example, certain species may survive because they were "lucky" enough to be in a protected environment at the time of impact. If chance events have been the overriding factor during life's history, then microevolution cannot be the exclusive explanation for the biological diversity we have today (see additional discussion of the role of chance in evolution in Chapter 17).

Review

- Why are evolutionary novelties a topic of scientists studying macroevolution?
- What is a preadaptation? What is paedomorphosis?
- What roles do extinction and adaptive radiation play in macroevolution?

BiologyNow™ Assess your understanding of **macroevolution** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 Explain the significance of reproductive isolating mechanisms, and distinguish among the different prezygotic and postzygotic barriers.

- **Reproductive isolating mechanisms** restrict gene flow between species.
- **Prezygotic barriers** are reproductive isolating mechanisms that prevent fertilization from taking place. **Temporal isolation** occurs when two species reproduce at different times of the day, season, or year. In **habitat isolation,** two closely related species live and breed in different habitats in the same geographic area. In **behavioral isolation,** distinctive courtship behaviors prevent mating between species. **Mechanical isolation** is due to incompatible structural differences in the reproductive organs of similar species. In **gametic isolation,** gametes from different species are incompatible, owing to molecular and chemical differences.
- **Postzygotic barriers** are reproductive isolating mechanisms that prevent gene flow after fertilization has taken place. **Hybrid inviability** is the death of interspecific embryos during development. **Hybrid sterility** prevents interspecific hybrids that survive to adulthood from reproducing successfully. **Hybrid breakdown** prevents the offspring of hybrids that survive to adulthood and successfully reproduce, from reproducing beyond one or a few generations.

2 Explain the mechanism of allopatric specification, and give an example.

- **Speciation** is the evolution of a new species from an ancestral population. **Allopatric speciation** occurs when one population becomes geographically isolated from the rest of the species and subsequently diverges. Speciation is more likely to occur if the original isolated population is small, because genetic drift is more significant in small populations. Examples of allopatric speciation include Death Valley pupfish, Kaibab squirrels, and Porto Santo rabbits.

3 Explain the mechanisms of sympatric speciation, and give both plant and animal examples.

- **Sympatric speciation** does not require geographic isolation.
- Sympatric speciation in plants results almost exclusively from **allopolyploidy,** in which a **polyploid** individual (one with more than two sets of chromosomes) is a hybrid derived from two species. Two examples of sympatric speciation by allopolyploidy are the kew primroses and hemp nettles.
- Sympatric speciation occurs in animals, such as fruit maggot flies and cichlids, but how often it occurs and under what conditions remain to be determined.

SUMMARY WITH KEY TERMS *(continued)*

4 Take either side in a debate on the pace of evolution, by representing the opposing views of gradualism and punctuated equilibrium.

- The interpretation of evolution, as observed in the fossil record, is currently being debated.
- According to the **punctuated equilibrium** model, evolution of species proceeds in spurts. Short periods of active speciation are interspersed with long periods of **stasis.**
- According to the **gradualism** model, populations slowly diverge from one another by the accumulation of adaptive characteristics within a population.

5 Define *macroevolution.*

- **Macroevolution** is large-scale phenotypic changes in populations that warrant their placement in taxonomic groups at the species level and higher—that is, new species, genera, families, orders, classes, and even phyla, kingdoms, and domains.

6 Discuss macroevolution in the context of novel features, including preadaptations, allometric growth, and paedomorphosis.

- Macroevolution includes the appearance of evolutionary novelties, which may be due to changes during **development,** the orderly sequence of events that occurs as an organism grows and matures. Slight genetic changes in regulatory genes could cause major structural changes in the organism.
- Evolutionary novelties may originate from **preadaptations,** structures that originally fulfilled one role but changed in a way that was adaptive for a different role. Feathers are an example of a preadaptation.
- Changes in **allometric growth,** varied rates of growth for different parts of the body, result in overall changes in the shape of an organism. Examples include the ocean sunfish and the male fiddler crab.
- **Paedomorphosis,** the retention of juvenile characteristics in the adult, occurs owing to changes in the timing of development. Adult axolotl salamanders, with external gills and tail fins, are an example of paedomorphosis.

7 Discuss the macroevolutionary significance of adaptive radiation and extinction.

- **Adaptive radiation** is the process of diversification of an ancestral species into many new species. **Adaptive zones** are new ecological opportunities that were not exploited by an ancestral organism. When many adaptive zones are empty, colonizing species rapidly diversify and exploit them. Hawaiian honeycreepers and silverswords both underwent adaptive radiation after their ancestors colonized the Hawaiian Islands.
- **Extinction** is the death of a species. When species become extinct, the adaptive zones that they occupied become vacant, allowing other species to evolve and fill those zones. **Background extinction** is the continuous, low-level extinction of species. **Mass extinction** is the extinction of numerous species and higher taxonomic groups in both terrestrial and marine environments.

POST-TEST

1. According to the biological species concept, two populations belong to the same species if (a) their members freely interbreed (b) individuals from the two populations produce fertile offspring (c) their members do not interbreed with individuals of different species (d) a and c are correct (e) a, b, and c are correct
2. The zebrass is an example of (a) a fertile hybrid (b) a sterile hybrid (c) prezygotic barriers (d) a biological species (e) allopolyploidy
3. A prezygotic barrier prevents (a) the union of egg and sperm (b) reproductive success by an interspecific hybrid (c) the development of the zygote into an embryo (d) allopolyploidy from occurring (e) changes in allometric growth
4. The reproductive isolating mechanism in which two closely related species live in the same geographic area but reproduce at different times is (a) temporal isolation (b) behavioral isolation (c) mechanical isolation (d) gametic isolation (e) hybrid inviability
5. Interspecific hybrids, if they survive, are (a) always sterile (b) always fertile (c) usually sterile (d) usually fertile (e) never sterile
6. The process by which populations of one species evolve into distinct species is known as (a) the evolutionary species concept (b) speciation (c) behavioral isolation (d) ploidy (e) hybridization
7. The first step leading to allopatric speciation is (a) hybrid inviability (b) hybrid breakdown (c) adaptive radiation (d) geographic isolation (e) paedomorphosis
8. The pupfish in the Death Valley region are an example of which evolutionary process? (a) background extinction (b) allopatric speciation (c) sympatric speciation (d) allopolyploidy (e) paedomorphosis
9. Sympatric speciation (a) is most common in animals (b) does not require geographic isolation (c) accounts for the evolution of the Hawaiian goose (nene) (d) involves the accumulation of gradual genetic changes (e) usually takes millions of years
10. Which of the following evolutionary processes is associated with allopolyploidy? (a) gradualism (b) allometric growth (c) sympatric speciation (d) mass extinction (e) preadaptation
11. According to the punctuated equilibrium model, (a) populations slowly diverge from one another (b) the evolution of species occurs in spurts interspersed with long periods of stasis (c) evolutionary novelties originate from preadaptations (d) reproductive isolating mechanisms restrict gene flow between species (e) the fossil record, being incomplete, does not accurately reflect evolution as it actually occurred
12. The evolutionary conversion of reptilian scales into feathers is an example of (a) allometric growth (b) paedomorphosis (c) gradualism (d) hybrid breakdown (e) preadaptation
13. Adaptive radiation is common following a period of mass extinction, probably because (a) the survivors of a mass extinction are remarkably well adapted to their environment (b) the unchanging environment following a mass extinction drives the evolutionary process (c) many adaptive zones are empty (d) many ecological niches are filled (e) the environment induces changes in the timing of development for many species

POST-TEST *(continued)*

14. Adaptive radiations do not appear to have ever occurred (a) on isolated islands (b) in birds such as honeycreepers (c) in environments colonized by few species (d) in plants such as silverswords (e) in environments with many existing species

15. The Hawaiian silverswords are an excellent example of which evolutionary process? (a) allometry (b) preadaptation (c) microevolution (d) adaptive radiation (e) extinction

CRITICAL THINKING

1. Why is allopatric speciation more likely to occur if the original isolated population is small?
2. Based on what you have learned about prezygotic and postzygotic isolating mechanisms, which reproductive isolating mechanism(s) would you say is/are probably at work between the Porto Santo rabbit and its mainland relative?
3. Based on what you have learned in the chapter, hypothesize what the common ancestor of the more than 20 species of desert pupfish may have looked like. (*Hint:* The ancestral species lived in one or more large lakes.) How could you test your hypothesis?
4. Could hawthorn and apple maggot flies be considered an example of assortative mating, which was discussed in Chapter 18? Explain your answer.
5. Because mass extinction is a natural process that may facilitate evolution during the period of thousands to millions of years that follow it, should humans be concerned about the current mass extinction that we are causing? Why or why not?

The Origin and Evolutionary History of Life

CHAPTER OUTLINE

- Chemical Evolution on Early Earth
- The First Cells
- The History of Life

The preceding three chapters were concerned with the evolution of organisms, but we have not yet dealt with what many regard as a fundamental question of biological evolution: How did life begin? Although biologists generally accept the hypothesis that life developed from nonliving matter, exactly how this process, called **chemical evolution,** occurred is not certain. Chemical evolution probably involved several stages. Current models suggest that small organic molecules first formed spontaneously and accumulated over time. These molecules may have accumulated rather than being broken down (as occurs today) because environmental conditions were different. The two factors that today break down organic molecules—free oxygen and living organisms—were absent from early Earth.

Large organic macromolecules such as proteins and nucleic acids could have then assembled from the smaller molecules. The macromolecules interacted with one another, combining into more complicated structures that could eventually metabolize and replicate. Natural selection favored macromolecular assemblages with cell-like structures. Their descendants eventually became the first true cells. After the first cells originated, they diverged over several billion years into the rich biological diversity that characterizes our planet today. Photosynthesis, aerobic respiration, and eukaryotic cell structure represent several major advances that evolved during the history of life.

Geologic evidence, in particular the fossil record, tells us much of what we know about the history of life, such as what kinds of organisms existed and where and when they lived. Certain organisms appear in the fossil record, then disappear and are replaced by others. Initially unicellular prokaryotes predominated, followed by unicellular eukaryotes. The first multicellular eukaryotes—soft-bodied animals that did not leave many fossils—appeared in the ocean approximately 630 million years ago (mya). Shelled animals and many other marine invertebrates (animals without backbones) appeared next, as exemplified by trilobites, members of a large group of primitive aquatic arthropods (see photograph). Marine invertebrates were followed by the first vertebrates (animals with backbones). The first fishes

with jaws appeared and diversified. Some of these gave rise to amphibians, the first vertebrates with limbs capable of moving about on land. Amphibians also spread and diversified. About 300 mya, amphibians gave rise to reptiles, which diversified and populated the land. Reptiles in turn gave rise independently to birds and to mammals. Plants underwent a comparable evolutionary history and diversification.

In this chapter we survey life over a vast span of time, starting some 3.8 billion years ago (bya) when our planet was relatively young. We examine proposed models about how life began and trace life's long evolutionary history from its beginnings to the present. ■

CHEMICAL EVOLUTION ON EARLY EARTH

Learning Objectives

1. Describe the conditions that geologists think existed on early Earth.
2. Contrast the prebiotic soup hypothesis and the iron-sulfur world hypothesis.

Many biologists speculate that life originated only once and that life's beginnings occurred under environmental conditions quite different from those of today. We must therefore examine the conditions of early Earth to understand the origin of life. Although we will never be certain about the exact conditions that existed when life arose, scientific evidence from many sources provides us with valuable clues that help us formulate plausible scenarios. Study of the origin of life is an active area of scientific research today, and many important contributions are adding to our understanding of how life began.

Astrophysicists and geologists estimate Earth is about 4.6 billion years old. The atmosphere of early Earth apparently included carbon dioxide (CO_2), water vapor (H_2O), carbon monoxide (CO), hydrogen (H_2), and nitrogen (N_2). It may also have contained some ammonia (NH_3), hydrogen sulfide (H_2S), and methane (CH_4), although ultraviolet radiation from the sun probably broke these reduced molecules down rapidly. The early atmosphere probably contained little or no free oxygen (O_2).

Four requirements must have existed for the chemical evolution of life: little or no free oxygen, a source of energy, the availability of chemical building blocks, and time. First, life could have begun only in the absence of free oxygen. Oxygen is quite reactive and would have oxidized the organic molecules that are necessary building blocks in the origin of life. Earth's early atmosphere was probably strongly reducing, which means that any free oxygen would have reacted with other elements to form oxides. Thus oxygen would have been tied up in compounds.

The origin of life would also have required energy to do the work of building biological molecules from simple inorganic chemicals. Early Earth was a place of high energy with violent thunderstorms; widespread volcanic activity; bombardment from meteorites and other extraterrestrial objects; and intense radiation, including ultraviolet radiation from the sun (Fig. 20-1). The young sun probably produced more ultraviolet radiation than it does today, and ancient Earth had no protective ozone layer to filter it.

A third requirement would have been the presence of the chemical building blocks needed for chemical evolution. These included water, dissolved inorganic minerals (present as ions), and the gases present in the early atmosphere. A final requirement for the origin of life was time for molecules to accumulate and react with one another. Earth is approximately 4.6 billion years old, and the earliest traces of life are approximately 3.8 billion years old; therefore, life had several hundred million years to get started.

Organic molecules formed on primitive Earth

PROCESS OF SCIENCE

Because organic molecules are the building materials for organisms, it is reasonable to first consider how they may have originated. Two main models seek to explain how the organic precursors of life originated: The **prebiotic soup hypothesis** proposes that these molecules formed near Earth's surface, whereas the **iron-sulfur world hypothesis** proposes that organic precursors formed at cracks in the ocean's floor.

Organic molecules may have been produced at Earth's surface

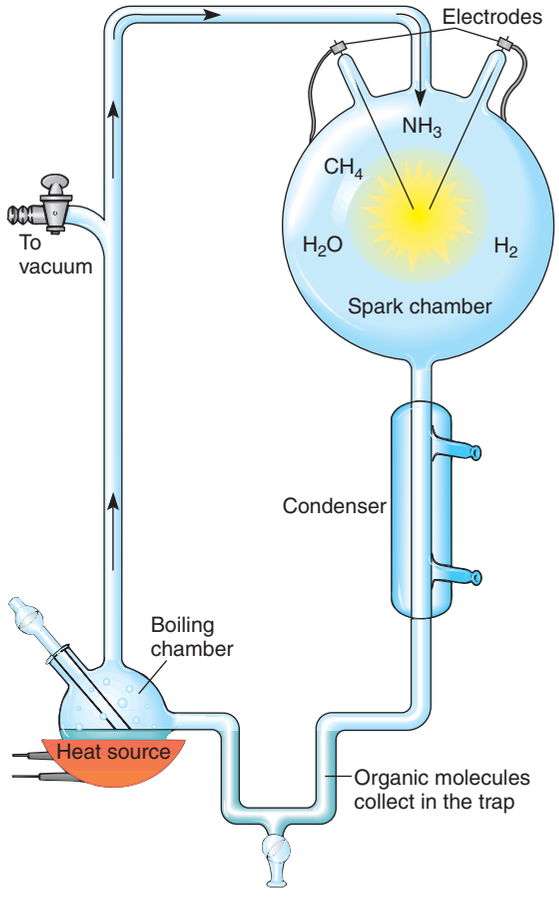
The concept that simple organic molecules such as sugars, nucleotide bases, and amino acids could form spontaneously from simpler raw materials was first advanced in the 1920s by two scientists working independently: A.I. Oparin, a Russian biochemist, and J.B.S. Haldane, a Scottish physiologist and geneticist.

Their hypothesis was tested in the 1950s by American biochemists Stanley Miller and Harold Urey, who designed a closed apparatus that simulated conditions that presumably existed on early Earth (Fig. 20-2). They exposed an atmosphere rich in H_2, CH_4, H_2O, and NH_3 to an electrical discharge that simulated lightning. Their analysis of the chemicals produced in a week revealed that amino acids and other organic molecules had formed. Although more recent data suggest that Earth's early atmosphere was not rich in methane or ammonia, similar experiments using different combinations of gases have produced a wide variety of organic molecules that are important in contemporary organisms. These include all 20 amino acids, several sugars, lipids, the nucleotide bases of RNA and DNA, and ATP (when phosphate is present). Thus, before life began, its chemical building blocks were probably accumulating as a necessary step in chemical evolution.

Oparin envisioned that the organic molecules would, over vast spans of time, accumulate in the shallow seas to form a "sea of organic soup." Under such conditions, he envisioned smaller organic molecules (monomers) combining to form larger ones (polymers). Evidence gathered since Oparin's time indicates that organic polymers may have formed and accumulated on rock or clay surfaces rather than in the primordial seas. Clay, which consists of microscopic particles of weathered rock, is particularly intriguing as a possible site for early polymerizations, because it binds organic monomers and contains zinc and iron ions that may have served as catalysts. Laboratory experiments have confirmed that organic polymers form spontaneously from monomers on hot rock or clay surfaces.

Organic molecules may have formed at hydrothermal vents

In a different scenario of chemical evolution, some biologists hypothesize that early polymerizations leading to the origin of life may have occurred in cracks in the deep ocean floor where hot water, carbon monoxide, and minerals such as sulfides of iron and nickel spew forth—the iron-sulfur world hypothesis.



ACTIVE FIGURE **20-2** **Testing the prebiotic soup hypothesis.**

Diagram of the apparatus that Miller and Urey used to simulate the reducing atmosphere of early Earth. An electrical spark was produced in the upper right flask to simulate lightning. The gases present in the flask reacted together, forming a variety of simple organic compounds that accumulated in the trap at the bottom.

BiologyNow™ See the **Miller-Urey experiment** unfold by clicking on this figure on your BiologyNow CD-ROM.

Such **hydrothermal vents** would have been better protected than Earth's surface from the catastrophic effects of meteorite bombardment.

Today these hot springs produce precursors of biological molecules and of energy-rich "food," including the highly reduced compounds, hydrogen sulfide and methane. These chemicals support a diverse community of microorganisms, clams, crabs, tube worms, and other animals (see *Focus On: Life without the Sun* in Chapter 53).

Testing the iron-sulfur world hypothesis at hydrothermal vents is difficult, but laboratory experiments simulating the high pressures and temperatures at the vents have yielded intriguing results. For example, iron and nickel sulfides catalyze reactions between carbon monoxide and hydrogen sulfide, producing acetic acid and other simple organic compounds. Also, experiments show that ammonia, one of the precursors of proteins and nucleic acids, is produced in abundance, suggesting that vents were ammonia-rich environments in the prebiotic world.

Review

- What are the four requirements for chemical evolution, and why is each essential?
- What is the prebiotic soup hypothesis?
- How does the iron-sulfur world hypothesis differ from the prebiotic soup hypothesis?

BiologyNow™ Assess your understanding of **chemical evolution on early Earth,** by taking the pretest on your BiologyNow CD-ROM.

THE FIRST CELLS

Learning Objectives

3 Outline the major steps hypothesized to have occurred in the origin of cells.

4 Explain how the evolution of photosynthetic autotrophs affected both the atmosphere and other organisms.

5 Describe the endosymbiont theory.

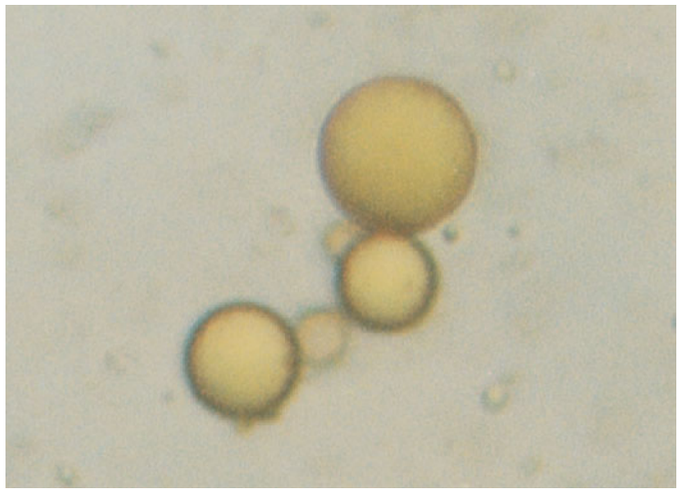
After the first polymers formed, could they have assembled spontaneously into more complex structures? Scientists have synthesized several different **protobionts,** which are assemblages of abiotically produced (that is, not produced by organisms) organic polymers. They have recovered protobionts that resemble living cells in several ways, thus providing clues as to how aggregations of complex nonliving molecules took that "giant leap" and became living cells. These protobionts exhibit many functional and structural attributes of living cells. They often divide in half (binary fission) after they have sufficiently "grown." Protobionts maintain an internal chemical environment that is different from the external environment (homeostasis), and some of them show the beginnings of metabolism (catalytic activity). They are highly organized, considering their relatively simple composition.

Microspheres are a type of protobiont formed by adding water to abiotically formed polypeptides (Fig. 20-3). Some microspheres are excitable: They produce an electrical potential across their surfaces, reminiscent of electrochemical gradients in cells. Microspheres can also absorb materials from their surroundings (selective permeability) and respond to changes in osmotic pressure as though membranes enveloped them, even though they contain no lipid.

The study of protobionts shows that relatively simple "pre-cells" have some of the properties of contemporary life. However, it is a major step (or several steps) to go from simple molecular aggregates such as protobionts to living cells. Although we have learned many things about how organic molecules may have formed on primitive Earth, the problem of how pre-cells evolved into living cells remains to be solved. One of the most significant parts of that process was the evolution of molecular reproduction.

Molecular reproduction was a crucial step in the origin of cells

In living cells, genetic information is stored in the nucleic acid DNA, which is transcribed into messenger RNA (mRNA), which in turn is translated into the proper amino acid sequence in proteins. All three macromolecules in the DNA ⟶ RNA ⟶ protein sequence contain precise information, but only DNA and RNA are capable of self-replication, although only in the presence of the proper enzymes. Because both RNA and DNA can form spontaneously on clay in much the same way that other organic polymers do, the question becomes which molecule, DNA or RNA, first appeared in the prebiotic world.



Steven Brooke and Richard LeDuc

FIGURE **20-3** **Microspheres.**
These tiny protobionts exhibit some of the properties of life.

Many scientists have suggested that RNA was the first informational molecule to evolve in the progression toward a self-sustaining, self-reproducing cell and that proteins and DNA came along later. According to a model known as the **RNA world,** the chemistry of prebiotic Earth gave rise to self-replicating RNA molecules that functioned as both enzymes and substrates for their own replication. We represent the replication of RNA in the RNA world scenario as a circular arrow:

One feature of RNA is that it often has catalytic properties; such enzymatic RNAs are called **ribozymes.** Before the evolution of true cells, ribozymes may have catalyzed their own replication in the clays, shallow rock pools, or hydrothermal vents where life originated. When RNA strands are added to a test tube containing RNA nucleotides but no enzymes, the nucleotides combine to form short RNA molecules.

The occurrence of an RNA world early in the history of life can never be proven, but experiments with **in vitro evolution,** also called **directed evolution,** have shown it is feasible. These experiments address an important question about the RNA world, namely, could RNA molecules have catalyzed the many different chemical reactions needed for life? In directed evolution, a large pool of RNA molecules with different sequences are mixed together and selected for their ability to catalyze a single biologically important reaction (Fig. 20-4). Those molecules that have at least some catalytic ability are then amplified

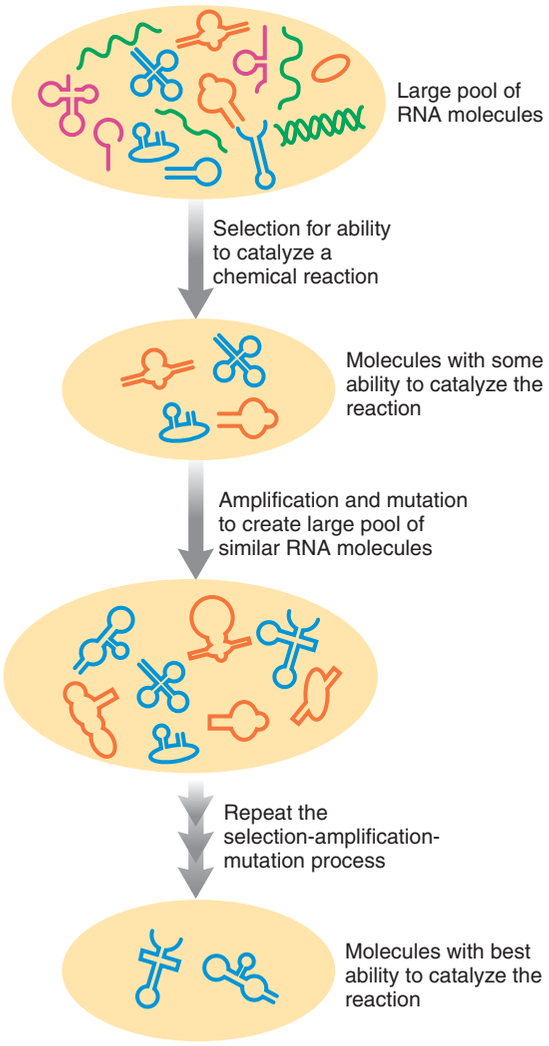


FIGURE **20-4** **In vitro evolution of RNA molecules.**

RNA molecules are selected from a large pool, based on their ability to catalyze a specific reaction, then amplified and mutated, a process that is then repeated 7 to 20 additional times. The final group of RNA molecules is the most efficient at catalyzing the chemical reaction selected for. Scientists have developed more than two dozen synthetic RNA catalysts by in vitro evolution.

and mutated before being exposed to another round of selection. After this cycle is repeated several times, the RNA molecules at the end of the selection process function efficiently as catalysts for the reaction. In vitro evolution studies have shown that RNA has a large functional repertoire—that is, RNA can catalyze a variety of biologically important reactions.

In the RNA world, biologists hypothesize that ribozymes initially catalyzed protein synthesis and other important biological reactions; only later did protein enzymes catalyze these reactions.

$$\text{RNA} \rightarrow \text{protein}$$

Interestingly, RNA directs protein synthesis by catalyzing peptide bond formation. Some single-stranded RNA molecules fold back on themselves as a result of interactions among the nucleotides composing the RNA strand. Sometimes the conformation (shape) of the folded RNA molecule is such that it weakly binds to an amino acid. If amino acids are held close together by RNA molecules, they may bond together, forming a polypeptide.

We have considered how the evolution of informational molecules may have given rise to RNA and later to proteins. If a self-replicating RNA capable of coding for proteins appeared before DNA, how did DNA, the universal molecule of heredity in cells, become involved? Perhaps RNA made double-stranded copies of itself that eventually evolved into DNA.

$$\text{DNA} \longleftarrow \text{RNA} \longrightarrow \text{protein}$$

The incorporation of DNA into the information transfer system was advantageous because the double helix of DNA is more stable (less reactive) than the single strand of RNA. Such stability in a molecule that stores genetic information would have provided a decided advantage in the prebiotic world (as it does today).

In the DNA/RNA/protein world, then, DNA became the information storage molecule, RNA remained involved in protein synthesis, and protein enzymes catalyzed most cell reactions, including DNA replication, RNA synthesis, and protein synthesis.

$$\text{DNA} \rightarrow \text{RNA} \rightarrow \text{protein}$$

RNA is still a necessary component of the information transfer system, because DNA is not catalytic. Thus natural selection at the molecular level favored the DNA ⟶ RNA ⟶ protein information sequence. Once DNA was incorporated into this sequence, RNA molecules assumed their present role as an intermediary in the transfer of genetic information.

Several additional steps had to occur before a true living cell could evolve from macromolecular aggregations. For example, the self-replicating genetic code must have arisen extremely early in the prebiotic world because all organisms possess it—but how did it originate? Also, how did a plasma membrane of lipid and protein evolve?

Biological evolution began with the first cells

No one knows exactly when the first cells first appeared on Earth. Nonfossil evidence—isotopic "fingerprints" of organic carbon in ancient rocks in Greenland—indicates that life existed as early as 3.8 bya. **Microfossils,** ancient remains of microscopic life, suggest that cells may have been thriving as long as 3.5 bya, although the original interpretations of the oldest carbon-rich "squiggles" in ancient rocks as microfossils have been recently challenged. The oldest fossil cells that are widely accepted are 2 billion years old.

The earliest cells were prokaryotic. **Stromatolites,** another type of fossil evidence of the earliest cells, are rocklike columns composed of many minute layers of prokaryotic cells (Fig. 20-5). Over time, sediment collects around the cells and mineralizes. Meanwhile, a new layer of living cells grows over the older, dead cells. Fossil stromatolite reefs are found in several places in the

Fred Bavendam/Peter Arnold, Inc.

Biological Photo Service

(b)

FIGURE **20-5** **Stromatolites.**

(a) These living stromatolites at Hamlin Pool in Western Australia consist of mats of cyanobacteria and minerals such as calcium carbonate. They are several thousand years old. **(b)** Cutaway view of a fossil stromatolite showing the layers of microorganisms and sediments that accumulated over time. This stromatolite, also from Western Australia, is about 3.5 billion years old.

world, including Great Slave Lake in Canada and the Gunflint Iron Formations along Lake Superior in the United States. Some fossil stromatolites are extremely ancient. One group in Western Australia, for example, is several billion years old. Stromatolite reefs are still living in hot springs and in warm, shallow pools of fresh and salt water.

The first cells were probably heterotrophic

The earliest cells probably obtained the organic molecules they needed from the environment, rather than synthesizing them. These primitive **heterotrophs** probably consumed many types of organic molecules that had formed spontaneously—sugars, nucleotides, and amino acids, to name a few. By fermenting these organic compounds, they obtained the energy they needed to support life. *Fermentation* is, of course, an anaerobic process (performed in the absence of oxygen), and the first cells were almost certainly **anaerobes.**

When the supply of spontaneously generated organic molecules gradually declined, only certain organisms could survive. Mutations had probably already occurred that permitted some cells to obtain energy directly from sunlight, perhaps by using sunlight to make ATP. These cells, which did not require the energy-rich organic compounds that were now in short supply in the environment, had a distinct selective advantage.

Photosynthesis requires not only light energy but also a source of electrons, which are used to reduce CO_2 when organic molecules such as glucose are synthesized (see Chapter 8). Most likely, the first photosynthetic **autotrophs**—organisms that produce their own food from simple raw materials—used the energy of sunlight to split hydrogen-rich molecules such as H_2S, releasing elemental sulfur (not oxygen) in the process. Indeed, the green sulfur bacteria and the purple sulfur bacteria still use H_2S as a hydrogen source for photosynthesis.[1]

The first photosynthetic autotrophs to obtain hydrogen by splitting water were the cyanobacteria. Water was quite abundant on early Earth, as it is today, and the selective advantage that splitting water gave cyanobacteria allowed them to thrive. The process of splitting water released oxygen as a gas (O_2). Initially, the oxygen released during photosynthesis oxidized minerals in the ocean and in Earth's crust, and for a long time oxygen did not begin to accumulate in the atmosphere. Eventually, however, oxygen levels increased in the ocean and the atmosphere.

Scientists estimate the timing of the events just described on the basis of geological and fossil evidence. Fossils from that period, which include rocks containing traces of chlorophyll, as well as the fossil stromatolites discussed earlier, indicate the first photosynthetic organisms appeared approximately 3.1 to 3.5 bya. This evidence suggests heterotrophic forms existed even earlier.

Aerobes appeared after oxygen increased in the atmosphere

By 2 bya, cyanobacteria had produced enough oxygen to begin significantly changing the composition of the atmosphere. The increase in atmospheric oxygen affected life profoundly. The oxygen poisoned *obligate anaerobes* (organisms that can't use oxygen for cellular respiration), and many species undoubtedly perished. Some anaerobes, however, survived in environments where oxygen did not penetrate; others evolved adaptations to neutralize the oxygen so it could not harm them. Some organisms, called **aerobes,** evolved a respiratory pathway that used oxygen to extract more energy from food. Aerobic respiration joined with the existing anaerobic process of glycolysis.

[1] Members of a third group of bacteria, the purple nonsulfur bacteria, use other organic molecules or hydrogen gas as a hydrogen source.

The evolution of organisms that could use oxygen in their metabolism had several consequences. Organisms that respire aerobically gain much more energy from a single molecule of glucose than anaerobes gain by fermentation (see Chapter 7). As a result, the newly evolved aerobic organisms were more efficient and more competitive than anaerobes. Coupled with the poisonous nature of oxygen to many anaerobes, the efficiency of aerobes forced anaerobes into relatively minor roles. Today the vast majority of organisms, including plants, animals, and most fungi, protists, and prokaryotes, use aerobic respiration, whereas only a few bacteria and even fewer protists and fungi are anaerobic.

The evolution of aerobic respiration stabilized both oxygen and carbon dioxide levels in the biosphere. Photosynthetic organisms used carbon dioxide as a source of carbon for synthesizing organic compounds. This raw material would have been depleted from the atmosphere in a relatively brief period without the advent of aerobic respiration, which released carbon dioxide as a waste product from the complete breakdown of organic molecules. Carbon thus started cycling in the biosphere, moving from the nonliving physical environment, to photosynthetic organisms, to heterotrophs that ate the photosynthetic organisms (see Chapter 53). Aerobic respiration released carbon back into the physical environment as carbon dioxide, and the carbon cycle continued. In a similar manner, molecular oxygen was produced by photosynthesis and used during aerobic respiration.

Another significant consequence of photosynthesis occurred in the upper atmosphere, where molecular oxygen reacted to form **ozone,** O_3 (Fig. 20-6). A layer of ozone eventually blanketed Earth, preventing much of the sun's ultraviolet radiation from penetrating to the surface. With the ozone layer's protection from the mutagenic effect of ultraviolet radiation, organisms could live closer to the surface in aquatic environments and eventually move onto land. Because the energy in ultraviolet radiation may have been necessary to form organic molecules, however, their abiotic synthesis decreased.

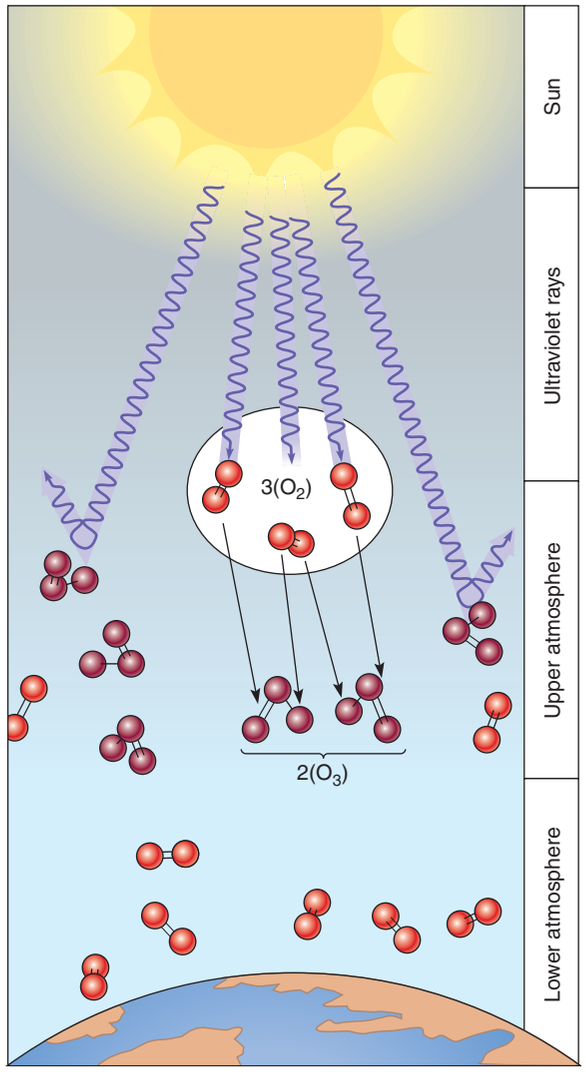

FIGURE **20-6** **How ozone forms.**

Ozone (O_3) forms in the upper atmosphere when ultraviolet radiation from the sun breaks the double bonds of oxygen molecules.

Eukaryotic cells descended from prokaryotic cells

Eukaryotes may have appeared in the fossil record as early as 1.5 to 1.6 bya, and geochemical evidence suggests that eukaryotes were present much earlier. Steranes, molecules derived from steroids, have been discovered in Australian rocks dated at 2.7 billion years. Because bacteria are not known to produce steroids, the steranes may be biomarkers for eukaryotes. (These ancient rocks lack fossil traces of ancient organisms because the rocks have since been exposed to heat and pressure that would have destroyed any fossilized cells. Steranes, however, are very stable in the presence of heat and pressure.)

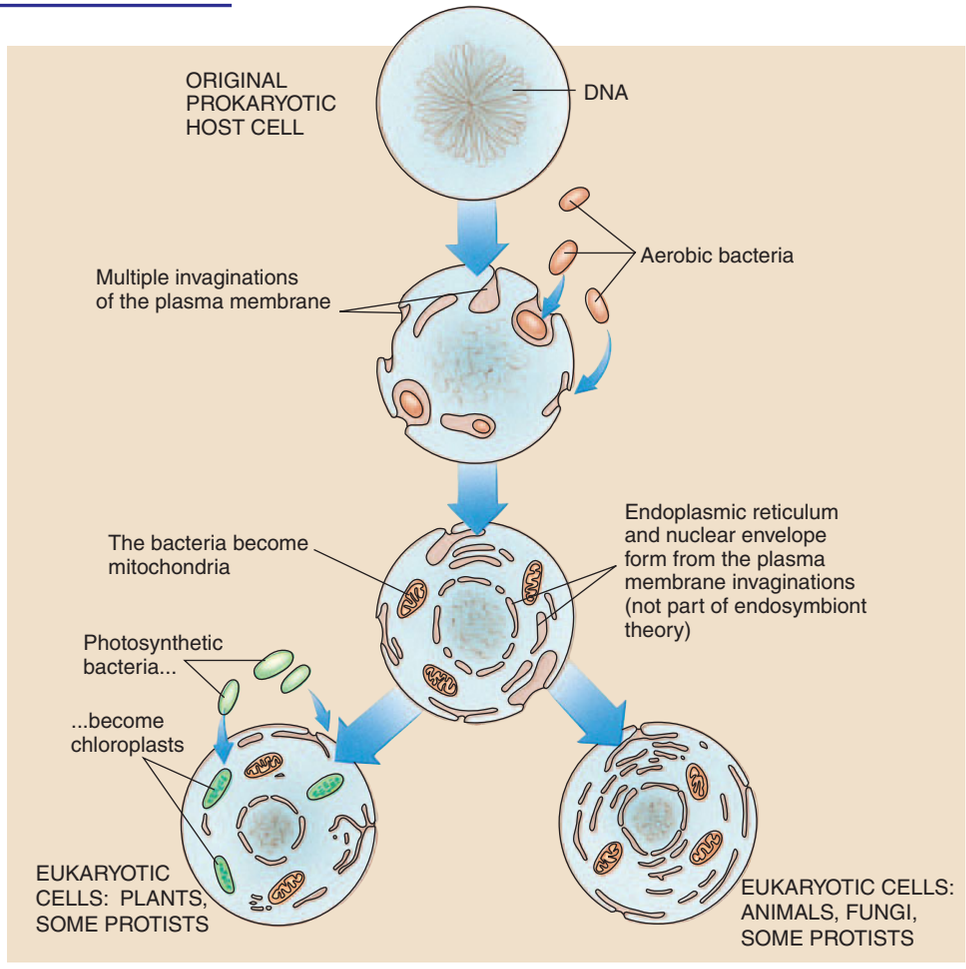
Eukaryotes arose from prokaryotes. Recall from Chapter 4 that prokaryotic cells lack nuclear envelopes as well as other membranous organelles such as mitochondria and chloroplasts. The **endosymbiont theory,** advanced by Lynn Margulis, declares that organelles such as mitochondria and chloroplasts may each have originated from mutually advantageous symbiotic relationships between two prokaryotic organisms (Fig. 20-7). Chloroplasts apparently evolved from photosynthetic bacteria (cyanobacteria) that lived inside larger heterotrophic cells, whereas mitochondria presumably evolved from aerobic bacteria (perhaps purple bacteria) that lived inside larger anaerobic cells. Thus early eukaryotic cells were assemblages of formerly free-living prokaryotes.

How did these bacteria come to be **endosymbionts,** which are organisms that live symbiotically inside a host cell? They may originally have been ingested, but not digested, by a host cell. Once incorporated, they could have survived and reproduced along with the host cell so that future generations of the host also contained endosymbionts. The two organisms developed a mutualistic relationship in which each contributed something to the other. Eventually the endosymbiont lost the ability to exist outside its host, and the host cell lost the ability to survive with-

FIGURE **20-7**

The endosymbiont theory.

Chloroplasts and mitochondria of eukaryotic cells are thought to have originated from various bacteria that lived as endosymbionts inside other cells.



out its endosymbionts. This theory stipulates that each of these partners brought to the relationship something the other lacked. For example, mitochondria provided the ability to carry out the aerobic respiration lacking in the original anaerobic host cell. Chloroplasts provided the ability to use a simple carbon source (CO_2) to produce needed organic molecules. The host cell provided a safe environment and raw materials or nutrients.

The principal evidence in favor of the endosymbiont theory is that mitochondria and chloroplasts possess some (although not all) of their own genetic material and translational components. They have their own DNA (as a circular molecule similar to that of prokaryotes; see Chapter 23) and their own ribosomes (which resemble prokaryotic rather than eukaryotic ribosomes). Mitochondria and chloroplasts also possess some of the machinery for protein synthesis, including tRNA molecules, and conduct protein synthesis on a limited scale independent of the nucleus. Furthermore, it is possible to poison mitochondria and chloroplasts with an antibiotic that affects prokaryotic but not eukaryotic cells. As discussed in Chapter 4, double membranes envelope mitochondria and chloroplasts. The outer membrane apparently developed from the invagination (infolding) of the host cell's plasma membrane, whereas the inner membrane is derived from the endosymbiont's plasma membrane. (The endosymbiont theory is discussed in greater detail in Chapter 24.)

Many endosymbiotic relationships exist today. Many corals have algae living as endosymbionts within their cells (see Fig. 52-11). In the gut of the termite lives a protozoon (*Myxotricha paradoxa*) that in turn has several different endosymbionts, including spirochete bacteria that are attached to the protozoon and function as whiplike flagella, allowing it to move.

The endosymbiont theory does not completely explain the evolution of eukaryotic cells from prokaryotes. It does not explain, for example, how a double membranous envelope came to surround the genetic material in the nucleus.

Review

- What major steps probably occurred in the origin of cells?
- How did the presence of molecular oxygen in the atmosphere affect early life?
- What kinds of evidence support the endosymbiont theory?

THE HISTORY OF LIFE

Learning Objectives

6 List the geological eras in chronological order, and give approximate dates for each.

7 Briefly describe the distinguishing organisms and major biological events of Precambrian time and of the Paleozoic, Mesozoic, and Cenozoic eras.

The sequence of biological, climate, and geological events that make up the history of life is recorded in rocks and fossils. The sediments of Earth's crust consist of five major rock strata (layers), each subdivided into minor strata, lying one on top of the other. Very few places on Earth show all layers, but the strata present typically occur in the correct order, with younger rocks on top of older ones. These sheets of rock formed from the accumulation of mud and sand at the bottoms of the ocean, seas, and lakes. Each layer contains certain characteristic fossils,

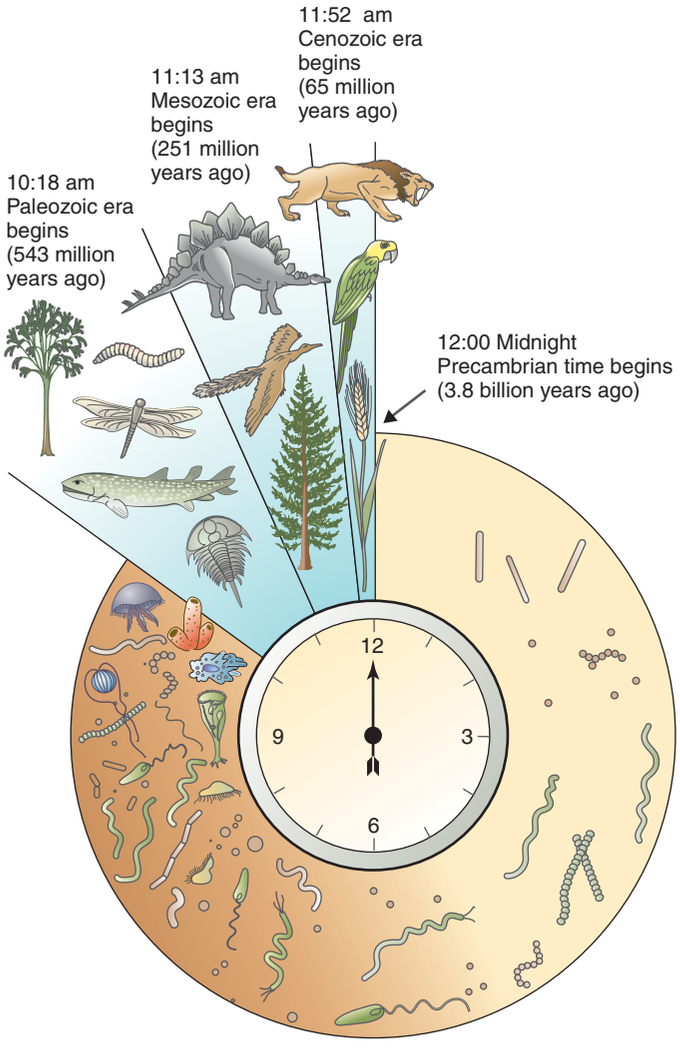

FIGURE **20-8** **An interpretive scale of biological time.**

Because it is difficult to interpret time in millions or billions of years, using a clock helps represent such vast spans of time. Life began 3.8 bya, at 12:00 midnight. More than 10 hours later, at 10:18 A.M., the Paleozoic era began. The beginning of the Mesozoic era, 251 mya, would be at 11:13 A.M. The Cenozoic era, which began 65 mya, would start at 11:52 A.M. The last epoch of the Cenozoic era, the Holocene epoch, began 10,000 years ago, which would be represented by the last 0.1 second before 12:00 noon. Representative life forms for each era are included.

known as **index fossils,** that identify deposits made at about the same time in different parts of the world (see Chapter 17).

Geologists divide Earth's 4.6-billion-year history into units of time based on major geological, climate, and biological events. Relatively little is known about Earth from its beginnings approximately 4.6 bya up to 543 mya, a period known informally as **Precambrian time.** More precisely, that part of Precambrian time from 2.5 bya to 543 mya is known as the **Proterozoic eon.** Beginning about 543 mya, the fossil record of ancient organisms is abundant. This most recent time, from 543 mya to the present, is divided into three **eras** based primarily on organisms that characterized each era (Fig. 20-8 and Table 20-1). Eras are subdivided into **periods,** which in turn are composed of **epochs.**

Precambrian deposits contain fossils of cells and simple animals

Signs of Precambrian life date back as early as 3.8 bya. Not much physical evidence is available, because the rocks of Precambrian time, being extremely ancient, are deeply buried in most parts of the world. Precambrian rocks are exposed in a few places, including the bottom of the Grand Canyon and along the shores of Lake Superior. More than 400 Precambrian rock formations have revealed microfossils.

During Precambrian time, widespread volcanic activity and giant upheavals raised mountains, and the heat, pressure, and churning associated with these movements probably destroyed most of whatever fossils had formed. Some evidence of life still remains as traces of graphite or pure carbon, which may be the transformed remains of primitive life. These remains are especially abundant in what were the ocean and seas of that time. In addition, geologists recovered fossils resembling cyanobacteria from several Precambrian formations. The fossils found in more recent Precambrian rocks show unambiguous examples of some major groups of bacteria, fungi, protists (including multicellular algae), and animals.

One rich source of Precambrian fossil deposits is the Ediacaran Hills (pronounced "ee-dee-ack′uh-ran") in South Australia. **Ediacaran fossils,** the oldest known fossils of multicellular animals, some a meter or more in length, are from very late in Precambrian time—from 600 to 543 mya. Experts interpret some of these fossils as early sponges, jellyfish, and comb jellies, but they have not yet identified all the simple, soft-bodied animals found there and at other late Precambrian sites. The oldest, simplest Ediacaran fossils are from 580-million-year-old rocks in Newfoundland and in the Mackenzie Mountains of northwest Canada.

A diversity of organisms evolved during the Paleozoic era

The **Paleozoic era** began approximately 543 mya and lasted approximately 292 million years. It is divided into six periods: Cambrian, Ordovician, Silurian, Devonian, Carboniferous, and Permian.

Rocks rich in fossils represent the oldest subdivision of the Paleozoic era, the **Cambrian period.** From about 565 mya to 525 mya, evolution was in such high gear, with the sudden appearance of many new animal body plans, that this period is nicknamed the **Cambrian explosion.** Fossils of all contemporary animal phyla are present, along with many bizarre, extinct phyla, in marine sediments. The sea floor was covered with sponges, corals, sea lilies, sea stars, snails, clamlike bivalves, primitive squidlike cephalopods, lamp shells (brachiopods), trilobites (see chapter opening photograph; also see Fig. 29-18).

TABLE **20-1** Some Important Biological Events in Geological Time

Time*	Era	Period	Epoch	Geological/ Climatic Conditions	Plants and Microorganisms	Animals
0.01 (10,000 years ago)	Cenozoic	Quaternary	Holocene	End of last Ice Age; warmer climate; higher sea levels as glaciers melt	Decline of some woody plants; rise of herbaceous plants	Age of *Homo sapiens*
2			Pleistocene	Multiple ice ages; glaciers in Northern Hemisphere	Extinction of some plant species	Extinction of many large mammals at end
5		Tertiary	Pliocene	Uplift and mountain-building; volcanoes; climate much cooler; North and South America join at Isthmus of Panama	Expansion of extensive grasslands and deserts; decline of forests	Many grazing mammals; large carnivorous mammals; human-like primates diversify
24			Miocene	Mountains form; climate drier and cooler	Flowering plants continue to diversify	Great diversity of grazing mammals and songbirds
33			Oligocene	Rise of Alps and Himalayas; most land low; volcanic activity in Rockies; climate cool and dry	Spread of forests; flowering plant communities expand	Apes appear; present mammalian families are represented
55			Eocene	Climate warmer	Flowering plants dominant	Modern mammalian orders appear and diversify; modern bird orders appear
65			Paleocene	Continental seas disappear; climate mild to cool and wet	Semitropical vegetation (flowering plants and conifers) widespread	Primitive mammals diversify rapidly
144	Mesozoic	Cretaceous		Continents separate; most continents low; large inland seas and swamps; climate warm	Rise of flowering plants	Dinosaurs reach peak, then become extinct at end; toothed birds become extinct; primitive mammals
206		Jurassic		Continents low; inland seas; mountains form; continental drift begins; climate mild	Gymnosperms common	Large, specialized dinosaurs; first toothed birds; primitive insectivorous mammals diversify
251		Triassic		Many mountains form; widespread deserts; climate warm and dry	Gymnosperms dominant; ferns common	First dinosaurs; first mammals
290	Paleozoic	Permian		Glaciers; continents rise and merge as Pangaea; climate variable	Conifers diversify; cycads appear	Modern insects appear; mammal-like reptiles; extinction of many Paleozoic invertebrates and vertebrates at end of Permian
354		Carboniferous		Lands low and swampy; climate warm and humid, becoming cooler later	Forests of ferns, club mosses, horsetails, and gymnosperms; mosses and liverworts	First reptiles; spread of ancient amphibians; many insect forms; ancient sharks abundant
408		Devonian		Glaciers; inland seas	Vascular plants diversify and become well established; first forests; gymnosperms appear; bryophytes appear	Many trilobites; fishes with jaws appear and diversify; amphibians appear; wingless insects appear
439		Silurian		Most continents remain covered by seas; climate warm	Algae dominant in aquatic environments; vascular plants appear	Jawless fishes diversify; coral reefs common; terrestrial arthropods
495		Ordovician		Sea covers most continents	Marine algae dominant; fossil spores of terrestrial plants (bryophytes?)	Invertebrates dominant; coral reefs appear; first fishes appear
543		Cambrian		Oldest rocks with abundant fossils; lands low; climate mild and wet	Algae; bacteria and cyanobacteria; fungi	Age of marine invertebrates; modern and extinct animal phyla represented; first chordates

*Time from beginning of period to present (millions of years).

Images not available due to copyright restrictions

In addition, small vertebrates—cartilaginous fishes, first reported in 1999—became established in the marine environment. Scientists have not determined the factors responsible for the Cambrian explosion, a period unmatched in the evolutionary history of life. There is some evidence that oxygen concentrations, which had continued to gradually increase in the atmosphere, passed some critical environmental threshold late in Precambrian time. Scientists who advocate the *oxygen enrichment hypothesis* note that until late in Precambrian time, Earth didn't have enough oxygen to support larger animals. The most important fossil sites that document the Cambrian explosion are the **Chenjiang site** in China (for early Cambrian fossils) and the **Burgess Shale** in British Columbia (for middle Cambrian fossils; Fig. 20-9).

According to geologists, seas gradually flooded the continents during the Cambrian period. In the **Ordovician period,** much land was covered by shallow seas, in which there was another burst of evolutionary diversification, although not as dramatic as the Cambrian explosion. The Ordovician seas were inhabited by giant cephalopods, squidlike animals with straight shells 5 to 7 m (16 to 23 ft) long and 30 cm (12 in) in diameter. Coral reefs first appeared during this period, as did small, jawless, bony-armored fishes called *ostracoderms* (Fig. 20-10). Lacking jaws, these fishes typically had round or slitlike mouth openings that may have sucked in small food particles from the water or scooped up organic debris from the bottom. Ordovician deposits also contain fossil spores of terrestrial (land-dwelling) plants, suggesting the colonization of land had begun.

During the **Silurian period,** jawless fishes diversified considerably, and jawed fishes first appeared. Definitive evidence of two life forms of great biological significance appeared in the Silurian period: terrestrial plants and air-breathing animals. The evolution of plants allowed animals to colonize the land, because plants provided the first terrestrial animals with food and shelter. All air-breathing land animals discovered in Silurian rocks were arthropods—millipedes, spider-like arthropods, and possibly centipedes. From an ecological perspective, the energy flow from plants to animals probably occurred via detritus, which is organic debris from decomposing organisms, rather than directly from living plant material. Millipedes eat plant detritus today, and spiders and centipedes prey on millipedes and other animals.

The **Devonian period** is frequently called the Age of Fishes. This period witnessed the explosive radiation of fishes with jaws, an adaptation that lets a vertebrate chew and bite. Armored *placoderms,* an extinct group of jawed fishes, diversified to exploit varied lifestyles (see Fig. 30-9b). Appearing in Devonian deposits are sharks and the two predominant types of bony fish: lobe-finned fishes and ray-finned

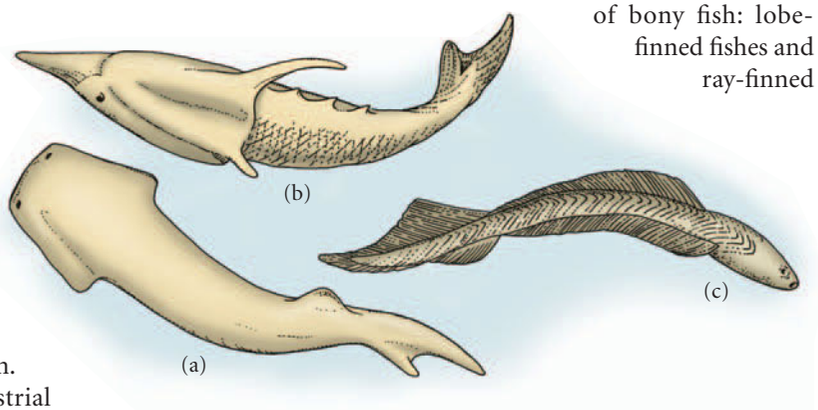

FIGURE **20-10** **Representative ostracoderms.**
(a) *Thelodus,* **(b)** *Pterapsis,* and **(c)** *Jamoytius* are fossil ostracoderms, primitive jawless fishes that appeared in the Devonian period. Ostracoderms ranged from 10 to 50 cm (4 to 20 in) in length.

fishes, which gave rise to the major orders of modern fishes (see Chapter 30). Upper (more recent) Devonian sediments contain fossil remains of salamander-like amphibians (*labyrinthodonts*) that were often quite large, with short necks and heavy, muscular tails (see Fig. 30-15). Wingless insects also originated in the late Devonian period. The early vascular plants diversified during the Devonian period in a burst of evolution that rivaled that of animals during the Cambrian explosion. With the exception of flowering plants, all major plant groups appeared during the Devonian. Forests of ferns, club mosses, horsetails, and seed ferns (an extinct group of ancient plants that had fernlike foliage but reproduced by forming seeds) flourished.

The **Carboniferous period** is named for the great swamp forests whose remains persist today as major coal deposits. Much of the land during this time was covered with low swamps filled with horsetails, club mosses, ferns, seed ferns, and gymnosperms (seed-bearing plants such as conifers) (Fig. 20-11). Amphibians, which underwent an **adaptive radiation** and exploited both aquatic and terrestrial ecosystems, were the dominant terrestrial carnivores of the Carboniferous period. Reptiles first appeared and diverged to form two major lines at this time. One line consisted of mostly small and mid-sized insectivorous (insect-eating) lizards; this line later led to lizards, snakes, crocodiles, dinosaurs, and birds. The other reptilian line led to a diverse group of Permian and early Mesozoic mammal-like reptiles. Two groups of winged insects, cockroaches and dragonflies, appeared in the Carboniferous period.

FIGURE **20-11** **Reconstruction of a Carboniferous forest.**
Plants of this period included giant ferns, horsetails, and club mosses as well as seed ferns and early gymnosperms.

Amphibians continued in importance during the **Permian period,** but they were no longer the dominant carnivores in terrestrial ecosystems. During the Permian period, reptiles diversified and dominated both carnivorous and herbivorous terrestrial lifestyles. One important group of mammal-like reptiles, originating in the Permian and extending into the Mesozoic era, were the *therapsids,* a group that included the ancestor of mammals (discussed shortly; also see Fig. 30-21). During the Permian period, seed plants diversified and dominated most plant communities. Cone-bearing conifers were widespread, and cycads (plants with crowns of fernlike leaves and large, seed-containing cones) and ginkgoes (trees with fan-shaped leaves and exposed, fleshy seeds) appeared.

The greatest **mass extinction** of all time occurred at the end of the Paleozoic era, between the Permian and Triassic periods, 251 mya. More than 90% of all existing marine species became extinct at this time, as did more than 70% of the vertebrate genera living on land. There is also evidence of a major extinction of plants. Many causes for the late Permian mass extinction have been suggested. Regardless of cause, evidence suggests the extinction occurred globally in a very compressed period, within a few hundred thousand years. This is extremely short in the geological time scale and suggests some sort of catastrophic event caused the mass extinction.

Dinosaurs and other reptiles dominated the Mesozoic era

The **Mesozoic era** began about 251 mya and lasted some 186 million years. It is divided into the Triassic, Jurassic, and Cretaceous periods. Fossil deposits from the Mesozoic era occur world-

No. GEO85638c, Field Museum of Natural History, Chicago

wide. Notable sites include the **Yixian formation** in northeastern China, the Solnhofen Limestone in Germany, northwestern Patagonia in Argentina, the Sahara Desert in central Niger, the badlands in South Dakota, and other sites in western North America.

The outstanding feature of the Mesozoic era was the origin, differentiation, and ultimately the extinction of a large variety of reptiles. For this reason, the Mesozoic era is commonly called the Age of Reptiles. Most of the modern orders of insects appeared during the Mesozoic era. Snails and bivalves (clams and their relatives) increased in number and diversity, and sea urchins reached their peak diversity. From a botanical viewpoint, the Mesozoic era was dominated by gymnosperms until the mid-Cretaceous period, when the flowering plants first diversified.

During the **Triassic period,** reptiles underwent an adaptive radiation leading to many groups. On land, the dominant Triassic groups were the mammal-like therapsids, which ranged from small-sized insectivores (insect-eating reptiles) to moderately large herbivores (plant-eating mammals), and a diverse group of *thecodonts,* early "ruling reptiles," that were primarily carnivores (Fig. 20-12a). The thecodont group was ancestral to dinosaurs, flying reptiles, and birds.

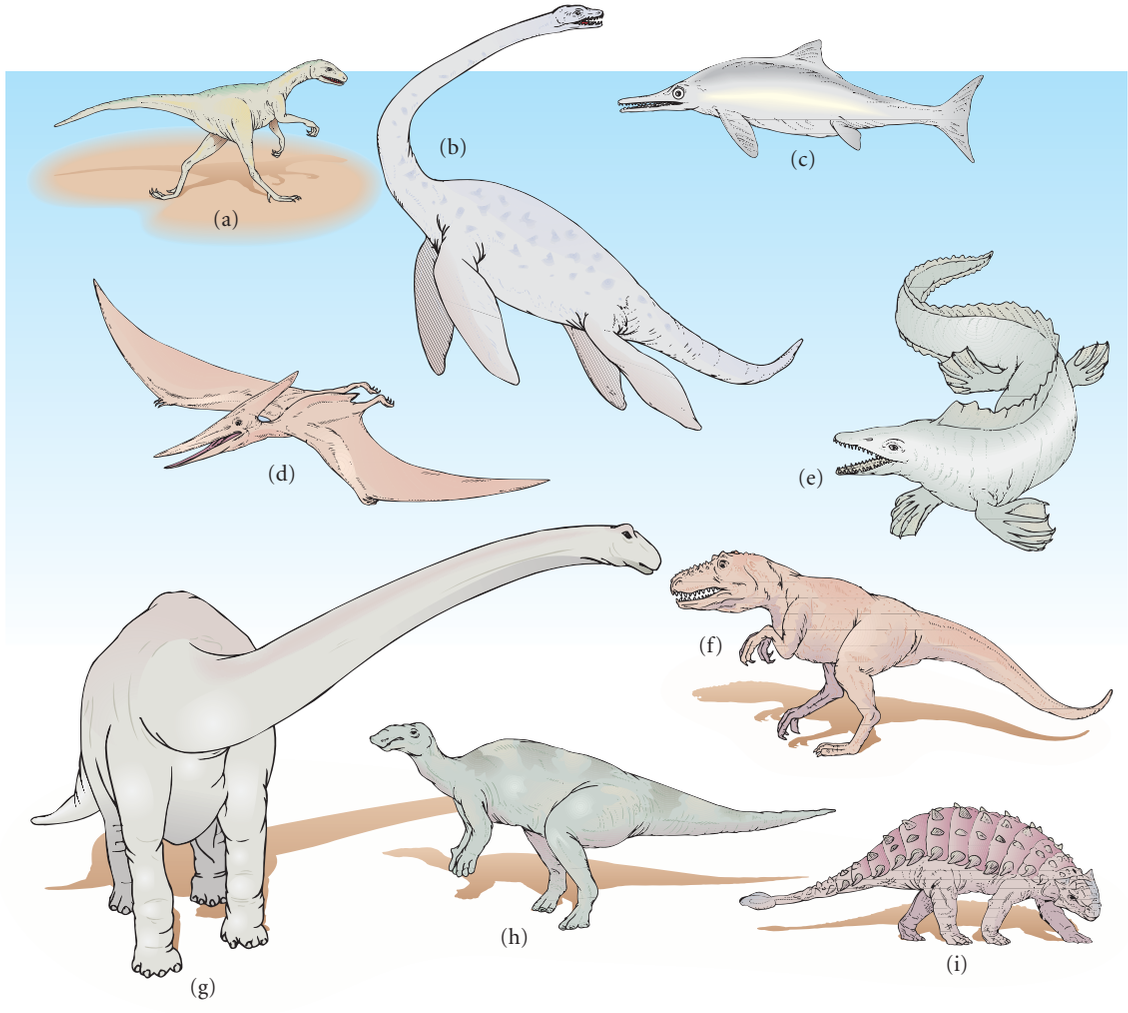

FIGURE **20-12** **Representative animals of the Mesozoic era.**

Figures are not drawn to scale. **(a)** This Triassic thecodont, *Euparkia,* was about 150 cm (5 ft) long. **(b)** *Elasmosaurus* was a long-necked plesiosaur. Other plesiosaurs had short necks and superficially resembled seals. **(c)** *Opthalmosaurus* was an ichthyosaur that superficially resembled a shark or porpoise. It was about 3.6 m (12 ft) long. **(d)** *Pteranodon* was a pterosaur from the Cretaceous period with a wingspan of 7 to 9.2 m (23–30 ft), depending on the species. Pterosaur wings were membranes of skin that were supported by an elongated fourth finger bone. **(e)** *Tylosaurus* was a large (about 10 m [33 ft] long) marine lizard (a mosasaur). **(f)** *Giganotosaurus,* whose fossil remains were discovered in Argentina, was the largest (more than 12 m [39 ft] in length) predatory saurischian. **(g)** *Argentinosaurus,* a herbivorous saurischian from Argentina, is the largest known animal to have ever walked on land. **(h)** *Hadrosaurus* was a duck-billed, plant-eating ornithischian. It was 7 to 10 m (23–33 ft) long and had hundreds of cheek teeth (its bill was toothless). **(i)** *Ankylosaurus* was a heavily armored ornithischian. Ankylosaurs were 2 to 6 m (7–20 ft) in length.

In the ocean, several important marine reptile groups, the plesiosaurs and ichthyosaurs, appeared in the Triassic. *Plesiosaurs* were aquatic reptiles with bodies up to 15 m (about 49 ft) long and paddle-like fins (Fig. 20-12b). *Ichthyosaurs,* also aquatic reptiles, had body forms superficially resembling those of sharks or porpoises, with short necks, large dorsal fins, and shark-type tails (Fig. 20-12c). Ichthyosaurs had very large eyes, which may have helped them see at diving depths of 500 m or more.

Pterosaurs, the first flying reptiles, appeared and underwent considerable diversification during the Mesozoic era (Fig. 20-12d). This group produced some quite spectacular forms, most notably the giant *Quetzalcoatlus,* known from fragmentary Cretaceous fossils in Texas to have had a wingspan of 11 to 15 m (36 to 49 ft).

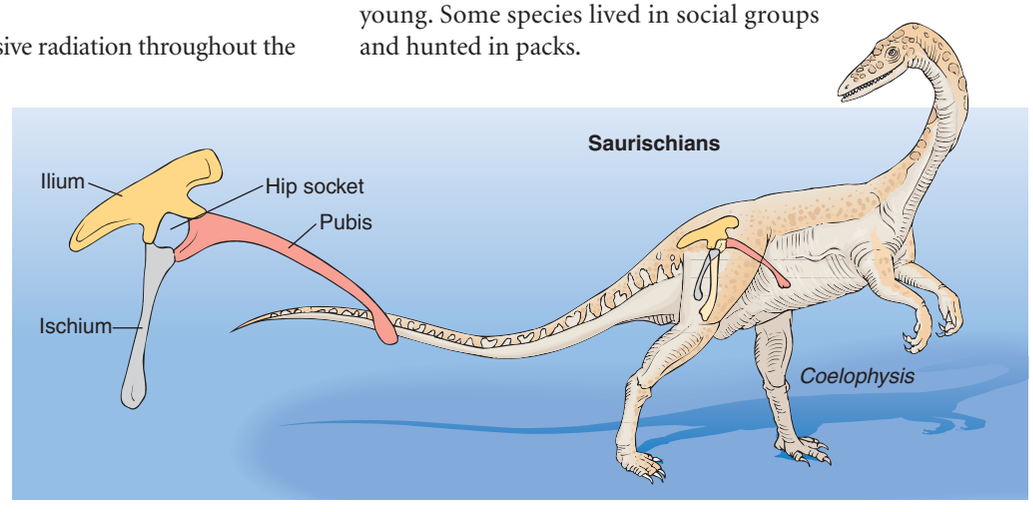
The first mammals to appear in the Triassic period were small insectivores that evolved from the mammal-like therapsids of the Triassic. Mammals diversified into a variety of mostly small, nocturnal insectivores during the remainder of the Mesozoic, with marsupial and placental mammals appearing later in the Mesozoic era.

During the **Jurassic** and **Cretaceous periods,** other important groups—such as crocodiles, lizards, snakes, and birds—appeared, and the dinosaurs diversified dramatically to "inherit the Earth." One group of lizards, the *mosasaurs,* were large, voracious marine predators during the late Cretaceous period (Fig. 20-12e). The mosasaurs, which are now extinct, attained lengths of 10 m (33 ft) or more.

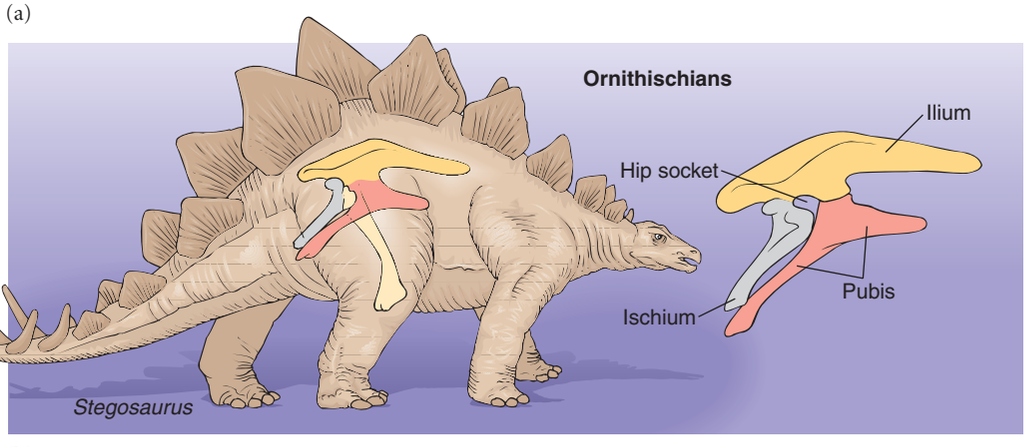
Dinosaurs underwent an impressive radiation throughout the Jurassic and Cretaceous periods. There were two main groups of dinosaurs: the *saurischians,* with pelvic bones similar to those of modern-day lizards, and the *ornithischians,* with pelvic bones similar to those of birds (Fig. 20-13). Some saurischians were fast, bipedal (walking on two feet) forms ranging from those the size of a dog to the ultimate representatives of this group, the gigantic carnivores of the Cretaceous period, *Tyrannosaurus, Giganotosaurus,* and *Carcharodontosaurus* (Figs. 20-12f and 20-14). Other saurischians were huge, quadrupedal (walking on four feet) dinosaurs that ate plants. Some of these were the largest terrestrial animals that have ever lived, including *Argentinosaurus,* with an estimated length of 30 m (98 ft) and an estimated weight of 72 to 90 metric tons (80 to 100 tons) (Fig. 20-12g).

The other group of dinosaurs, the ornithischians, was entirely herbivorous. Although some ornithischians were bipedal, most were quadrupedal. Some had no front teeth and possessed stout, horny, birdlike beaks. In some species these beaks were broad and ducklike, hence the common name, *duck-billed dinosaurs* (Fig. 20-12h). Other ornithischians had great armor plates, possibly as protection against carnivorous saurischians. *Ankylosaurus* had a broad, flat body covered with armor plates (actually bony scales embedded in the skin) and large, laterally projecting spikes (Fig. 20-12i).

Over the past few decades scientists have reconsidered many traditional ideas about dinosaurs and no longer think they were all cold-blooded, slow-moving monsters living in swamps. Recent evidence suggests that at least some dinosaurs were warm-blooded, agile, and able to move extremely fast. Many dinosaurs appear to have had complex social behaviors, including courtship rituals and parental nurturing of their young. Some species lived in social groups and hunted in packs.



(a)



(b)

FIGURE **20-13**

Saurischian and ornithischian dinosaurs.

The two orders of dinosaurs are distinguished primarily by differences in their pelvic bones. (In each dinosaur figure, the pale yellow femur is shown relative to the pelvic bone.) **(a)** The saurischian pelvis. Note the opening (hip socket), a trait possessed by no quadrupedal vertebrates other than dinosaurs. **(b)** The ornithischian pelvis also has the hole in the hip socket but differs from the saurischian pelvis in that it has a backward-directed extension of the pubis.

Birds appeared by the late Jurassic period, and most paleontologists think they evolved directly from dinosaurs (see *On the Cutting Edge: The Origin of Flight in Birds*). Excellent bird fossils, many showing the outlines of feathers, are preserved from the Jurassic period. *Archaeopteryx,* the oldest known bird in the fossil record, lived about 150 mya (see Fig. 30-19b). It was about the size of a pigeon and had rather feeble wings that it used to glide rather than actively fly. Although *Archaeopteryx* is considered a bird, it had many reptilian features, including a mouthful of teeth and a long, bony tail. Thousands of well-preserved bird fossils have been found in early Cretaceous deposits in China. These include *Sinornis,* a 135-million-year-old sparrow-sized bird capable of perching, and the magpie-sized *Confuciusornis,* the earliest known bird with a toothless beak. *Confuciusornis* may date back as far as 142 million years.

At the end of the Cretaceous period, 65 mya, dinosaurs, pterosaurs, and many other animals abruptly became extinct (see Fig. 19-17). Many gymnosperms, with the exception of conifers, also perished. Evidence suggests that a catastrophic collision of a large extraterrestrial body with Earth dramatically changed the climate at the end of the Cretaceous period. Part of the evidence is a thin band of dark clay, with a high concentration of iridium, located between Mesozoic and Cenozoic sediments at more than 200 sites around the world. Iridium is rare on Earth but abundant in meteorites, leading many to conclude that Earth was hit by a large extraterrestrial object at that time. (The force of the impact would have driven the iridium into the atmosphere, to be deposited later on the land by precipitation.) The Chicxulub crater, buried under the Yucatan Peninsula in Mexico, is the apparent site of the collision at the close of the Cretaceous period. The impact produced giant tsunamis (tidal waves) that deposited materials from the extraterrestrial body around the perimeter of the Gulf of Mexico, from Alabama to Guatemala. It may have caused global forest fires and giant smoke and dust clouds that lowered temperatures for many years.

Although scientists widely accept that a collision with an extraterrestrial body occurred 65 mya, they have reached no consensus about the effects of such an impact on organisms. The extinction of many marine organisms at or immediately after the time of the impact was probably the result of the environmental upheaval that the collision produced. However, many clam species associated with the mass extinction at the end of the Cretaceous period seem to have gone extinct *before* the impact, suggesting that other factors caused some of the massive extinctions occurring then.

The Cenozoic era is the Age of Mammals

With equal justice the **Cenozoic era** could be called the Age of Mammals, the Age of Birds, the Age of Insects, or the Age of Flowering Plants. This era is marked by the appearance of all these forms in great variety and numbers of species. The Cenozoic era extends from 65 mya to the present. It is subdivided into two periods: the **Tertiary period,** encompassing some 63 million years, and the **Quaternary period,** which covers the last 2 million years. The Tertiary period is subdivided into five epochs, named from earliest to latest: Paleocene, Eocene, Oligocene, Miocene, and Pliocene. The Quaternary period is subdivided into the Pleistocene and Holocene epochs.

Flowering plants, which arose during the Cretaceous period, continued to diversify during the Cenozoic era. During the Paleocene and Eocene epochs, fossils indicate that plant communities ranging from tropical to semitropical extended to relatively high latitudes. Palms, for example, are found in Eocene deposits in Wyoming. Later in the Cenozoic era, there is evidence of more open habitats. Grasslands and savannas spread throughout much of North America during the Miocene epoch, with deserts developing later in the Pliocene and Pleistocene epochs. During the Pleistocene epoch, plant communities changed dynamically in response to the fluctuating climates associated with the multiple advances and retreats of continental glaciers.

During the Eocene epoch, there was an explosive radiation of birds, which acquired adaptations for many different habitats. The jaws and beak of the flightless giant bird *Diatryma,* for example, may have been adapted primarily for crushing and slicing vegetation in Eocene forests, marshes, and grasslands (Fig. 20-15). Other paleontologists hypothesize that these giant birds were carnivores that killed or scavenged mammals and other vertebrates.

During the Paleocene epoch, an explosive radiation of primitive mammals occurred. Most of these were small forest dwellers that are not closely related to modern mammals. During the Eocene epoch, mammals continued to diverge, and all the modern orders first appeared. Again, many of the mammals were small, but there were also some larger herbivores—the *titanotheres,* for example, which got progressively larger during the Eocene epoch (Fig. 20-16a).

During the Oligocene epoch, many modern families of mammals appeared, including the first apes in Africa. Many lineages showed adaptations that suggest a more open type of habitat, such as grassland or savanna. Many mammals were

PROCESS OF SCIENCE

Hypothesis: Bird flight originated in ancestral animals that lived in trees and glided from treetops.

Method: Evaluate recently discovered fossils of the feathered dinosaur, *Microraptor gui*.

Results: *Microraptor gui* was a small, lightweight dinosaur with feathers on its forelimbs, hindlimbs, and tail. The hindlimb feathers would have made it difficult for *Microraptor* to run on the ground to power flight.

Conclusion: *Microraptor gui* is a significant fossil find that supports the hypothesis that early birds flew by gliding from the treetops.

The evolution of birds is arguably one of the most interesting chapters in Earth's history of life. Given the substantial fossil evidence, most paleontologists have concluded the ancestors of birds were dinosaurs, specifically the *dromaeosaurs,* a group of ground-dwelling, bipedal, carnivorous theropods. Beginning in 1997, paleontologists made several discoveries of fossil dinosaurs with feathers, indicating that feathers appeared before birds. They think that feathers evolved as one or a series of evolutionary novelties, or **preadaptations.** The first feathers may have provided thermal insulation but were subsequently modified for flight (see Chapter 19).

Once dinosaurs and early birds had feathers, how did they fly? Did tree-dwelling animals glide as an intermediate step in bird flight, or did ground-dwelling animals flap their wings and run to provide thrust and lift for a takeoff? The question about how flight originated in birds has intrigued biologists for more than a century. In 1915, for example, American zoologist William Beebe hypothesized that the ancestors of birds were probably tree-dwelling gliders that had feathers on all four limbs.* Because no fossil evidence supported his suggestion, scientists did not consider it seriously at the time.

Almost a century later, in 2003, a group of Chinese paleontologists led by Xing Xu and Zhonghe Zhou of the Institute of Vertebrate Paleontology and Paleoanthropology in Beijing announced the discovery of two nearly complete fossils of the organism that Beebe had hypothesized.† The fossils of a small, feathered dramaeosaur dinosaur were found in Liaoning Province in northeastern China. The dinosaur, *Microraptor gui,* had feathers on both forelimbs and hindlimbs as well as its long tail (see figure). It was small—77 cm in length, including the tail—and appeared to be adapted to life in the trees.

The feathers on *M. gui* were very similar to those of modern-day birds. Downy feathers covered the body, and each limb had about 12 "primary" flight feathers and about 18 shorter, "secondary" feathers. *M. gui*'s flight feathers were asymmetrical, a characteristic associated with flight or gliding in modern birds. The primary and secondary feathers followed a similar pattern on both the forelimbs and hindlimbs, and this pattern resembles that on modern birds. In part because *M. gui's* breastbone was not structured to attach large flight muscles, Xu, Zhou, and colleagues hypothesize that *M. gui* glided rather than flapped its wings. They suggest that stretching out the feathered forelimbs and hindlimbs would make a perfect airfoil for gliding, somewhat like the stretched web of skin in flying squirrels today. However, the flight question may not be resolved until functional anatomists and paleontologists make detailed studies of *M. gui.* Analysis of the shoulder and wing anatomy may clarify whether *M. gui* could power flight or merely glide. Study of the hips may resolve if *M. gui* could rotate its legs to glide.

M. gui, which is about 126 million years old, is not a direct ancestor of birds. Birds had already evolved when *M. gui* existed. The earliest known bird, *Archaeopteryx,* lived about 145 million years ago and therefore predates *M. gui* by about 20 million years. *M. gui* is considered a *basal member*—that is, an earlier evolutionary branch—of the most recent ancestor of *Archaeopteryx* and other birds. Xu and Zhou hypothesize that like *M. gui,* earlier feathered dinosaurs were four-winged organisms that lived and glided in the trees. They suggest that, during the course of bird evolution, the feathered hindlimbs became reduced and eventually lost.

However, an alternative hypothesis is that feathered hindlimbs may have been a failed evolutionary experiment restricted to dromaeosaurs and not important as an intermediate step in bird evolution. Further analysis of *M. gui* and future discoveries of older dromaeosaur fossils may shed some light on the importance of feathered hindlimbs.

Clearly, *M. gui* is a significant discovery that has given paleontologists and biologists much to consider in the evolutionary transition from dinosaurs to birds. Conflicting explanations are at the heart of the scientific process because they stimulate additional research that leads to a clearer picture. However, science rarely, if ever, deals in absolutes. Biologists will continue to study and debate the evolution of flight in birds for many years.

larger and had longer legs for running, specialized teeth for chewing coarse vegetation or for preying on animals, and increases in their relative brain sizes. Such adaptations continued to evolve in the Miocene and Pliocene epochs. Human ancestors appeared in Africa during the late Miocene and early Pliocene epochs. The genus *Homo* appeared approximately 2.3 mya. (Primate evolution, including human evolution, is discussed in Chapter 21.)

The Pliocene and Pleistocene epochs witnessed a spectacular North and South American large-mammal fauna, including mastodons, saber-toothed cats, camels, giant ground sloths, giant armadillos, and many other species (Fig. 20-16b–f). However, many of the large mammals became extinct at the end of the Pleistocene. This extinction was possibly due to climate change—the Pleistocene epoch was marked by several ice ages—and/or to the influence of humans, which had spread from Africa to Europe and Asia, and later to North and South America by crossing a land bridge between Siberia and Alaska. Strong archaeological evidence shows that this mass extinction event was concurrent with the appearance of human hunters.

Figures are not drawn to scale. **(a)** *Brontotherium*, a titanothere, was 2.5 m (8 ft) tall at the shoulder. **(b)** The elephant-like mastodon (*Mammut*) was at home in forests, lakes, and rivers. *Mammut* was 2.5 m (8 ft) tall at the shoulder. **(c)** The saber-toothed cat (*Smilodon*), which had short, powerful legs and was about the size of the modern African lion, was found in both North and South America. **(d)** This camel-like mammal (*Macrauchenia*), which was about 3 m (10 ft) tall, probably browsed in forest clearings in South America. **(e)** *Megatherium* was a South American giant ground sloth. As long as 6 m (20 ft), *Megatherium* had 18-cm (7-in) claws that may have stripped bark from trees or stabbed prey. **(f)** The giant armadillo (*Glyptodon*) lived on the pampas of South America. Encased in bony armor, *Glyptodon* was about 2 m (6.5 ft) long.

SUMMARY WITH KEY TERMS

1 Describe the conditions that geologists think existed on early Earth.

- Biologists generally agree that life originated from nonliving matter by **chemical evolution.** Although chemical evolution is very difficult to test experimentally, hypotheses about the origin of life are testable.
- Four requirements for chemical evolution are (1) the absence of oxygen, which would have reacted with and oxidized abiotically produced organic molecules; (2) energy to form organic molecules; (3) chemical building blocks, including water, minerals, and gases present in the atmosphere, to form organic molecules; and (4) sufficient time for molecules to accumulate and react.

2 Contrast the prebiotic soup hypothesis and the iron-sulfur world hypothesis.

- During chemical evolution, small organic molecules formed spontaneously and accumulated.
- The **prebiotic soup hypothesis** proposes that organic molecules formed near Earth's surface in a "sea of organic soup" or on rock or clay surfaces.
- The **iron-sulfur world hypothesis** suggests that organic molecules were produced at **hydrothermal vents,** cracks in the deep ocean floor.

3 Outline the major steps hypothesized to have occurred in the origin of cells.

- After small organic molecules formed and accumulated, macromolecules assembled from the small organic molecules. Macromolecular assemblages called **protobionts** formed from macromolecules. Cells arose from the macromolecular assemblages.
- According to a model known as the **RNA world,** RNA was the first informational molecule to evolve in the progression toward a self-sustaining, self-reproducing cell. Natural selection at the molecular level resulted in the information sequence: DNA ⟶ RNA ⟶ protein.

4 Explain how the evolution of photosynthetic autotrophs affected both the atmosphere and other organisms.

- The first cells were prokaryotic **heterotrophs** that obtained organic molecules from the environment. They were almost certainly **anaerobes.** Later, **autotrophs,** arose—organisms that produce their own organic molecules by photosynthesis.
- The evolution of photosynthesis ultimately changed early life because it generated oxygen, which accumulated in the atmosphere, and permitted the evolution of **aerobes,** organisms that could use oxygen for a more efficient type of cellular respiration.

5 Describe the endosymbiont theory.

- Eukaryotic cells arose from prokaryotic cells. According to the **endosymbiont theory,** certain eukaryotic organelles (mitochondria and chloroplasts) evolved from prokaryotic **endosymbionts** within larger prokaryotic hosts.

6 List the geological eras in chronological order, and give approximate dates for each.

- The Paleozoic era began about 543 mya and ended 251 mya.
- The Mesozoic era began about 251 mya and ended 65 mya.
- The Cenozoic era began about 65 mya and extends to the present.

7 Briefly describe the distinguishing organisms and major biological events of Precambrian time and of the Paleozoic, Mesozoic, and Cenozoic eras.

- During **Precambrian time,** which extended from approximately 3.8 bya up to 543 mya, life began and diverged into different groups of bacteria, protists (including algae), fungi, and simple multicellular animals.
- During the **Paleozoic era,** which lasted approximately 292 million years, all major groups of plants, except for flowering plants, and all animal phyla appeared. Fish and amphibians flourished, and reptiles appeared and diversified. The greatest mass extinction of all time occurred at the end of the Paleozoic era, 251 mya. More than 90% of all existing marine species and more than 70% of land-dwelling vertebrate genera became extinct, as well as many plant species.
- The **Mesozoic era** lasted some 186 million years. During the Mesozoic era, flowering plants appeared and reptiles diversified. Dinosaurs, which descended from early reptiles, dominated. Insects flourished, and birds and early mammals appeared. At the end of the Cretaceous period, 65 mya, a great many animals abruptly became extinct. A collision of Earth with a large extraterrestrial body may have resulted in dramatic climate changes that played a role in this mass extinction episode.
- In the **Cenozoic era,** which extends from 65 mya to the present, flowering plants, birds, insects, and mammals diversified greatly.

POST-TEST

1. Energy, the absence of oxygen, chemical building blocks, and time were the requirements for (a) chemical evolution (b) biological evolution (c) the Cambrian explosion (d) the mass extinction episode at the end of the Cretaceous period (e) directed evolution
2. Protobionts (a) form spontaneously in hydrothermal vents in the ocean floor (b) are heterotrophs that obtain the organic molecules they need from the environment (c) are assemblages of abiotically produced organic polymers that resemble living cells in several ways (d) are autotrophs that use sunlight to split hydrogen sulfide (e) are fossilized mats of cyanobacteria
3. Many scientists think that _____ was the first information molecule to evolve. (a) DNA (b) RNA (c) a protein (d) an amino acid (e) a lipid
4. The first cells were probably (a) heterotrophs (b) autotrophs (c) anaerobes (d) both a and c (e) both b and c
5. According to the endosymbiont theory, (a) life originated from nonliving matter (b) the pace of evolution quickened at the start of the Cambrian period (c) chloroplasts, mitochondria, and possibly other organelles originated from intimate relationships among prokaryotic organisms (d) banded iron formations reflect the buildup of sufficient oxygen in the atmosphere to oxidize iron at

POST-TEST *(continued)*

Earth's surface (e) the first photosynthetic organisms appeared 3.1 to 3.5 bya

6. Geological time from the first traces of life to the beginning of the Paleozoic era some 543 mya is informally known as (a) the Cenozoic era (b) the Paleozoic era (c) the Mesozoic era (d) Precambrian time (e) the Cambrian period
7. Geologists divide Earth's history, from Precambrian time to the present, into (a) three periods (b) three epochs (c) three eras (d) five periods (e) five eras
8. Ediacaran fossils (a) are the oldest known fossils of multicellular animals (b) come from the Burgess Shale in British Columbia (c) contain remains of large salamander-like organisms (d) are the oldest fossils of early vascular plants (e) contain a high concentration of iridium
9. The correct chronological order of geological eras, starting with the oldest, is (a) Paleozoic, Cenozoic, and Mesozoic (b) Mesozoic, Cenozoic, and Paleozoic (c) Mesozoic, Paleozoic, and Cenozoic (d) Paleozoic, Mesozoic, and Cenozoic (e) Cenozoic, Paleozoic, and Mesozoic
10. The time of greatest evolutionary diversification in the history of life occurred during the (a) Cambrian period (b) Ordovician period (c) Silurian period (d) Carboniferous period (e) Permian period
11. The greatest mass extinction episode in the history of life occurred at what boundary? (a) Pliocene–Pleistocene (b) Permian–Triassic (c) Mesozoic–Cenozoic (d) Cambrian–Ordovician (e) Triassic–Jurassic
12. The Mesozoic era is divided into three periods, which are (a) Cambrian, Ordovician, and Silurian (b) Devonian, Carboniferous, and Permian (c) Triassic, Jurassic, and Cretaceous (d) Cretaceous, Tertiary, and Quaternary (e) Pliocene, Pleistocene, and Holocene
13. The Age of Reptiles corresponds to the (a) Paleozoic era (b) Mesozoic era (c) Cenozoic era (d) Pleistocene epoch (e) Permian period
14. Evidence exists that a catastrophic collision between Earth and a large extraterrestrial body occurred 65 mya, resulting in the extinction of (a) Precambrian worms, mollusks, and soft-bodied arthropods (b) jawless ostracoderms and jawed placoderms (c) dinosaurs, pterosaurs, and many gymnosperm species (d) mastodons, saber-toothed cats, and giant ground sloths (e) ferns, horsetails, and club mosses
15. Flowering plants and mammals diversified and became dominant during the (a) Paleozoic era (b) Mesozoic era (c) Cenozoic era (d) Devonian period (e) Cambrian period

CRITICAL THINKING

1. If you were experimenting on how protobionts evolved into cells and you developed a protobiont that was capable of self-replication, would you consider it a living cell? Why or why not?
2. If living cells were created in a test tube from nonbiological components by chemical processes, would this accomplishment prove that life evolved in a similar manner billions of years ago? Why or why not?
3. Why did the evolution of multicellular organisms such as plants and animals have to be preceded by the evolution of oxygen-producing photosynthesis?

The Evolution of Primates

John Reader/Science Photo Library/Photo Researchers, Inc.

Fossilized remains of a Neandertal man. Each of these fossils, which were found in La Chapelle-aux-Saints, France, has been carefully catalogued and studied. Some of the bones are deformed by osteoarthritis.

CHAPTER OUTLINE

- Primate Adaptations
- Primate Classification
- Hominid Evolution
- Cultural Evolution

Twelve years after Darwin wrote *The Origin of Species by Natural Selection,* he published another controversial book, *The Descent of Man,* which addressed human evolution. In it, Darwin hypothesized that humans and apes share a common ancestry. For nearly a century after Darwin, fossil evidence of human ancestry remained fairly incomplete. However, research over the last several decades, especially in Africa, has yielded a rapidly accumulating set of fossils that gives an increasingly clear answer to the question "Where did we come from?"

Humans and other **primates,** such as lemurs, tarsiers, monkeys, and apes, are mammals that share such traits as flexible hands and feet with five digits, a strong social organization, and front-facing eyes, which permit depth perception. Mammals (class Mammalia) arose from mammal-like reptiles known as *therapsids* more than 200 million years ago (mya), during the Mesozoic era (see Fig. 30-21). These early mammals remained a minor component of life on Earth for almost 150 million years and then rapidly diversified during the Cenozoic era (the last 65 million years). Mammals are **endothermic** (they use metabolic energy to maintain a constant body temperature); produce body hair for such functions as insulation, protective coloration, and waterproofing; and feed their young with milk from mammary glands. Most mammals are **viviparous,** which means that their fertilized eggs develop into young offspring within the female body.

Scientists hypothesize that the three groups of living mammals—the monotremes, marsupials, and placental mammals—all are descended from the same common ancestor. The **monotremes** are mammals, such as the duck-billed platypus, that lay eggs (see Chapter 30). The **marsupials,** such as kangaroos and opossums, give birth to their young in a very underdeveloped condition, and then carry them in an abdominal pouch. **Placental mammals,** the largest and most successful group, possess a **placenta,** an organ that exchanges materials between the mother and the embryo/fetus developing in the uterus. When placental mammals give birth, their young are more developed than the newborn young of marsupials.

Paleontologists hypothesize that the first primates descended from small, shrewlike placental mammals that lived in trees and ate insects. These early primates appeared about 55 mya. Many traits of the 233 living primate species are related to their **arboreal** (tree-dwelling) past. This chapter focuses on humans and their ancestors (see photograph), who differ from most other primates because they did not remain in the trees but instead adapted to a terrestrial way of life.

Fossil evidence has allowed **paleoanthropologists,** scientists who study human evolution, to infer not only the structure but also the habits of early humans and other primates. Teeth and bones are the main fossil evidence studied by paleoanthropologists. Much information can be obtained by studying teeth, which have changed dramatically during the course of primate and human evolution. Because tooth enamel is more mineralized (harder) than bone, teeth are more likely to fossilize. The teeth of each primate species, living or extinct, are distinctive enough to identify the species, approximate age, diet, and even sex of the individual. Consider *Australopithecus robustus,* which lived in southern Africa about 2 mya, at a time when the climate was becoming more arid and the forests were giving way to grasslands. Its large jaws and molars (broad-ridged teeth in the back of the mouths of adult mammals) indicate its diet included tough foods such as roots, tubers, and seeds. ■

PRIMATE ADAPTATIONS

Learning Objective

1 Describe the structural adaptations that primates have for life in treetops.

Fossil evidence indicates that the first primates with traits characteristic of modern primates appeared by the early Eocene epoch about 55 mya. These early primates had digits with nails, and their eyes were directed somewhat forward on the head. The climate was mild then, and early primates were widely distributed over much of North America, Europe, and Asia. (Recall from Chapter 17 that North America was still attached to Europe at that time.) As the climate became cooler and drier toward the end of the Eocene epoch, many of these early primates became extinct.

Several novel adaptations evolved in early primates that allowed them to live in trees. One of the most significant primate features is that they have five highly flexible digits: four lateral digits (fingers) plus a partially or fully opposable first digit (thumb and, in many primates, big toe; Fig. 21-1). An **opposable thumb** positions the fingers opposite the thumb, enabling primates to grasp objects such as tree branches with precision. Nails (instead of claws) provide a protective covering for the tips of the digits, and the fleshy pads at the ends of the digits are sensitive to touch. Another arboreal feature is long, slender limbs that rotate freely at the hips and shoulders, giving primates full mobility to climb and search for food in the treetops.

Having eyes located in the front of the head lets primates integrate visual information from both eyes simultaneously; they have *stereoscopic* (three-dimensional) vision. Stereoscopic vision is vital in an arboreal environment, especially for species that leap from branch to branch, because an error in depth perception may cause a fatal fall. In addition to sharp sight, primates hear acutely.

Primates share several other characteristics, including a relatively large brain size. Biologists have suggested that the increased sensory input associated with their sharp vision and greater agility favored the evolution of larger brains. Primates are generally very social and intelligent animals that reach sexual maturity relatively late in life. They typically have long life spans. Females usually bear one offspring at a time; the baby is helpless and requires a long period of nurturing and protection.

Review

- How are primate hands and feet adapted to an arboreal existence?
- Why is the location of primate eyes in front of the head an important adaptation for an arboreal existence?

BiologyNow™ Assess your understanding of **primate adaptations** by taking the pretest on your BiologyNow CD-ROM.

PRIMATE CLASSIFICATION

Learning Objectives

2 List the three suborders of primates, and give representative examples of each.

3 Distinguish among anthropoids, hominoids, and hominids.

4 Describe skeletal and skull differences between apes and hominids.

Now that we have surveyed the general characteristics of primates, let's look at how they are classified. Many biologists currently divide the order Primates into three groups, or suborders (Fig. 21-2). The suborder Prosimii includes lemurs, galagos, and lorises, the suborder Tarsiiformes includes tarsiers, and the suborder Anthropoidea includes **anthropoids** (monkeys, apes, and humans).

All lemurs are restricted to the island of Madagascar off the coast of Africa. Because of extensive habitat destruction and hunting, they are very endangered. Lorises, which live in tropical areas of Southeast Asia and Africa, resemble lemurs in many respects, as do galagos, which live in sub-Saharan Africa. Lemurs, lorises, and galagos have retained several early mammalian features, such as elongated, pointed faces.

Tarsiers are found in rain forests of Indonesia and the Philippines (Fig. 21-3). They are small primates (about the size of a small rat) and are very adept leapers. These nocturnal primates resemble anthropoids in a number of ways, including their shortened snouts and forward-pointing eyes.

Suborder Anthropoidea includes monkeys, apes, and humans

Anthropoid primates arose during the middle Eocene epoch, at least 45 mya. Several different fossil anthropoids have been identified, from Asia and North Africa, and there is a growing consensus about the relationships of these fossil groups to one

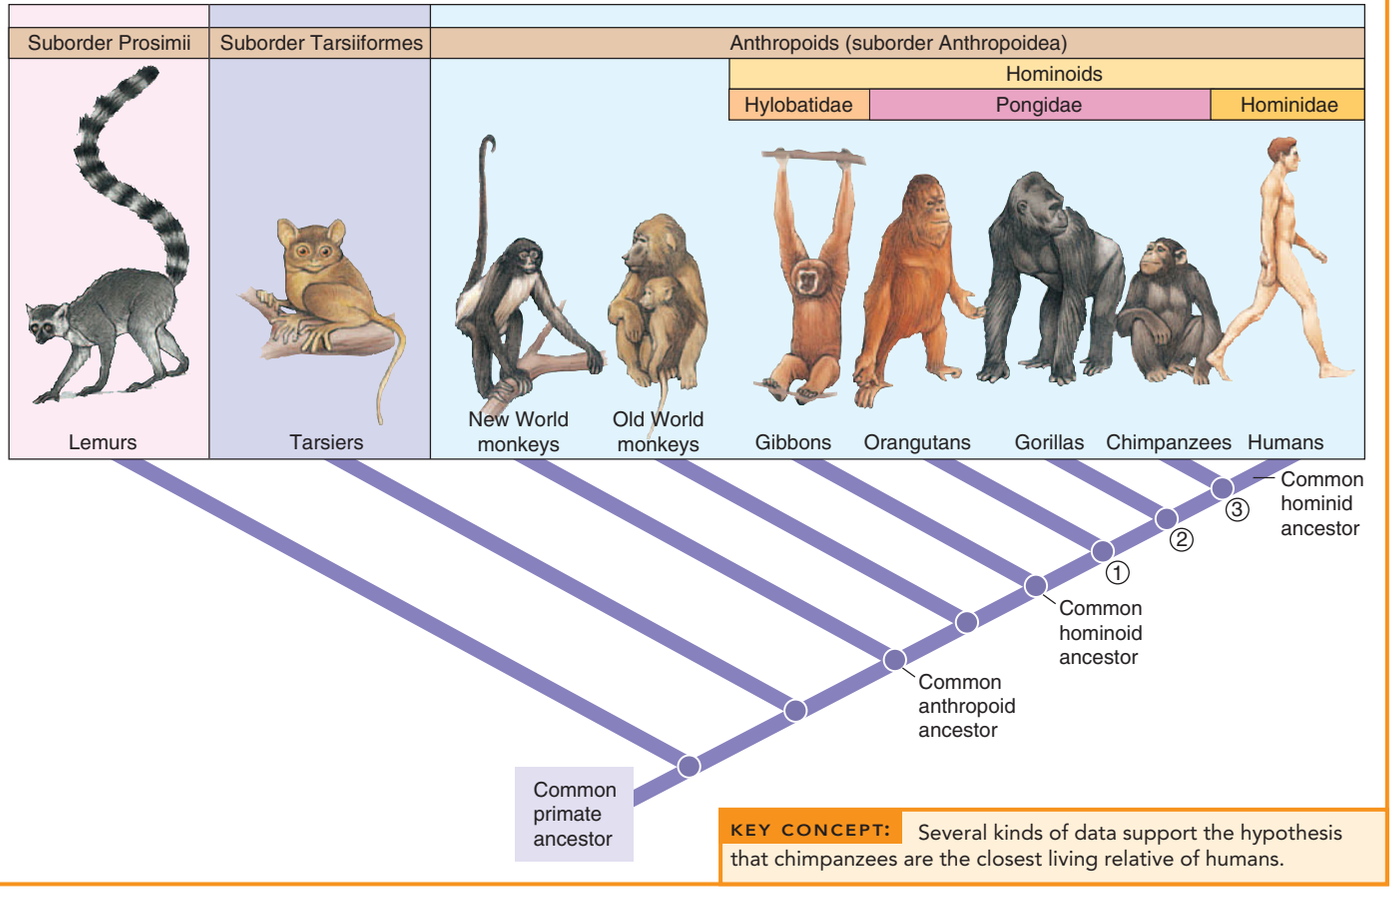

FIGURE **21-2** **Primate evolution.**

This branching diagram, called a cladogram, shows evolutionary relationships among living primates, based on current scientific evidence. The nodes *(circles)* represent branch points where a species splits into two or more lineages. ① The divergence of orangutans from the ape/hominid line occurred some 12 to 16 mya. ② Gorillas separated from the chimpanzee/hominid line an estimated 6 to 8 mya, and ③ the hominid (human) lineage diverged from that of chimpanzees about 4 to 6 mya. *(Figures not drawn to scale.)*

Frans Lanting/Minden Pictures

FIGURE **21-3** **Tarsiers.**

The huge eyes of the tarsier (*Tarsius bancanus*) help it find insects, lizards, and other prey when it hunts at night. When a tarsier sees an insect, it pounces on it and grasps the prey with its hands. Tarsiers live in the rain forests of Indonesia and the Philippines.

another and to living anthropoids. Evidence indicates that anthropoids originated in Africa or Asia. The oldest known anthropoid fossils, such as 42-million-year-old *Eosimias,* have been found in China and Myanmar. Given details about their dentition and the few bones that have been discovered, scientists infer that *Eosimias* and other ancestral anthropoids were small, insect-eating arboreal primates that were active during the day. Once they arose, anthropoids quickly spread throughout Europe, Asia, and Africa and arrived in South America much later. (Paleoanthropologists date the oldest known South American primate, *Branisella,* from Bolivia, at 26 million years.)

One significant difference between anthropoids and other primates is in the size of their brains. The cerebrum, in particular, is more developed in monkeys, apes, and humans, where it functions as a highly complex center for learning, voluntary movement, and interpretation of sensation.

Monkeys are generally diurnal (active during the day) tree dwellers. They tend to eat fruit and leaves, with nuts, seeds, buds, insects, spiders, birds' eggs, and even small vertebrates playing a smaller part in their diets. The two main groups of monkeys, New World monkeys and Old World monkeys, are named for the hemispheres where they diversified. Monkeys in South and Central America are called New World monkeys, whereas monkeys in Africa, Asia, and Europe are called Old World monkeys. New and Old World monkeys have been evolving separately for tens of millions of years.

One of the most important unanswered questions in anthropoid evolution concerns *how* monkeys arrived in South America. Africa and South America had already drifted apart (see Chapter 17), so the ancestors of New World monkeys may have rafted from Africa to South America on floating masses of vegetation. The South Atlantic Ocean would have been about half as wide as it is today, and islands could have provided "stepping stones." Alternatively, the ancestors of New World monkeys may have dispersed from Asia to North America to South America. Once established in the New World, these monkeys rapidly diversified.

New World monkeys are restricted to Central and South America and include marmosets, capuchins, howler monkeys, squirrel monkeys, and spider monkeys. New World monkeys are arboreal, and some have long, slender limbs that permit easy movement in the trees (Fig. 21-4a). A few have **prehensile tails** capable of wrapping around branches and serving as fifth limbs. Some New World monkeys have shorter thumbs, and in certain

FIGURE **21-4** **New and Old World monkeys.**

(b) The Anubis baboon (*Papio anubis*) is an Old World monkey native to Africa. Note that its nostrils are directed downward.

Image not available due to copyright restrictions

S. Meyers/Okapia/Photo Researchers, Inc.

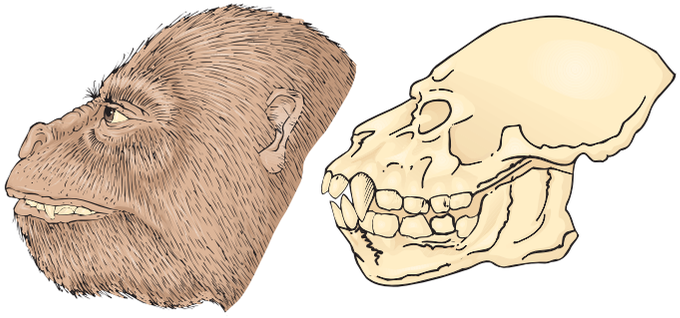
(b)

cases the thumbs are totally absent. Their facial anatomy differs from that of the Old World monkeys; they have flattened noses with the nostrils opening to the side. They live in groups and perform complex social behaviors.

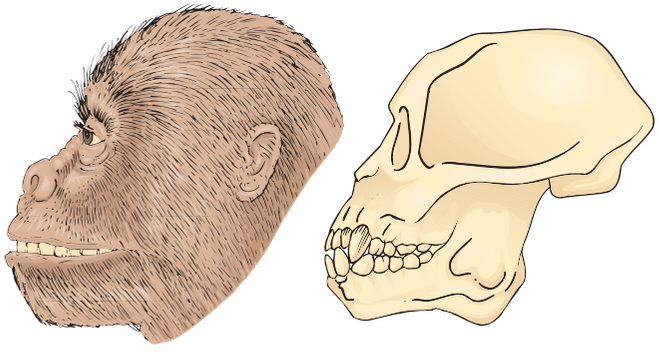
Old World monkeys are distributed in tropical parts of Africa and Asia. In addition to baboons and macaques (pronounced muh-kacks´), the Old World group includes guenons, mangabeys, langurs, and colobus monkeys. Most Old World monkeys are arboreal, although some, such as baboons and macaques, spend much of their time on the ground (Fig. 21-4b). The ground dwellers, which are **quadrupedal** ("four-footed"; they walk on all fours), arose from arboreal monkeys. None of the Old World monkeys has a prehensile tail, and some have extremely short tails. They have a fully opposable thumb, and unlike the New World monkeys, their nostrils are closer together and directed downward. Old World monkeys are intensely social animals.

Many classification schemes place apes and humans in three families

Old World monkeys shared a common ancestor with the **hominoids,** a group composed of apes and **hominids** (humans and their ancestors). A fairly primitive anthropoid, discovered in Egypt, was named *Aegyptopithecus* (Fig. 21-5a). A cat-sized, forest-dwelling arboreal monkey with a few apelike characteristics, *Aegyptopithecus* lived during the Oligocene epoch, approximately 34 mya.



(a) Oligocene anthropoid, *Aegyptopithecus*



(b) Miocene ape, *Dryopithecus*

FIGURE **21-5** ***Aegyptopithecus and Dryopithecus.***

(a) Fossils of *Aegyptopithecus,* a fairly primitive anthropoid, were discovered in Egypt. **(b)** *Dryopithecus,* a more advanced ape, may have given rise to modern hominoids. *(Figures not drawn to scale.)*

During the Miocene epoch, approximately 20 mya, apes and Old World monkeys diverged. Paleoanthropologists discovered the oldest fossils with hominoid features in East Africa, mostly in Kenya. *Proconsul,* for example, appeared early in the Miocene epoch, about 20 mya. It had a larger brain than monkeys, apelike teeth and diet (fruits), but a monkey-like body. At least 30 other early hominoid species lived during the Miocene epoch, but most of them became extinct and were not the common ancestor of modern apes and humans.

Miocene fossils of forest-dwelling, chimpanzee-sized apes called **dryopithecines,** which lived about 15 mya, are of special interest because this hominoid lineage may have given rise to modern apes as well as to the human line (Fig. 21-5b). The dryopithecines, such as *Dryopithecus, Kenyapithecus,* and *Morotopithecus,* were distributed widely across Europe, Africa, and Asia. As the climate gradually cooled and became drier, their range became more limited. These apes had highly modified bodies for swinging through the branches of trees, although there is also evidence that some of them may have left the treetops for the ground as dense forest gradually changed into open woodland. Many questions about the relationships among the various early apes have been generated by the discovery of these and other Miocene hominoids. As future fossil finds are evaluated, they may lead to a rearrangement of ancestors in the hominoid family tree.

Many biologists classify the five genera of hominoids alive today into three families: Gibbons (*Hylobates*) are known as *lesser apes* and are placed in the family Hylobatidae. The family Pongidae includes orangutans (*Pongo*), gorillas (*Gorilla*), and chimpanzees (*Pan*), and the family Hominidae includes humans (*Homo*). Recent molecular evidence indicates a close relationship between humans and the greater apes, particularly chimpanzees, and some scientists now classify them in the same family.

Gibbons are natural acrobats that can **brachiate,** or arm-swing, with their weight supported by one arm at a time (Fig. 21-6a). Orangutans are also tree dwellers, but chimpanzees and especially gorillas have adapted to life on the ground (Fig. 21-6b–d). Gorillas and chimpanzees have retained long arms typical of brachiating primates but use these to assist in quadrupedal walking, sometimes known as **knuckle-walking** because of the way they fold (flex) their digits when moving. Apes, like humans, lack tails. They are generally much larger than monkeys, although gibbons are a notable exception.

Evidence of the close relatedness of orangutans, gorillas, chimps, and humans is abundant at the molecular level. The amino acid sequence of the chimpanzee's hemoglobin is identical to that of the human; hemoglobin molecules of the gorilla and rhesus monkey differ from the human's by 2 and 15 amino acids, respectively. DNA sequence analyses indicate that chimpanzees are likely to be our nearest living relatives among the apes (see Table 17-1). Molecular evidence suggests that orangutans may have diverged from the gorilla, chimpanzee, and hominid lines about 12 to 16 mya. Gorillas may have diverged from the chimpanzee and hominid lines some 6 to 8 mya, whereas chimpanzee and hominid lines probably separated about 4 to 6 mya.

HOMINID EVOLUTION

Learning Objectives

5 Compare the following early hominids: *Sahelanthropus tchadensis, Ardipithecus ramidus, Australopithecus anamensis, Australopithecus afarensis,* and *Australopithecus africanus.*

6 Distinguish among the following members of genus *Homo: Homo habilis, Homo ergaster, Homo erectus, Homo heidelbergensis, Homo neanderthalensis,* and *Homo sapiens.*

7 Discuss the current debate over the origin of modern humans, and briefly describe the opposing out-of-Africa and multiregional hypotheses.

Image not available due to copyright restrictions

PROCESS OF SCIENCE

Scientists have a growing storehouse of hundreds of hominid fossils, which provide useful data about general trends in the body design, appearance, and behavior of ancestral humans. For example, before their brains enlarged early hominids clearly adopted a **bipedal** (two-footed) posture. Despite the wealth of fossil evidence, interpretations of hominid characteristics, taxonomy, and phylogeny continue to be vigorously debated, and new discoveries raise new questions. As in other scientific fields, ideas about hominid evolution are influenced by the different perspectives of the various workers studying it. The lack of scientific consensus regarding certain aspects of hominid evolution is, therefore, an expected part of the scientific process.

Evolutionary changes from the earliest hominids to modern humans are evident in some of the characteristics of the skeleton and skull. Compared with the ape skeleton, the human skeleton shows distinct differences that reflect human's ability to stand erect and walk on two feet (Fig. 21-7). These differences

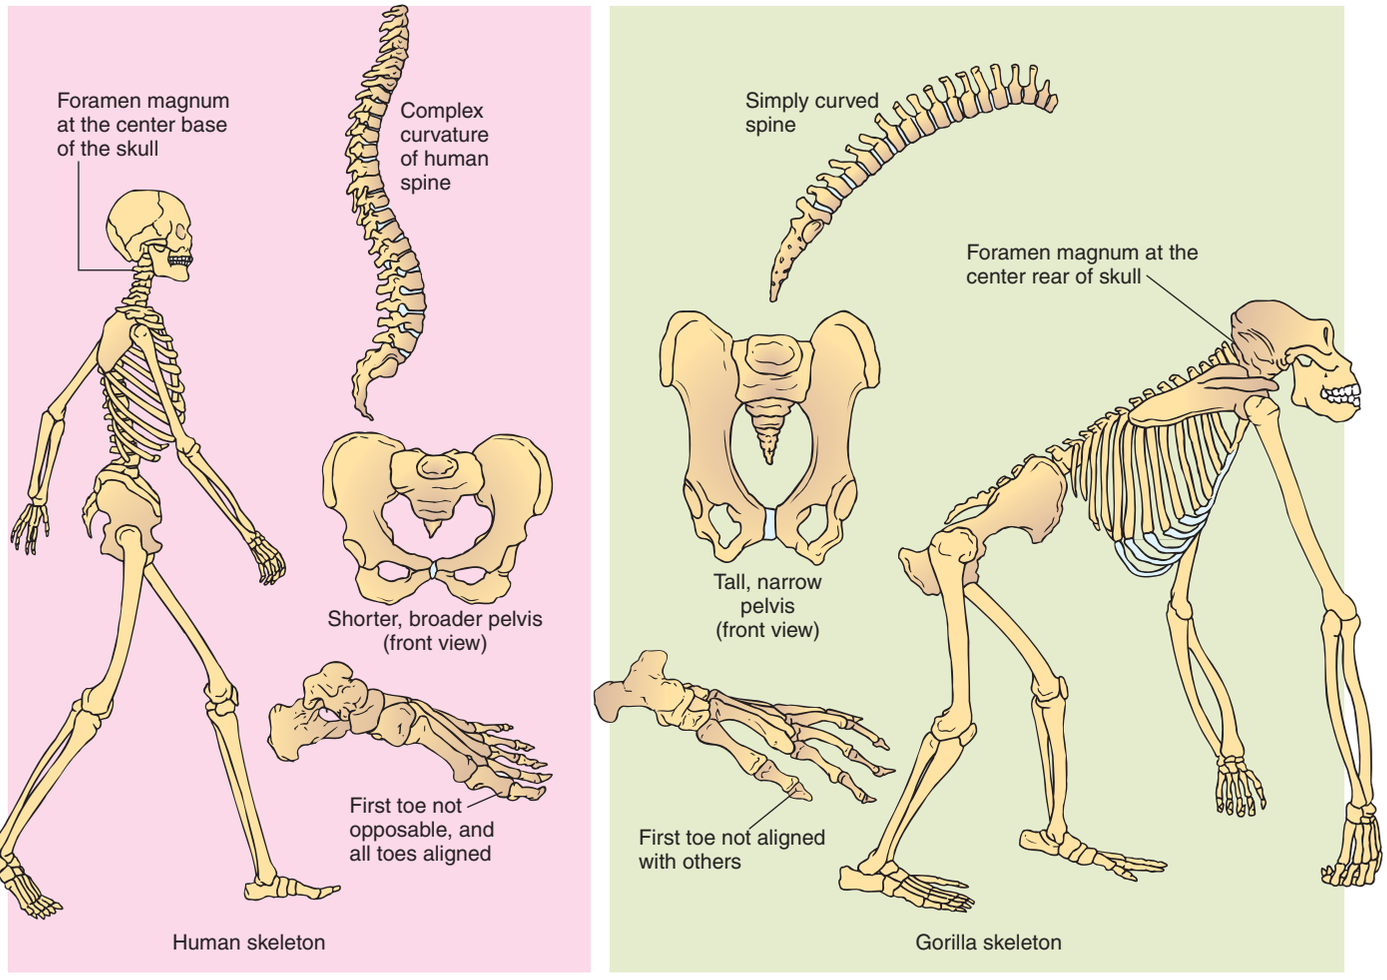

FIGURE **21-7** **Gorilla and human skeletons.**

When gorilla and human skeletons are compared, the skeletal adaptations for bipedalism in humans become apparent.

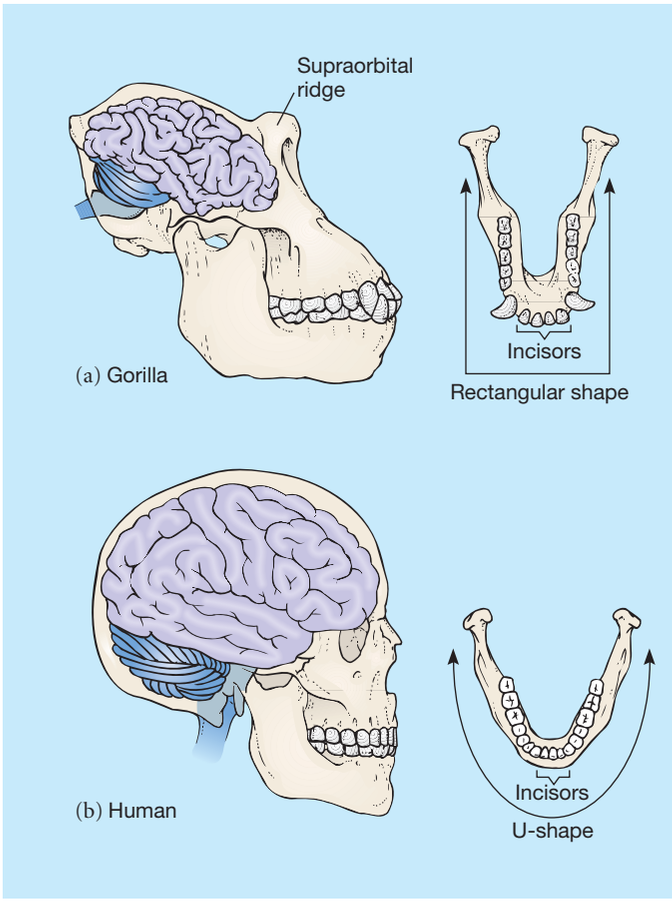
also reflect the habitat change for early hominids, from an arboreal existence in the forest to a life spent at least partly on the ground. The curvature of the human spine provides better balance and weight distribution for bipedal locomotion. The human pelvis is shorter and broader than the ape pelvis, allowing better attachment of muscles used for upright walking. In apes the **foramen magnum,** the hole in the base of the skull for the spinal cord, is located in the middle of the rear of the skull. In contrast, the human foramen magnum is centered in the skull base, positioning the head for erect walking. An increase in the length of the legs relative to the arms, and alignment of the big toe with the rest of the toes, further adapted the early hominids for bipedalism.

Another major trend in hominid evolution was an increase in brain size relative to body size (Fig. 21-8). The ape skull has prominent bony ridges above the eye sockets, whereas modern human skulls lack these **supraorbital ridges.** Human faces are flatter than those of apes, and the jaws are different. The arrangement of teeth in the ape jaw is somewhat rectangular, compared with a rounded, or U-shaped, arrangement in humans. Apes have larger front teeth (canines and incisors) than do humans, and their canines are especially large. Gorillas and orangutans also have larger back teeth (premolars and molars) than humans.

We now examine some of the increasing number of generally recognized fossil hominids in the human lineage. As you read the following descriptions of human evolution, keep in mind that much of what is discussed is still open to interpretation and major revision as additional discoveries are made. It is also important to remember that, although we present human evolution in a somewhat linear fashion, from ancient hominids to anatomically and behaviorally modern humans, the human family tree is not a single trunk but has several branches (Fig. 21-9). *Homo sapiens* is the only species of hominid in existence today, but more than one hominid species coexisted at any given time for most of the past 4 million years. In addition, don't make the mistake of thinking that your smaller-brained ancestors were inferior to yourself. Ancestral hominids were evolutionarily successful in that they were well adapted to their environment and survived for millions of years.

The earliest hominid may belong to the genus *Sahelanthropus*

Hominid evolution began in Africa. Although most hominid fossils have been discovered in East Africa, in 2002 French paleon-



ACTIVE FIGURE **21-8** **Gorilla and human heads.**

(a) The ape skull has a pronounced supraorbital ridge. **(b)** The human skull is flatter in the front and has a pronounced chin. The human brain, particularly the cerebrum *(purple),* is larger than that of an ape, and the human jaw is structured so that the teeth are arranged in a U shape. Human canines and incisors are also smaller than those of apes.

FIGURE **21-9** **One interpretation of hominid evolution.**

Dashed lines show possible evolutionary relationships. Paleoanthropologists do not completely agree about certain specific details of the human family tree and hold many possible interpretations of classification and lines of descent.

tologist Michel Brunet and an international team made a stunning discovery in a dry lakebed in Chad, which is in central Africa. The fossil, which has been reliably dated at 6 to 7 million years old, may be the earliest known hominid. Viewed from the back, the skull of ***Sahelanthropus tchadensis,*** with its small brain case, resembles a chimpanzee. However, viewed from the front the face and teeth have many characteristics of larger-brained human ancestors. Most paleoanthropologists place *Sahelanthropus* close to the base of the human family tree—that is, close to the last common ancestor of hominids and chimpanzees. This discovery is important in its own right, but it is also significant because it shows that early hominids had more variation and lived over a larger area of Africa than had been originally hypothesized.

As with most aspects of human evolution, scientists differ in interpreting *Sahelanthropus.* Some paleoanthropologists hypothesize that *Sahelanthropus* was a forerunner of modern apes, specifically the gorilla, and not one of the earliest humans. This point remains controversial, largely because there are currently no skeletal bones to indicate if *Sahelanthropus* walked upright, a hallmark characteristic of hominids. Future fossil discoveries may clarify this important issue.

Australopithecines are the immediate ancestors of genus *Homo*

After *Sahelanthropus,* the next oldest hominid belongs to the genus *Ardipithecus,* which appeared more than 5 mya. *Ardipithe-*

cus gave rise to *Australopithecus,* a genus that includes several species that lived between 4 and 1 mya. *Ardipithecus* and *Australopithecus* were two genera of early hominids, often referred to as **australopithecines,** or "southern man apes." Both *Ardipithecus* and *Australopithecus* had longer arms, shorter legs, and smaller brains relative to modern humans.

The actual number of australopithecine species for which fossil evidence has been found is under debate. In some cases, differences in the relatively few skeletal fragments could indicate either variation among individuals within a species or evidence of separate species. Most paleoanthropologists recognize at least six species of australopithecines.

To date, two sets of fossils of ***Ardipithecus ramidus*** have been reported, one in 1992 that was dated at 4.4 million years, and the other in 2001 that was dated at 5.2 to 5.8 million years. The specific epithet *ramidus* is derived from a word meaning "root" in the Afar language, spoken in the region of Ethiopia where the fossils were found. Although not as primitive as *Sahelanthropus, Ardipithecus* is close to the "root" of the human family tree.

Hominids that existed between 3.9 and 4.2 mya are assigned to the species ***Australopithecus anamensis,*** first named in 1995 by paleoanthropologist Meave Leakey (1942–) and her coworkers from fossils discovered in East Africa. This hominid species, which has a mixture of apelike and human-like features, presumably arose from *Ardipithecus ramidus.* A comparison of male and female *A. anamensis* body sizes and canine teeth reveals **sexual dimorphism,** marked phenotypic differences between the two sexes of the same species. (The modern-day gorilla is sexually dimorphic.) The back teeth and jaws of *A. anamensis* are larger than those of modern chimpanzees, whereas the front teeth are smaller and more like those of later hominids. A fossil leg bone, the tibia, indicates that *A. anamensis* had an upright posture and was bipedal, although it also may have foraged in the trees. Thus, bipedalism occurred early in human evolution and may have been the first human adaptation.

Australopithecus afarensis, another primitive hominid, appears to have arisen directly from *A. anamensis.* Many fossils of *A. afarensis* skeletal remains have been discovered in Africa, including a remarkably complete skeleton nicknamed Lucy found in Ethiopia in 1974 by a team led by American paleoanthropologist Donald Johanson. Lucy, a small hominid approximately 1.04 m (3 ft, 5 in) is thought to be about 3.2 million years old. In 1978, British paleoanthropologist Mary Leakey (1913–1996) and coworkers discovered beautifully preserved fossil footprints of three *A. afarensis* individuals who walked more than 3.6 mya. In 1994 the first adult skull of *A. afarensis* was found. The skull, characterized by a relatively small brain, pronounced supraorbital ridges, a jutting jaw, and large canine teeth, is an estimated 3 million years old. It is probable that *A. afarensis* did not construct tools or make fires, because no evidence of tools or fire has been found at fossil sites.

Many paleoanthropologists think *A. afarensis* gave rise to several australopithecine species, including ***Australopithecus africanus,*** which may have appeared as early as 3 mya. The first *A. africanus* fossil was discovered in South Africa in 1924, and since then hundreds have been found. This hominid walked erect and possessed hands and teeth that were distinctly human-like. Given the characteristics of the teeth, paleoanthropologists think *A. africanus* ate both plants and animals. Like *A. afarensis,* it had a small brain, more like that of its primate ancestors than of present-day humans.

Three australopithecine species (*Australopithecus robustus* from South Africa, and *A. aethiopicus* and *A. boisei,* both from East Africa) are larger than *A. africanus* and have extremely large molars, very powerful jaws, relatively small brains, and bony skull crests. Most females lacked the skull crests and had substantially smaller jaws, another example of sexual dimorphism in early hominids. The teeth and jaws suggest a diet, perhaps of tough roots and tubers, that would require powerful grinding. These so-called *robust australopithecines* may or may not be closely related but are generally thought to represent evolutionary offshoots, or side branches, of human evolution. The first robust australopithecine, *A. aethiopicus,* appeared about 2.5 mya. Some researchers classify robust australopithecines in a separate genus, *Paranthropus.*

Homo habilis is the oldest member of genus *Homo*

The first hominid to have enough uniquely human features to be placed in the same genus as modern humans is ***Homo habilis.*** It was first discovered in the early 1960s at Olduvai Gorge in Tanzania. Since then paleoanthropologists have discovered other fossils of *H. habilis* in East and South Africa. *Homo habilis* was a small hominid with a larger brain and smaller premolars and molars than the australopithecines. This hominid appeared approximately 2.3 mya and persisted for about 0.75 million years. Fossils of *H. habilis* have been found in numerous areas in Africa. These sites contain primitive tools, stones that had been chipped, cracked, or hammered to make sharp edges for cutting or scraping.[1] *Oldowan* pebble choppers and flakes, for example, were probably used to cut through animal hides to obtain meat and to break bones for their nutritious marrow.

The relationship between the australopithecines and *H. habilis* is not clear. Using physical characteristics of their fossilized skeletons as evidence, many paleoanthropologists have inferred that the australopithecines were ancestors of *H. habilis.* Some researchers do not think *H. habilis* belongs in the genus *Homo,* and they suggest it should be reclassified as *Australopithecus habilis.* Discoveries of additional fossils may help clarify these relationships.

Homo erectus apparently evolved from *Homo habilis*

Investigators found the first fossil evidence of ***Homo erectus*** in Indonesia in the 1890s. Since then, searchers have found numerous fossils of *H. erectus* throughout Africa and Asia. Paleoanthro-

[1] Investigators found the oldest known stone tools in the mid-1990s in Gona, Ethiopia. These ancient tools were made some 2.6 mya, but because searchers have found no hominid remains at the site yet, no one knows who made the tools.

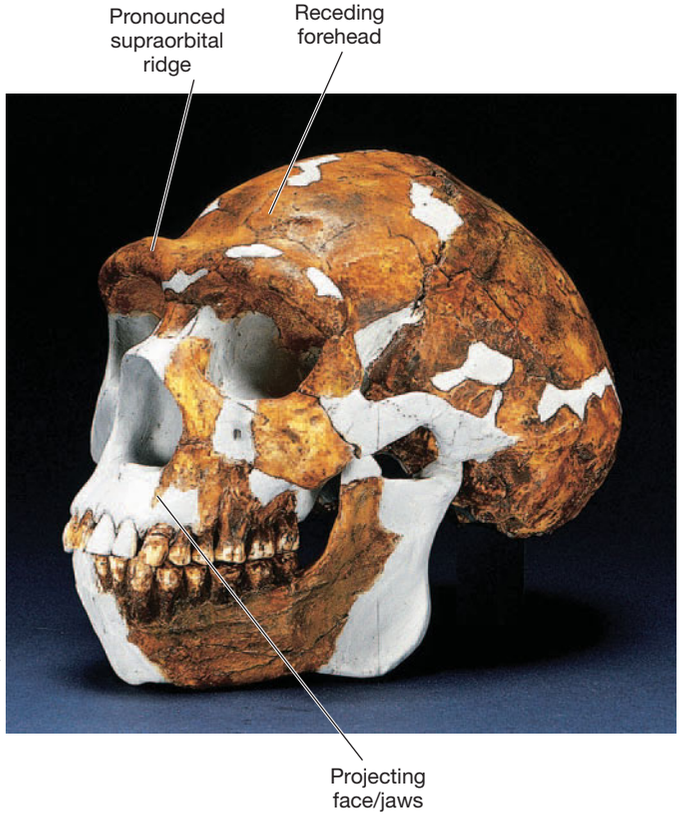
pologists think *Homo erectus* originated in Africa about 1.7 mya and then spread quickly to Europe and Asia. Peking man and Java man, discovered in Asia, were later examples of *H. erectus,* which existed until at least 200,000 years ago; some populations of *H. erectus* may have persisted more recently.

Homo erectus was taller than *H. habilis.* Its brain, which was larger than that of *H. habilis,* got progressively larger during the course of its evolution. Its skull, although larger, did not possess totally modern features, retaining the heavy supraorbital ridge and projecting face that are more characteristic of its ape ancestors (Fig. 21-10). *Homo erectus* is the first hominid to have fewer differences between the sexes.

The increased intelligence associated with an increased brain size enabled these early humans to make more advanced stone tools, known as *Acheulean* tools, including hand axes and other implements that scientists have interpreted as choppers, borers, and scrapers. Their intelligence also allowed these humans to survive in cold areas. *Homo erectus* obtained food by hunting or scavenging and may have worn clothing, built fires, and lived in caves or shelters. Evidence of weapons (spears) has been unearthed at *Homo erectus* sites in Europe.

Ideas regarding *Homo erectus,* like many other aspects of human evolution, are changing with each new fossil discovery. Many scientists hypothesize that the fossils classified as *H. erectus* really represent two species, ***Homo ergaster,*** an earlier African species, and *H. erectus,* a later East Asian offshoot. The best known fossils of *H. ergaster* come from the Lake Turkana region in Kenya. Researchers who support this split speculate that *Homo ergaster* may be the direct ancestor of later humans, whereas *Homo erectus* may be an evolutionary dead end.

Other paleoanthropologists do not think that *H. erectus* should be split into two species. They cite evidence of a 1-million-year-old *H. erectus* fossil that was discovered in Africa in 2002. This fossil shares striking similarities with Asian *H. erectus* fossils. It is a significant discovery because it enables paleoanthropologists to compare *H. erectus* fossils from the same period but from two different places, Africa and Asia. Scientists hope that further analysis of this fossil and of future fossil discoveries will clarify the status of *Homo erectus.*



Ken Mowbray

FIGURE **21-10** ***Homo erectus* skull from China.**
The reconstructed portions are white. Note the receding forehead, pronounced supraorbital ridge, and projecting face and jaws.

Archaic *Homo sapiens* appeared about 800,000 years ago

Archaic *Homo sapiens* are regionally diverse descendants of *Homo erectus* or *Homo ergaster* that lived in Africa, Asia, and Europe from about 800,000 to 100,000 years ago. They thus overlapped both *H. erectus* populations and the later appearing Neandertals (discussed in the next section). Some researchers classify archaic *Homo sapiens* as a separate species, ***Homo heidelbergensis.***

Neandertals appeared approximately 230,000 years ago

Fossils of **Neandertals**[2] were first discovered in the Neander Valley in Germany. They lived throughout Europe and western Asia from about 230,000 to 30,000 years ago. These early humans had short, sturdy builds. Their faces projected slightly, their chins and foreheads receded, they had heavy supraorbital ridges and jawbones, and their brains and front teeth were larger than those of modern humans. Their nasal cavities were large, and their cheekbones were receding. Scientists have suggested that the large noses provided larger surface areas in Neandertal sinuses, enabling them to better warm the cold air of Ice Age Eurasia as inhaled air traveled through the head to the lungs.

Scientists have not reached a consensus about whether the Neandertals are a separate species from modern humans. Many think the anatomical differences between Neandertals and modern humans mean that they were separate species, ***Homo neanderthalensis*** and ***Homo sapiens.*** Other scientists disagree and think that Neandertals were a group of *Homo sapiens.*

Neandertal tools, known as *Mousterian* tools, include the oldest known spear points (Fig. 21-11). Neandertal tools were more sophisticated than those of *H. erectus.* Studies of Neandertal sites indicate that they hunted large animals. The existence of skeletons of elderly Neandertals and of Neandertals with healed fractures may demonstrate that they cared for the aged

[2] Neandertal was formerly spelled "Neanderthal." The silent "h" has been dropped in modern German but not in the scientific name.

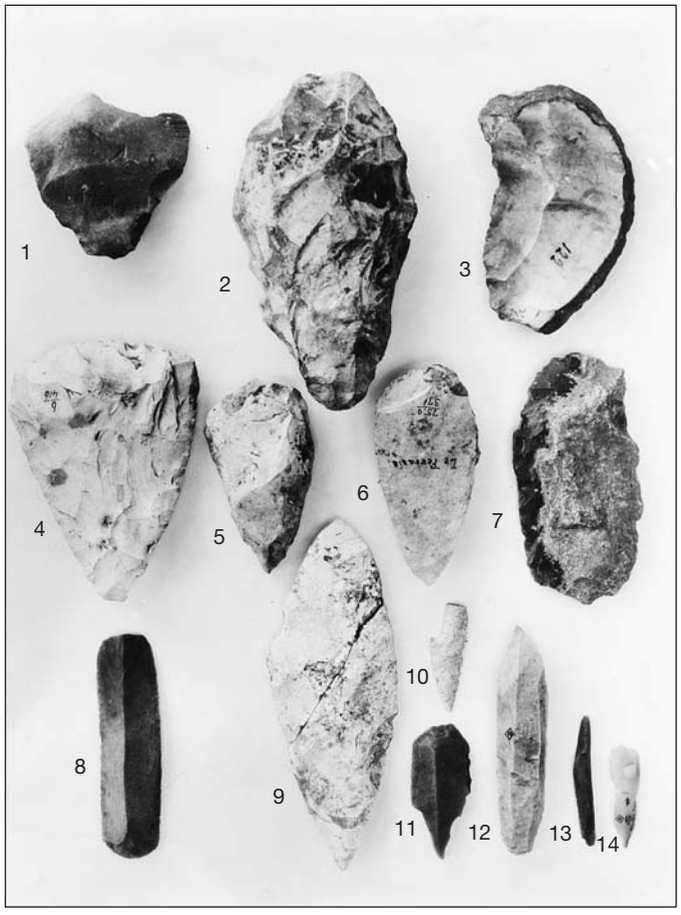


Photo Researchers, Inc.

FIGURE **21-11** **Mousterian tools.**

Paleoanthropologists named Mousterian tools after a Neandertal site in Le Moustier, France. Mousterian tools included a variety of skillfully made stone tools, such as hand axes, flakes, scrapers, borers, and spear points. (*1* to *7* are earlier tools, and *8* to *14* are later tools.)

and the sick, an indication of advanced social cooperation. They apparently had rituals, possibly of religious significance, and sometimes buried their dead.

PROCESS OF SCIENCE

The disappearance of the Neandertals some 30,000 years ago is a mystery that has sparked debate among paleoanthropologists. Other groups of *H. sapiens* with more modern features coexisted for tens of thousands of years with the Neandertals. Perhaps the other humans outcompeted or exterminated the Neandertals, leading to their extinction. It is also possible that the Neandertals interbred with these humans, diluting their features beyond recognition.

Analysis of **mitochondrial DNA** (**mtDNA**) contributes useful data for such controversies. Each of the several hundred mitochondria within a cell has about 10 copies of a small loop of DNA that codes for transfer RNAs, ribosomal RNAs, and certain respiratory enzymes. MtDNA is only transmitted through the maternal line because eggs, not sperm, contribute mitochondria. Mitochondrial DNA mutates more rapidly than nuclear DNA, so mtDNA is a sensitive indicator of evolution. Researchers extracted the mtDNA from a Neandertal bone and evaluated it. It differs significantly from all modern human mtDNA sequences, although it is more similar to human than to chimpanzee mtDNA. This finding suggests that Neandertals are an evolutionary dead end that did not interbreed with more modern humans.

The question of the relationship between Neandertals and anatomically modern humans remains controversial, however. In 1999 researchers reported the discovery of a 4-year-old child's remains in Portugal. The skeleton, dated at 24,500 years of age, has traits of both modern humans and Neandertals (short lower limb bones). The child lived several thousand years after Neandertals are thought to have disappeared, and the researchers who discovered it view it as an example of mixed ancestry, meaning that Neandertals and anatomically modern humans are members of the same species who interbred freely. Other scientists disagree with their interpretation and think the so-called Neandertal features of the child may reflect normal variation inherent in the human species.

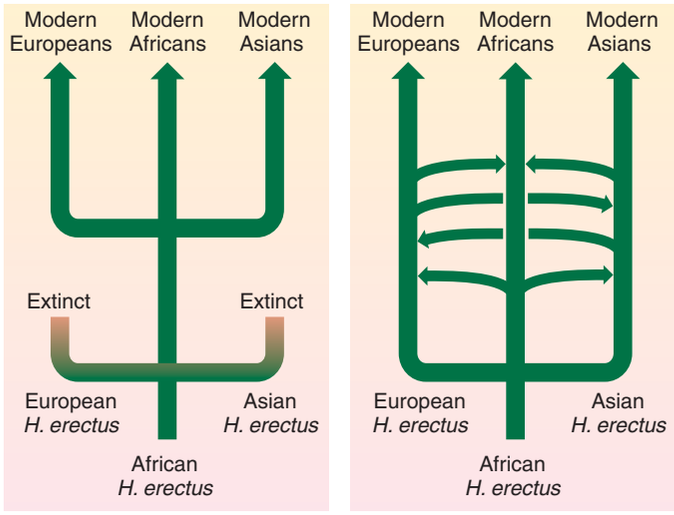
Biologists debate the origin of modern *Homo sapiens*

Homo sapiens with anatomically modern features existed in Africa and the Middle East at least 100,000 years ago. The *H. sapiens* skull lacked a heavy brow ridge and had a distinct chin. By about 30,000 years ago, anatomically modern humans were the only members of genus *Homo* remaining. Paleoanthropologists refer to European populations of these ancient people as **Cro-Magnons.** Their weapons and tools were complex and often made of materials other than stone, including bone, ivory, and wood. They made stone blades that were extremely sharp. Cro-Magnons developed art, including cave paintings, engravings, and sculpture, possibly for ritual purposes. Their sophisticated tools and art indicate they may have possessed language, which they would have used to transmit their culture to younger generations.

PROCESS OF SCIENCE

Two opposing hypotheses currently exist about the origin of these modern humans: the *out-of-Africa* hypothesis and the *multiregional* hypothesis (Fig. 21-12). The out-of-Africa hypothesis holds that modern *H. sapiens* evolved from *H. erectus* in Africa between 200,000 and 100,000 years ago and then migrated to Europe and Asia, displacing the Neandertals and other more primitive humans living there. According to the multiregional hypothesis, modern humans originated, beginning as early as 2 mya, as separately evolving *H. erectus* populations living in several parts of Africa, Asia, and Europe. Each of these populations evolved in its own distinctive way but occasionally met and interbred with other populations, preventing complete reproductive isolation. The variation found today in different geographic populations therefore represents a continuation of this multiregional process.

Data from *Homo* fossils, as well as molecular biology and population genetics studies of modern humans, have been cited in support of both hypotheses, and both have vigorous defenders and strong detractors. Such disagreement is an important



(a) Out-of-Africa hypothesis (b) Multiregional hypothesis

FIGURE **21-12** **Competing hypotheses on the origin of modern humans.**

Scientists agree that *Homo erectus* arose in Africa and migrated to other continents. What happened then is the subject of controversy. **(a)** According to the out-of-Africa hypothesis, all but the African line of *H. erectus* went extinct. In Africa, *H. erectus* evolved into modern humans, which migrated to other continents. **(b)** According to the multiregional hypothesis, modern humans evolved from *H. erectus* populations in different regions of the world. The smaller horizontal arrows in **(b)** represent gene flow (migration and interbreeding) among the different populations.

part of the scientific process, because it stimulates research that may ultimately resolve the issue.

Analysis of DNA provides evidence on the origin of modern humans

Molecular anthropology, the comparison of biological molecules from present-day individuals of regional human populations, provides clues that help scientists unravel the origin of modern humans and trace human migrations. The out-of-Africa hypothesis was originally supported by studies in the late 1980s of mtDNA from various human populations. In 1992 researchers found that the statistical assumptions used in one analysis of mtDNA were wrong, raising questions about the validity of this purported test of the out-of-Africa hypothesis. Multiple subsequent molecular studies comparing DNA sequences from different human groups, however, all have produced essentially the same answer—that modern humans have descended from an early human population that lived in southern Africa.

For example, a 1996 study examined the genetic variation in two stretches of DNA on human chromosome 12 from 1600 people living in 42 different populations around the world (13 African, 2 Middle Eastern, 7 European, 9 Asian, 3 Pacific, and 8 Amerindian populations). The DNA segments varied depending on where the populations lived. Based on the results, scientists divided the present-day human population into three groups: sub-Saharan Africans, northeastern Africans, and non-Africans. (Sub-Saharan Africa includes all countries located south of the Sahara Desert.) The sub-Saharan Africans showed the greatest genetic diversity, whereas the non-African populations were the least diverse. These findings are consistent with the predictions of the out-of-Africa hypothesis for two reasons. First, proponents of the hypothesis expect the sub-Saharan populations to be more diverse because they are older and have had a longer time to accumulate that diversity. Second, the small populations thought to have emigrated from Africa could not have been representative of the total diversity present in the larger African population (recall the discussion in Chapter 18 on the founder effect and genetic drift).

Such research has not disproved the multiregional hypothesis, but it indicates the direction for additional research on other segments of human DNA. A series of recent genetic studies of both mtDNA and nuclear DNA has strengthened the case for Africa as the birthplace of modern humans, and in 1999 scientists announced that the ancestors common to all humans were probably ancient Khoisans, an indigenous group in southern Africa. This conclusion was based on separate analyses of DNA from both mitochondria and the Y chromosome. Both studies indicated that the Khoisan people are the most ancient of all human groups.

Some molecular research has suggested that the out-of-Africa hypothesis may not be as simple as originally envisioned—that is, humans from Africa may not have completely replaced the archaic humans on other continents but may have interbred to some extent with them as they evolved into modern humans. Although many of the human genes that were analyzed have demonstrated an African ancestry, a few appear to have arisen in Asia and to have been introduced at a later time into African populations, probably by migration from Asia to Africa. Thus, certain ancestral human populations in both Africa and Asia may have contributed to the gene pool of modern humans.

CULTURAL EVOLUTION

Learning Objective

8 Describe cultural evolution and its impact on the biosphere.

Genetically speaking, humans are not very different from other primates. At the level of our DNA sequences, we are roughly 98% identical to gorillas and 99% identical to chimpanzees. Our rela-

tively few genetic differences, however, give rise to several important distinguishing features, such as greater intelligence and the ability to capitalize on it through **cultural evolution,** which is the transmission of knowledge from one generation to the next. (Note that researchers increasingly agree that humans are not the only animals to have culture. Chimpanzees have primitive cultures that include tool-using techniques, hunting methods, and social behaviors, all of which vary from one population to another. These cultural traditions are passed from one generation to the next by teaching and imitation; see Chapter 50.)

Human culture is dynamic; it is modified as people obtain new knowledge. Human cultural evolution is generally divided into three stages: (1) the development of hunter-gatherer societies, (2) the development of agriculture, and (3) the Industrial Revolution.

Early humans were hunters and gatherers who relied on what was available in their immediate environment. They were nomadic, and as the resources in a given area were exhausted or as the population increased, they migrated to a different area. These societies required a division of labor and the ability to make tools and weapons, which were needed to kill game, scrape hides, dig up roots and tubers, and cook food. Although scientists are not certain when hunting was incorporated into human society, they do know it declined in importance approximately 15,000 years ago. This may have been due to a decrease in the abundance of large animals, triggered in part by overhunting. A few isolated groups of hunter-gatherer societies, such as the Inuit of the northern polar region and the Mbuti of Africa, have survived into the 21st century.

Development of agriculture resulted in a more dependable food supply

Evidence that humans had begun to cultivate crops approximately 10,000 years ago includes the presence of agricultural tools and plant material at archaeological sites. Agriculture, which involves keeping animals as well as cultivating plants, resulted in a more dependable food supply. Archaeological evidence suggests agriculture arose in several steps. Although there is variation from one site to another, plant cultivation, in combination with hunting, usually occurred first. Animal domestication generally followed later, although in some areas, such as Australia, early humans did not domesticate animals.

Agriculture, in turn, often led to more permanent dwellings, because considerable time was invested in growing crops in one area. Villages and cities often grew up around the farmlands, but the connection between agriculture and the establishment of villages and towns is complicated by certain discoveries. For example, Abu Hureyra in Syria was a village founded *before* agriculture arose. The villagers subsisted on the rich plant life of the area and the migrating herds of gazelle. Once people turned to agriculture, however, they seldom went back to hunting and gathering to obtain food.

Other advances in agriculture include the domestication of animals, which people kept to supply food, milk, and hides. Archaeological evidence indicates that wild goats and sheep were probably the first animals to be domesticated in southwest Turkey, northern Iraq, and Iran. In the Old World, people also used animals to prepare fields for planting. Another major advance in agriculture was irrigation, which began more than 5000 years ago in Egypt.

Producing food agriculturally was more time-consuming than hunting and gathering, but it was also more productive. In hunter-gatherer societies, everyone shares the responsibility for obtaining food. In agricultural societies, fewer people are needed to provide food for everyone. Thus agriculture freed some people to pursue other endeavors, including religion, art, and various crafts.

Cultural evolution has had a profound impact on the biosphere

Cultural evolution has had far-reaching effects on both human society and on other organisms. The Industrial Revolution, which began in the 18th century, drew populations to concentrate in urban areas near centers of manufacturing. Advances in agriculture encouraged urbanization, because fewer and fewer people were needed in rural areas to produce food for everyone. The spread of industrialization increased the demand for natural resources to supply the raw materials for industry.

Cultural evolution has permitted the human population, which reached 6.3 billion in 2003, to expand so dramatically that there are serious questions about Earth's ability to support so many people indefinitely (see Chapter 51). According to the U.N. Food and Agricultural Organization, about 828 million people lack access to the food needed to be healthy and lead productive lives. To further compound the problem, the United Nations projects that 3 billion *additional* people will be added to the world population by the year 2050.

Cultural evolution has resulted in large-scale disruption and degradation of the environment. Tropical rain forests and other natural environments are rapidly being eliminated. Soil, water, and air pollution occur in many places. Since World War II, soil degradation caused by poor agricultural practices, overgrazing, and deforestation has occurred in an area equal to 17% of Earth's total vegetated surface area. Many species cannot adapt to the rapid environmental changes caused by humans and thus are becoming extinct. The decrease in biological diversity from species extinction is alarming (see Chapter 55).

On a positive note, people are aware of the damage we are causing, and have the intelligence to modify behavior to improve these conditions. Education, including the study of biology, may help future generations develop environmental sensitivity, making cultural evolution our salvation rather than our destruction.

SUMMARY WITH KEY TERMS

1 Describe the structural adaptations that primates have for life in treetops.

- Primates are **placental mammals** that arose from small, **arboreal** (tree dwelling), shrewlike mammals. Primates possess five grasping digits, including an opposable thumb or toe; long, slender limbs that move freely at the hips and shoulders; and eyes located in front of the head.

2 List the three suborders of primates, and give representative examples of each.

- Primates are divided into three suborders. The suborder Prosimii includes lemurs, galagos, and lorises. The suborder Tarsiiformes includes tarsiers. The suborder Anthropoidea includes **anthropoids** (monkeys, apes, and humans).

3 Distinguish among anthropoids, hominoids, and hominids.

- Anthropoids include monkeys, apes, and humans. Early anthropoids branched into two groups: the New and Old World monkeys.
- **Hominoids** include apes and humans. Hominoids arose from the Old World monkey lineage. There are four modern genera of apes: gibbons, orangutans, gorillas, and chimpanzees.
- The **hominid** line consists of humans and their ancestors.

4 Describe skeletal and skull differences between apes and hominids.

- Unlike ape skeletons, hominid skeletons have adaptations that reflect the ability to stand erect and walk on two feet. These adaptations include a complex curvature of the spine; a shorter, broader pelvis; a **foramen magnum** at the base of the skull; and a first toe that is aligned with the other toes.
- The human skull lacks a pronounced **supraorbital ridge,** is flatter in the front, and has a pronounced chin. The human brain is larger, and the jaw is structured so that the teeth are arranged in a U shape.

5 Compare the following early hominids: *Sahelanthropus tchadensis, Ardipithecus ramidus, Australopithecus anamensis, Australopithecus afarensis,* and *Australopithecus africanus.*

- Hominid evolution began in Africa. The earliest known hominids belong to ***Sahelanthropus tchadensis.***
- *Ardipithecus* and *Australopithecus* species are often referred to as **australopithecines.** *Australopithecus* species were **bipedal** (walked on two feet), a hominid feature. ***Ardipithecus ramidus,*** which appeared about 5.2 to 5.8 mya, presumably gave rise to ***Australopithecus anamensis.*** *A. anamensis* may have given rise to another primitive hominid, ***Australopithecus afarensis.*** Many paleoanthropologists think *A. afarensis* gave rise to several australopithecine species, including ***Australopithecus africanus.***
- The genus *Australopithecus* contains the immediate ancestors of the genus *Homo.*

6 Distinguish among the following members of genus *Homo: Homo habilis, Homo ergaster, Homo erectus, Homo heidelbergensis, Homo neanderthalensis,* and *Homo sapiens.*

- ***Homo habilis*** was the earliest known hominid with some of the human features lacking in the australopithecines, including a slightly larger brain. *H. habilis* fashioned crude tools from stone.
- ***Homo erectus*** had a larger brain than *H. habilis;* made more sophisticated tools; and may have worn clothing, built fires, and lived in caves or shelters. Some scientists hypothesize that fossils identified as *Homo erectus* represent two different species, ***Homo ergaster,*** an earlier African species that gave rise to archaic *Homo sapiens,* and *Homo erectus,* a later Asian offshoot that may be an evolutionary dead end.
- **Archaic *Homo sapiens*** lived in Africa, Asia, and Europe from about 800,000 to 100,000 years ago. Some researchers classify archaic *Homo sapiens* as a separate species, ***Homo heidelbergensis.***
- **Neandertals** lived from about 230,000 to 30,000 years ago. Neandertals had short, sturdy builds; receding chins and foreheads; heavy supraorbital ridges and jawbones; larger front teeth; and nasal cavities with unusual triangular bony projections. Many scientists think that Neandertals were a separate species, ***Homo neanderthalensis,*** whereas some scientists think Neandertals were a type of modern human.
- Anatomically modern humans ***(Homo sapiens)*** existed 100,000 years ago. By about 30,000 years ago, anatomically modern humans were the only members of genus *Homo* remaining. European remains of these ancient people are referred to as **Cro-Magnons.**

7 Discuss the current debate over the origin of modern humans, and briefly describe the opposing out-of-Africa and multiregional hypotheses.

- Two hypotheses purport to explain the origin of modern humans. The out-of-Africa hypothesis holds that modern *H. sapiens* arose in Africa and migrated to Europe and Asia, displacing the more primitive humans living there. According to the multiregional hypothesis, modern humans originated as separately evolving populations of *H. erectus* living in several parts of Africa, Asia, and Europe. Each of these populations occasionally met and interbred with other populations, thereby preventing complete reproductive isolation.
- **Molecular anthropology,** the comparison of biological molecules from individuals of regional human populations, generally favors the African origin of modern humans.

8 Describe cultural evolution and its impact on the biosphere.

- **Cultural evolution** is the transmission of knowledge from one generation to the next. Large human brain size makes cultural evolution possible. Two significant advances in cultural evolution were the development of agriculture and the Industrial Revolution.

POST-TEST

1. The first primates evolved about 55 mya from (a) shrewlike monotremes (b) therapsids (c) shrewlike placental mammals (d) tarsiers (e) shrewlike marsupials

2. The anthropoids are more closely related to _____ than to _____. (a) tarsiers; lemurs (b) lemurs; monkeys (c) tree shrews; tarsiers (d) lemurs; tarsiers (e) tree shrews; monkeys

POST-TEST *(continued)*

3. Unlike Old World monkeys, some New World monkeys have (a) body hair (b) five grasping digits (c) a well-developed cerebrum (d) a bipedal walk (e) a prehensile tail
4. Apes and humans are collectively called (a) mammals (b) primates (c) anthropoids (d) hominoids (e) hominids
5. With what group do hominoids share the most recent common ancestor? (a) Old World monkeys (b) New World monkeys (c) tarsiers (d) lemurs (e) lorises and galagos
6. The _____ in humans is centered at the base of the skull, positioning the head for erect walking. (a) supraorbital ridge (b) foramen magnum (c) pelvis (d) bony skull crest (e) femur
7. Scientists collectively call humans and their *immediate* ancestors (a) mammals (b) primates (c) anthropoids (d) hominoids (e) hominids
8. The earliest hominid belongs to the genus (a) *Aegyptopithecus* (b) *Dryopithecus* (c) *Sahelanthropus* (d) *Homo* (e) *Pan*
9. The earliest hominid scientists placed in the genus *Homo* is (a) *H. habilis* (b) *H. ergaster* (c) *H. erectus* (d) *H. heidelbergensis* (e) *H. neanderthalensis*
10. Some scientists now think that fossils identified as *Homo erectus* represent which two different species? (a) *H. habilis* and *H. erectus* (b) *H. ergaster* and *H. erectus* (c) *H. heidelbergensis* and *H. ergaster* (d) *H. neanderthalensis* and *H. erectus* (e) *H. neanderthalensis* and *H. sapiens*
11. Archaic *Homo sapiens* appeared about _____ years ago. (a) 5 million (b) 800,000 (c) 230,000 (d) 100,000 (e) 5000
12. _____were an early group of humans with short, sturdy builds and heavy supraorbital ridges that lived throughout Europe and western Asia from about 230,000 to 30,000 years ago. (a) australopithecines (b) dryopithecines (c) archaic *Homo sapiens* (d) Neandertals (e) Cro-Magnons
13. The modern human skull *lacks* (a) small canines (b) a foramen magnum centered in the base of the skull (c) pronounced supraorbital ridges (d) a U-shaped arrangement of teeth on the jaw (e) a large cranium (brain case)
14. The comparison of genetic material from individuals of regional populations of humans, used to help unravel the origin and migration of modern humans, is known as (a) paleoarchaeology (b) cultural anthropology (c) molecular anthropology (d) cytogenetics (e) genetic dimorphism
15. Place the following hominids in chronological order of appearance, beginning with the earliest: *H. habilis, H. sapiens, H. neanderthalensis,* and *H. erectus.* (a) *H. habilis, H. erectus, H. sapiens, H. neanderthalensis* (b) *H. erectus, H. habilis, H. sapiens, H. neanderthalensis* (c) *H. erectus, H. habilis, H. neanderthalensis, H. sapiens* (d) *H. neanderthalensis, H. habilis, H. erectus, H. sapiens* (e) *H. habilis, H. erectus, H. neanderthalensis, H. sapiens*

CRITICAL THINKING

1. What types of as-yet-undiscovered scientific evidence might help explain how monkeys got to South America from the Old World?
2. What was the common ancestor of chimpanzees and humans—a chimpanzee, a human, or neither? Explain your answer.
3. If you were evaluating whether other early humans exterminated the Neandertals, what kinds of archaeological evidence might you look for?
4. The remains of Cro-Magnons have been found in southern Europe alongside reindeer bones, but reindeer currently exist only in northern Europe and Asia. Can you explain the apparent discrepancy?

Understanding Diversity: Systematics

Larry and Denise Tackett

Pygmy seahorse. This newly described species, generally light orange in color, has been found at depths from 42 to 297 feet.

CHAPTER OUTLINE

- Binomial Nomenclature
- Taxonomic Categories
- Kingdoms or Domains?
- Reconstructing Phylogeny
- Two Major Approaches to Systematics

About 1.7 million species of living organisms have been described, and about 15,000 new species are discovered each year. The recently discovered pygmy seahorse (*Hippocampus denise*) shown here was described in 2003. Widespread in the western Pacific, this seahorse measures only about 16 mm including its tail (making it one of the smallest fishes). Biologists speculate that at least several million additional species remain to be identified. The total number of living species is estimated to be between 4 million and 100 million. Biologists estimate that to date they have identified less than 10% of bacteria, about 5% of fungi species, only about 2% of nematode (roundworm) species, and less than 20% of insect species.

The variety of living organisms and the variety of ecosystems they form are referred to as **biological diversity,** or **biodiversity.** The totality of life on Earth represents our biological heritage, and the quality of life for all organisms depends on the health and balance of this worldwide web of organisms. For example, we depend on organisms to maintain the life-sustaining composition of gases in the atmosphere, to form soil, break down wastes, recycle nutrients, and provide food for one another. We humans exploit many species for economic benefit. One very anthropocentric (human-centered) example of the practical importance of biodiversity is that more than 40% of the prescriptions that pharmacists dispense in the United States derive from living organisms. Investigators are just learning how to effectively screen organisms for potential drugs. Unfortunately, human activity is seriously reducing biodiversity, and species are becoming extinct more rapidly than researchers can study them (see the discussion on declining biodiversity in Chapter 55).

Alarmed by these extinctions, biologists are mobilizing to more rapidly identify new species and to conserve biodiversity. Many biologists agree that describing and classifying all the surviving species of the world should be one of the great scientific

goals of the 21st century. An important step toward that goal is the Catalogue of Life, the work of a collaborative international research team that is setting up a comprehensive global database made available on the Internet. Another project launched in 2002 by the U.N. Environment Programme and the Global Environment Facility focuses on identifying new species in subterranean ecosystems.

To study the diverse life forms that share this planet and to effectively communicate findings, biologists must organize their knowledge. The scientific study of the diversity of organisms and their evolutionary relationships is called **systematics.** An important aspect of systematics is **taxonomy,** the science of naming, describing, and classifying organisms. The term **classification** means arranging organisms into groups based on their similarities, which reflect historical relationships among lineages.

Biologists continuously debate the best methods for inferring the history of life from the data they have, so classifying organisms and establishing their relationships is complex and often controversial. Recently developed molecular approaches to taxonomy are revolutionizing this dynamic science. In 2003, Paul Hebert, of the University of Guelph in Canada, and his colleagues proposed in the British *Proceedings of the Royal Society* that we identify all living things by DNA rather than by their physical structure. Hebert suggested that each organism has a DNA barcode (much like grocery store products) and that biologists can learn to read these barcodes and use them to identify species. DNA is already used to identify bacteria, and Hebert and his colleagues suggest extending this approach to other kinds of organisms.

Systematics proceeds by constantly re-evaluating data, hypotheses, and theoretical constructs. As new data are discovered and old data are reinterpreted, the ideas of systematists change. As a result, our understanding of how organisms are related and the way we classify organisms are continuously being revised.

In this chapter, we explore some approaches and methods used by systematists to infer the evolutionary history of life. In Chapters 23 through 30 we introduce the major groups of organisms that share this planet. We describe how systematists have classified these organisms based on current data from morphology, development, the fossil record, behavior, and molecular biology. ■

BINOMIAL NOMENCLATURE

Learning Objective

1 State at least two justifications for the use of scientific names and classifications of organisms.

Because there are millions of kinds of organisms, scientists need a system for accurately identifying them. Imagine you were going to develop a classification system. How would you use what you already know about living things to assign them to categories? Would you place insects, bats, and birds in one category because they all have wings and fly? And would you, perhaps, place squid, whales, fish, penguins, and Olympic backstroke champions in another category because they all swim? Or would you classify organisms according to a culinary scheme, placing lobsters and tuna in the same part of the menu, perhaps identifying them as "seafood"? Any of these schemes might be valid, depending on your purpose. Similar methods have been used throughout history. For example, St. Augustine in the fourth century classified animals as useful, harmful, or superfluous—to humans. During the Renaissance, scholars began to develop categories based on the characteristics of the organisms themselves.

Of the many classification systems that were developed, the one designed by Carolus Linnaeus in the mid-18th century (described briefly in Chapter 1) has survived with some modification to the present day. As we discuss in the next section, Linnaeus grouped organisms according to their similarities, mainly structural similarities.

Before the mid-18th century, each species had a lengthy descriptive name, sometimes constisting of 10 or more Latin words! Linnaeus simplified scientific classification, developing a **binomial system of nomenclature** in which each species is assigned a unique two-part name.The first part of a scientific name designates the **genus** (pl., *genera*), and the second part is called the **specific epithet.** Note that the specific epithet alone is *not* the species' name. In fact, the same specific epithet can be used as the second name of species in different genera. For example, *Quercus alba* is the scientific species name for the white oak, and *Salix alba* is the species name for the white willow. (*Alba* comes from a Latin word meaning "white.") Thus, both parts of the name must be used to accurately identify the species.

The genus name is always capitalized, whereas the specific epithet is usually not. Both names are underlined or italicized. The genus, or generic, name can be used alone to designate all species in the genus (for example, the genus *Quercus* includes all oak species). However, the specific epithet is never used alone; it must always follow the full or abbreviated genus name (for example, *Quercus alba* or *Q. alba*).

Scientific names are generally derived from Greek or Latin roots or from latinized versions of the names of persons, places, or characteristics. For example, the generic name for the bacterium *Escherichia coli* is based on the name of the scientist, Theodor Escherich, who first described it. The specific epithet *coli* reminds us that *E. coli* lives in the colon (large intestine).

Most areas of biology depend on scientific names and classification. For example, to study the effects of pollution on an aquatic community, biologists must be able to accurately record the relative numbers of each type of organism present and changes in their populations over time. This requires that all investigators identify each species accurately by name.

Scientific names permit biology to be a truly international science. Even though the common names of an organism may

vary in different locations and languages, an organism can be universally identified by its scientific name. A researcher in Puerto Rico knows exactly which organisms were used in a study published by a Russian scientist and therefore can repeat or extend the Russian's experiments using the same species.

Review

- What are the key features of the binomial system of nomenclature?
- Why is it important to use scientific, rather than common, names for organisms?

TAXONOMIC CATEGORIES

Learning Objective

2 Arrange the Linnaean categories in hierarchical fashion, from most inclusive to least inclusive.

Classifiying organisms helps biologists organize their knowledge. Linnaeus devised a system for assigning species to a hierarchy of groups. As you move up the hierarchy, each group is more inclusive. When he set up his system, Linnaeus did not have a theory of evolution in mind. Nor did he have any idea of the vast number of extant (living) and extinct organisms that would later be discovered. Yet his system has proved remarkably flexible and adaptable to new biological knowledge and theory. Very few other 18th-century inventions survive today in a form that would still be recognizable to their originators.

The range of taxonomic categories from species to kingdom forms a hierarchy (Fig. 22-1; Table 22-1). Closely related species are assigned to the same genus, and closely related genera are grouped in a single **family.** Families are grouped into **orders,** orders into **classes,** classes into **phyla,** and phyla into **kingdoms** and/or **domains.**

A **taxon** (pl., *taxa*) is a formal grouping of organisms at any given level, such as the species, genus, or phylum. For example, class Mammalia is a taxon that includes many different orders. Each taxon can be separated into subgroupings, for example, subphyla or superclasses. Subphylum Vertebrata, a subgroup of phylum Chordata, is a taxon that contains several classes, including Amphibia and Mammalia.

Some systematists are moving away from the hierarchical Linnaean categories because they do not fit well with recent findings. Also, systematists have experienced some difficulty renaming and reclassifying organisms as quickly as new species are identified and relationships among organisms are adjusted. One group of biologists has proposed a very different classification known as PhyloCode. This system groups organisms into clades; a *clade* is defined as a set of organisms with a common ancestor. Whether (and how soon) biologists will give up conventional nomenclature and the hierarchical system of classification remains to be seen.

KINGDOMS OR DOMAINS?

Learning Objectives

3 Describe the three domains and six kingdoms of organisms introduced in this chapter, and give the rationales for and against this system of classification.

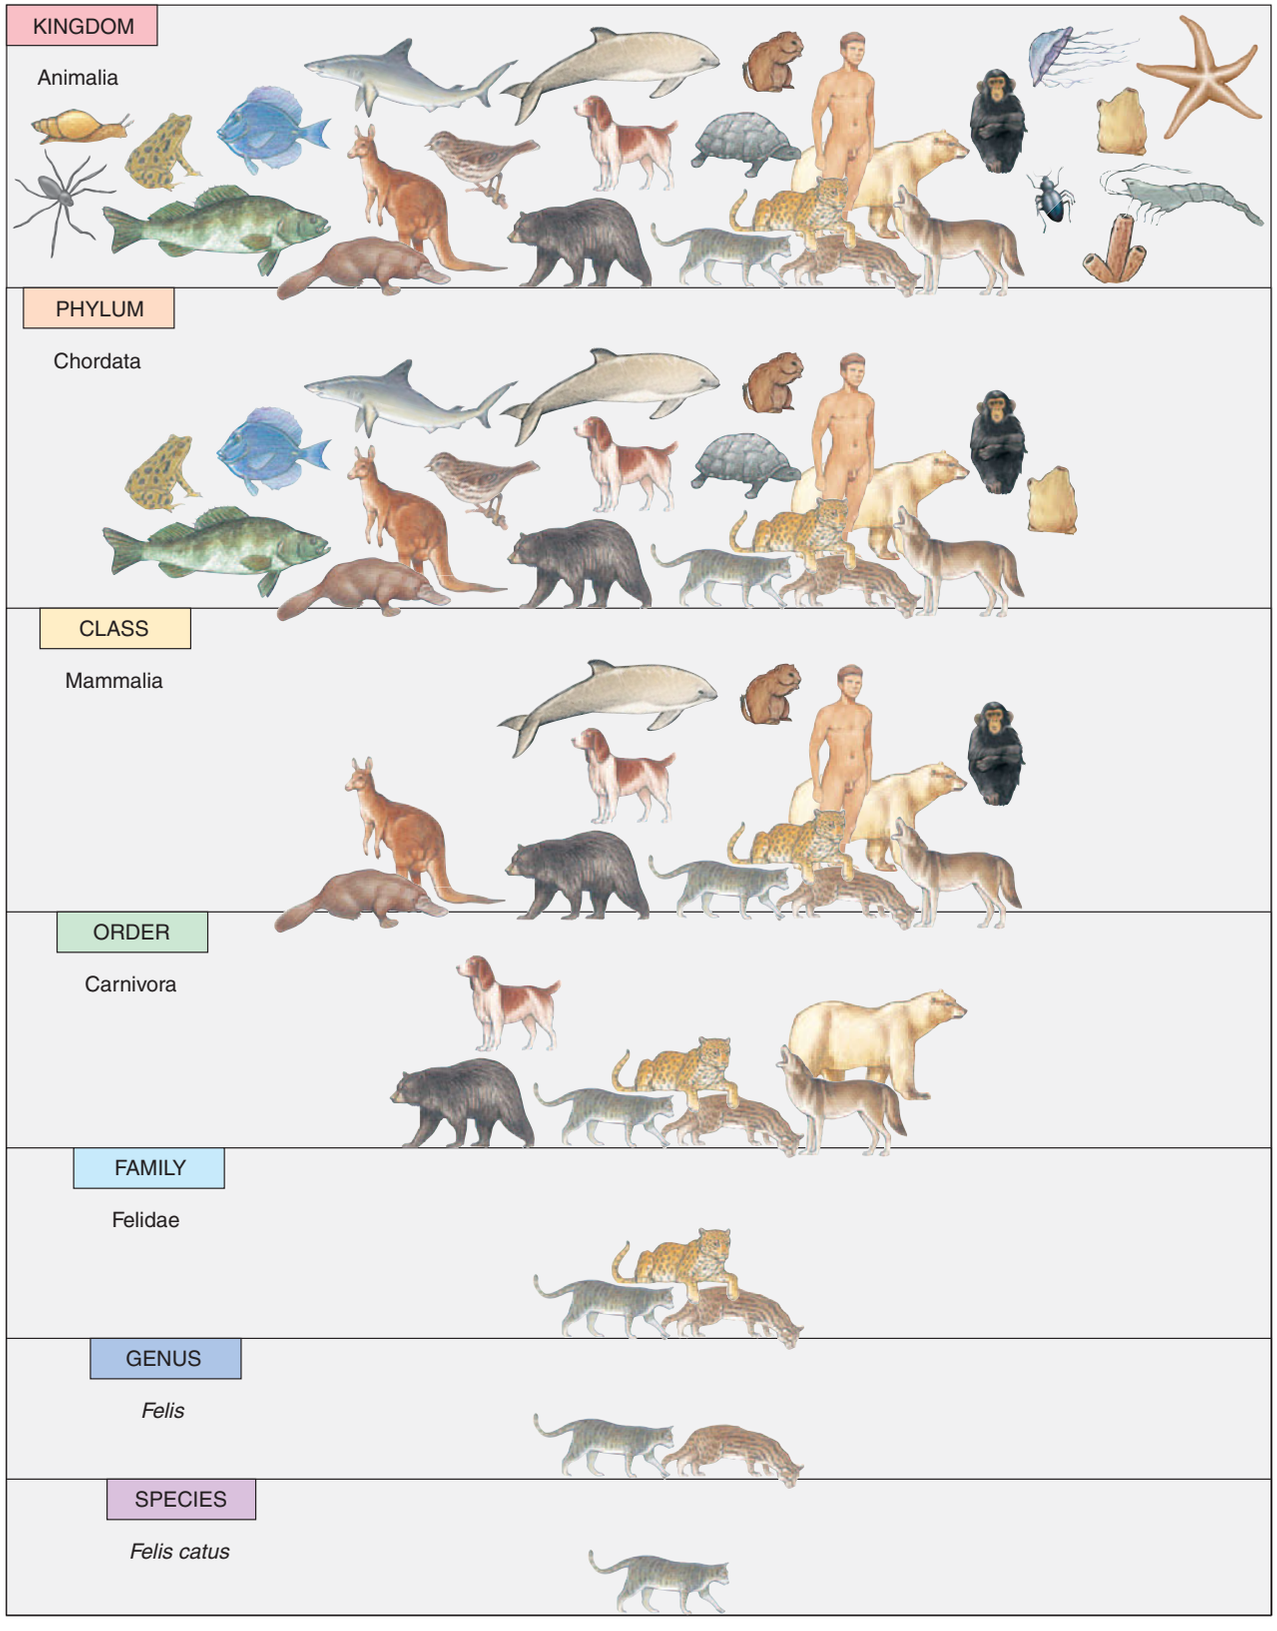
4 Given its distinguishing characters, classify an organism in the appropriate domain and kingdom.

PROCESS OF SCIENCE

The history of taxonomy at the kingdom level is a good example of the process of science. From the time of Aristotle to the mid-19th century, biologists divided organisms into two kingdoms: **Plantae** and **Animalia.** After the development of microscopes, it became increasingly obvious that many organisms could not be easily assigned to either the plant or the animal kingdom. For example, the unicellular organism *Euglena,* which has been classified at various times in the plant kingdom and in the animal kingdom, carries on photosynthesis in the light but in the dark uses its flagellum to move about in search of food (see Fig. 24-6). In 1866 a German biologist, Ernst Haeckel, proposed that a third kingdom, **Protista,** be established to accommodate bacteria and other microorganisms, such as *Euglena,* that

TABLE 22-1 Classification of Corn

Kingdom	**Plantae** Terrestrial, multicellular, photosynthetic organisms
Phylum	**Anthophyta** Vascular plants with flowers, fruits, and seeds
Class	**Monocotyledones** Monocots: Flowering plants with one seed leaf (cotyledon) and flower parts in threes
Order	**Commelinales** Monocots with reduced flower parts, elongated leaves, and dry 1-seeded fruits
Family	**Poaceae** Grasses with hollow stems; fruit is a grain; and abundant endosperm in seed
Genus	***Zea*** Tall annual grass with separate female and male flowers
Species	***Zea mays*** Only one species in genus—corn



ACTIVE FIGURE **22-1** **The principal categories used in classification.**

The domestic cat (*Felis catus*) is classified here to illustrate the hierarchical organization of our taxonomic system. Each level is more inclusive than the one below it.

BiologyNow™ Explore **the tree of life** by clicking on this figure on your BiologyNow CD-ROM.

did not seem to fit into the plant or animal kingdoms. Today, many biologists place algae (including multicellular forms), protozoa, water molds, and slime molds in kingdom Protista.

In 1937 the French marine biologist Edouard Chatton suggested the term *procariotique* ("before nucleus") to describe bacteria, and the term *eucariotique* ("true nucleus") to describe all other cells. This dichotomy between prokaryotes and eukaryotes is now universally accepted by biologists as a fundamental evolutionary divergence. In the 1960s advances in electron microscopy and biochemical techniques revealed further cell differences that inspired many new proposals for classifying organisms.

In 1969 R.H. Whittaker proposed a five-kingdom classification based mainly on cell structure and how organisms derived nutrition from their environment. Whittaker suggested that the fungi (which include the mushrooms, molds, and yeasts) be removed from the plant kingdom and classified in their own kingdom **Fungi.** After all, fungi are not photosynthetic and must absorb nutrients produced by other organisms. Fungi also differ from plants in the composition of their cell walls, in their body structures, and in their modes of reproduction. Kingdom **Prokaryotae** was established to accommodate the bacteria, which are fundamentally different from all other organisms in that they do not have distinct nuclei and other membranous organelles and do not undergo mitotic division.

In the late 1970s, Carl Woese (pronounced "woes"), of the University of Illinois, and his colleagues began to study the evolutionary relationships among organisms by analyzing their RNA. A component of ribosomes, small subunit ribosomal RNA (SSU rRNA)), specifically the 16S[1] rRNA nucleotide sequence, is highly conserved: The gene that codes SSU rRNA is present in all known organisms, and its function has remained the same through time. Using sequence analysis, Woese used variations in this universal molecule to challenge the long-held view that all prokaryotes were closely related and very similar to one another. He proposed that there are two fundamentally different groups of bacteria, Archaebacteria and Eubacteria and that the prokaryotes account for two of three of the major branches of organisms.

Woese's hypothesis gained support in 1996 when Carol J. Bult of the Institute for Genomic Research in Rockville, Maryland, reported in the journal *Science* that she and her colleagues had sequenced the complete genome of a methane-producing archaebacterium *Methanococcus jannaschii.* When these researchers compared gene sequences with those of two previously sequenced eubacteria, they found that fewer than half of the genes matched. Given this molecular evidence, many biologists divided the prokaryotes into kingdom **Eubacteria** and kingdom **Archaebacteria.**

Most systematists now use a level of classification above the kingdom, called a **domain,** based on fundamental molecular differences among the Eubacteria, Archaebacteria, and eukaryotes. They classify organisms in three domains: **Archaea** (which corresponds to kingdom Archaebacteria), **Eubacteria** (also called Bacteria), and **Eukarya** (eukaryotes; Fig. 22-2). An important character that distinguishes the Archaea from the Eubacteria is the absence of the compound peptidoglycan in the cell walls of the Archaea (discussed in Chapter 23). Gene sequencing indicates the Archaea have a combination of bacteria-like and eukaryote-like genes and appear more closely related to the Eukarya than to the Eubacteria. For example, the Archaea do not have the simple RNA polymerase characteristic of Eubacteria.

[1] The number 16S refers to the sedimentation coefficient (a measure of relative size) when centrifuged.

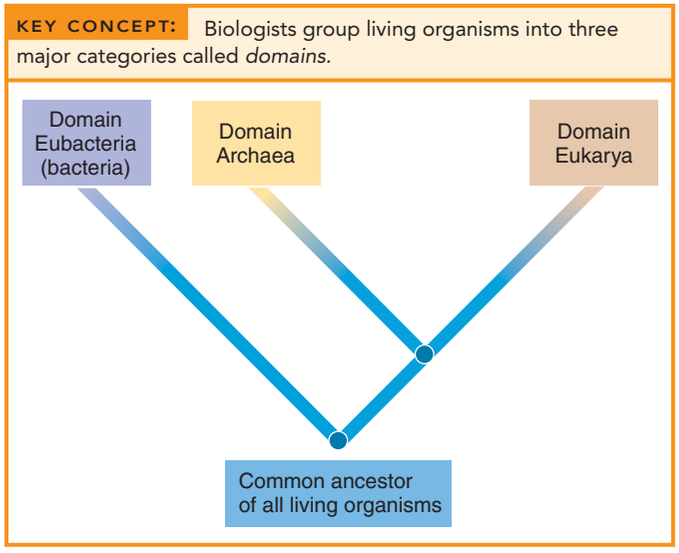


FIGURE **22-2** **The three domains.**

This branching diagram, called a *cladogram,* illustrates the evolutionary relationships among organisms in the three domains. The branches portray ancestral populations of each group through time. Each node (circle) represents the immediate common ancestor of the groups that branch from it.

Increasingly, many biologists now classify organisms in domains rather than kingdoms. However, some biologists use both kingdoms and domains, classifying organisms into three domains and six kingdoms; we use this classification in the seventh edition of *Biology.* The six kingdoms are Eubacteria, Archaebacteria, Protista, Fungi, Plantae, and Animalia (Fig. 22-3 and Table 22-2).

In recent years, biologists have been surprised to discover that evolution is not linear. During the course of evolution, genes were not only passed down vertically from one generation to the next but were also exchanged laterally (horizontally), for example, by occasional interbreeding between closely related species. Such movement of genes from organisms in one taxon to related organisms in another taxon is called **lateral gene transfer.**

The evolution of systematics reflects the creative and dynamic process of science. Systematists are very responsive to new data, and consequently classification of organisms at all levels is a challenging and continuously changing process. As we discuss in Chapter 24, some biologists are moving toward a 10-kingdom system of classification. An important goal is to base classification on evolutionary change and relationships, so that we can use classification to reconstruct the history of life.

FIGURE **22-3**

The six-kingdom system of classification.

Compare this cladogram to Figure 22-2. Note that kingdoms Protista, Plantae, Animalia, and Fungi can be assigned to domain Eukarya. The Protista are a very diverse group with several major branches. Systematists may eventually divide them into two or more kingdoms. Note that this diagram is greatly simplified. As in Figure 22-2, the nodes represent branch points where a species splits and two or more populations diverge and evolve independently.

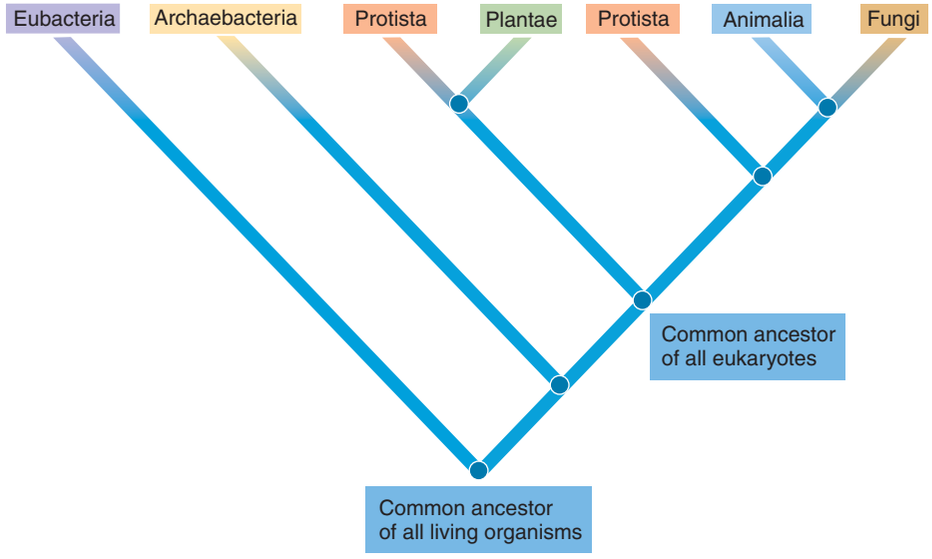

TABLE **22-2** **Domain and Kingdoms: Eubacteria, Archaebacteria, Protista, Fungi, Plantae, and Animalia**

Domain	Kingdom	Characteristics	Ecological Role and Comments
Eubacteria	Eubacteria	Prokaryotes (lack distinct nuclei and other membranous organelles); unicellular; microscopic; cell walls generally composed of peptidoglycan.	Most are decomposers; some parasitic (and pathogenic): some chemosynthetic autotrophs; some photosynthetic; important in recycling nitrogen and other elements; some used in industrial processes.
Archaea	Archaebacteria	Prokaryotes; unicellular; microscopic; peptidoglycan absent in cell walls; differ biochemically from eubacteria.	Methanogens are anaerobes that inhabit sewage, swamps, and animal digestive tracts; extreme halophiles inhabit salty environments; extreme thermophiles inhabit hot, sometimes acidic environments.
Eukarya	Protista	Eukaryotes; mainly unicellular or simple multicellular. Three informal groups (not taxa) include protozoa; algae; and slime molds and water molds.	Protozoa are an important part of zooplankton. Algae are important producers, especially in marine and freshwater ecosystems; important oxygen source.
	Fungi	Eukaryotes; heterotrophic; absorb nutrients; do not photosynthesize; body composed of threadlike hyphae that form tangled masses that infiltrate food or habitat; cell walls of chitin.	Decomposers; some parasitic (and pathogenic); some used as food; yeast used in making bread and alcoholic beverages; some used to make industrial chemicals or antibiotics; responsible for much spoilage and crop loss.
	Plantae	Eukaryotes; multicellular; photosynthetic; possess multicellular reproductive organs; alternation of generations; cell walls of cellulose.	Terrestrial biosphere depends on plants in their role as primary producers; important source of oxygen in Earth's atmosphere.
	Animalia	Eukaryotes; multicellular heterotrophs; many exhibit tissue differentiation and complex organ systems; most able to move about by muscular contraction; nervous tissue coordinates responses to stimuli.	Consumers; some specialized as herbivores, carnivores, or detritus feeders.

Review

- Contrast the three domains.
- What are the advantages of a "six-kingdom" system over a "two-kingdom" system?
- What types of organisms are especially difficult to assign to a kingdom?
- In which domain and kingdom would you classify each of the following? (a) oak tree (b) amoeba (c) *Escherichia coli* (d) tapeworm (e) black bread mold

BiologyNow™ Assess your understanding of **kingdoms and domains** by taking the pretest on your BiologyNow CD-ROM.

RECONSTRUCTING PHYLOGENY

Learning Objectives

5 Critically summarize the difficulties encountered in choosing taxonomic criteria.

6 Apply the concept of shared derived characters to the classification of organisms.

7 Identify methods of molecular biology now used by taxonomists, and summarize the advantages of molecular taxonomy.

8 Contrast monophyletic, paraphyletic, and polyphyletic taxa.

In Chapter 17 you learned that evolution is the accumulation of inherited changes within populations over time. Recall that a **population** is made up of all the individuals of the same species that live in a particular area. A population has a dimension in space—its geographic range—and also a dimension in time. Each population extends backward in time. Somewhat like branches of a tree, a population may diverge from other populations enough to become a new species (that is, a new tree branch; see Chapters 18 and 19). Species have various degrees of evolutionary relationships with one another, depending on the degree of genetic divergence since their populations branched from a common ancestor.

PROCESS OF SCIENCE

The goal of systematics is to reconstruct **phylogeny** (literally, "production of phyla"), the evolutionary history of a group of organisms from a common ancestor. As they determine evolutionary relationships among and between species and higher taxa, systematists build classifications based on common ancestry. Once phylogenies are established, they help answer other questions in biology. For example, phylogenies help us understand evolutionary patterns that might provide clues to the origin and spread of HIV and other pathogens. Phylogenies also help predict characteristics of newly discovered species. Systematists may classify a new species based on specific characters that it shares with other organisms in a particular grouping. They may then infer that the new species shares other characters with organisms in that group.

As you read the following sections, remember that phylogenies are testable hypotheses. They are supported or falsified by the available data. Thus, systematics is a dynamic science that changes as biologists discover new species and use ever more sophisticated techniques to investigate the evolutionary relationships among organisms.

Homologous structures are important in determining evolutionary relationships

Just how to determine phylogeny and how to group species into higher taxa—genera, families, orders, classes, or phyla—can be difficult decisions. Traditionally, many biologists have based their judgments about the degree of relationship on the extent of similarity among living species and, when available, on the fossil record.

When they evaluate similarities, systematists now consider structural, physiological, developmental, behavioral, and molecular traits. When comparing these similarities, they look for homology in different organisms. Recall from Chapter 17 that **homology** refers to the presence, in two or more species, of a structure derived from a recent common ancestor. For example, the bones in the wings of a bird and a bat are homologous. In contrast, similar structures in two or more species not derived from a recent common ancestor sometimes result when unrelated or distantly related species become adapted to similar environmental conditions. For example, although the wings of a butterfly are adapted for flight, they have a different structure from bird wings, and these animals do not share a common winged ancestor. Sharks and dolphins have similar, but independently derived, body forms because they have become adapted to similar environments (aquatic) and lifestyles (predatory). A characteristic that superficially appears homologous, but is actually independently acquired, is described as exhibiting **homoplasy.**

Shared derived characters provide clues about phylogeny

Organisms sharing many homologous structures are considered closely related, while organisms sharing few homologous characters are presumed less closely related. However, distinguishing between homology and homoplasy is not always straightforward. Therefore, carefully selecting similarities that indicate evolutionary relationships is extremely important.

How does a systematist interpret the significance of these similarities? In making decisions about taxonomic relationships, the systematist first examines the characteristics in the largest group (such as phylum or class) of organisms being studied and interprets them as indicating the most remote common ancestry. These **shared ancestral characters,** or **plesiomorphic characters,** are features that were present in an ancestral species and remain present in all groups descended from that ancestor. For example, the vertebral column, present in all vertebrates, is an ancestral character for study of classes within the subphylum Vertebrata. Studying the presence or absence of the vertebral column does not help us discriminate among various classes of vertebrates. For example, we could not distinguish between amphibians and mammals, because all individuals in these classes have a vertebral column.

Shared derived characters, or **synapomorphic characters,** are traits found in two or more taxa that first appeared in their most recent common ancestor. A feature viewed as a *derived character* in a more inclusive (broader) taxon may also be considered an *ancestral character* in a less inclusive (narrower) taxon. More recent common ancestry is indicated by classification into less and less inclusive taxonomic groups with more and more specific shared derived characters. For example, the three small bones in the middle ear are useful in identifying a branch point between reptiles and mammals. The evolution of this derived character was a unique event, and only mammals have these bones. However, if we compare mammals with one another, the three ear bones are a shared ancestral character, because all mammals have them. Consequently, they have no value in distinguishing among mammalian taxa. Other characters must be used to establish branch points among the mammals.

If we compare dogs, goats, and dolphins (all of which are mammals), we find that dogs and goats have abundant hair whereas dolphins do not. Hair is an ancestral trait in mammals and therefore cannot be used as evidence that dogs and goats share a more recent common ancestor. In contrast, the virtual absence of hair in mature dolphins is a derived character within mammals. When we compare dogs, dolphins, and whales, we find that dolphins and whales share this derived character, providing evidence that these animals evolved from a common ancestor not shared by dogs.

Biologists carefully choose taxonomic criteria

Both fishes and dolphins have streamlined body forms, but this characteristic is homoplastic and does not indicate close evolutionary relationships. The dolphin shares important homologous derived characters (synapomorphies) with mammals such as humans: mammary glands, which produce milk for the young, three small bones in the middle ear, and a muscular diaphragm that helps move air into and out of the lungs. Thus the dolphin is classified as a mammal.

Although dolphins have more shared derived characters in common with humans than with fishes, some characters are shared by all three of these animals. Among these ancestral characters are a dorsal tubular nerve cord and, during embryonic development, a notochord (skeletal rod) and rudimentary gill slits. These shared ancestral characters (plesiomorphies) indicate a common ancestry and serve as a basis for classification. The ancestry is more remote between the dolphin and the fish than between the dolphin and the human. Therefore, although fishes, humans, and dolphins are grouped together in a more inclusive taxon, the phylum Chordata, humans and dolphins are also classified together in class Mammalia, a less inclusive taxon within phylum Chordata, indicating that they are more closely related.

PROCESS OF SCIENCE

Determining which traits best illustrate evolutionary relationships can be challenging. What, for example, are the most important taxonomic characteristics of a bird? We might list feathers, beak, wings, absence of teeth, egg laying, and the fact that they are endotherms (animals that use metabolic heat to maintain a constant body temperature despite variations in surrounding temperature). Some mammals, for example, monotremes such as the duck-billed platypus, have many of these same characteristics: beaks, endothermy, absence of teeth, and egg laying. Yet we do not classify them as birds (Fig. 22-4). No mammal, however, has feathers. Is this trait absolutely diagnostic of birds? According to the conventional taxonomic wisdom, the presence or absence of feathers determines what is and is not a bird. This applies only to modern birds, however. A number of dinosaur fossils indicates that some extinct reptiles had feathers.

Usually organisms are classified on the basis of a combination of traits rather than on any single trait. The significance of these combinations is determined inductively, that is, by integrating and interpretating the data. Such induction is a necessary part of the process of science. Taxonomists may hypothesize, for example, that all birds should have beaks, feathers, no teeth, and so forth. Then they re-examine the living world and observe whether any organisms might reasonably be called birds that do not fit the current definition of "birdness." If not, the definition stands. If too many exceptions emerge, the definition may be modified or abandoned. Sometimes the taxonomist determines that an apparent exception—the bat, for instance—resembles a bird only superficially and should not be considered one. The bat has all the basic characteristics of a mammal, such as hair and mammary glands that produce milk for the young.

Molecular biology provides additional characters

When a new species evolves, it does not always exhibit obvious phenotypic differences relative to closely related species. For example, two distinct species of fruit flies may appear identical. Some of their DNA, proteins, and other molecules, however, are different. Such variations in the structure of specific macromolecules among species, just like differences in anatomical structure, result from mutations. Macromolecules that are functionally similar in two different types of organisms are considered homologous if their subunit sequence is similar.

The science of **molecular systematics** focuses on the use of molecular structure to clarify evolutionary relationships. Advances in molecular biology have provided the tools for biologists to compare the macromolecules of various organisms. DNA, RNA, and amino acid sequencing are used to compare macromolecules. Comparisons of amino acid sequences of proteins and nucleotide sequences of nucleic acids provide systematists with valuable information about the degree of relatedness among organisms. The more subunit sequences of two species correspond, the more closely related they are considered to be. The number of differences in certain DNA or RNA nucleotide sequences or in amino acid sequences in two groups of organisms may reflect how much time has passed since the groups branched from a common ancestor. (This can be true only if the rates of change have remained constant.) Thus specific genes and specific proteins are sometimes used as **molecular clocks** (see Chapter 17).

FIGURE **22-4** **Is this animal a bird?**

A few mammals, such as the duck-billed platypus, lay eggs, have beaks, and lack teeth. However, the platypus does not have feathers, and it nourishes its young with milk secreted from mammary glands.

Jean Philippe Varin/Jacana/Photo Researchers, Inc.

PROCESS OF SCIENCE

Systematists compare ribosomal RNA structure to help determine phylogenies (evolutionary histories). All known organisms have ribosomes that function in protein synthesis, and certain ribosomal RNA nucleotide sequences have been highly conserved in evolution. Recall that the division of organisms into three domains was based, in large part, on the comparison of ribosomal RNA by Carl Woese and his research team at the University of Illinois. All prokaryotic ribosomes contain three types of RNA, named in order of increasing size: 5S, 16S, and 23S. The 5S and 16S RNAs have been extensively used to determine evolutionary relationships among bacteria because the number of base pairs is manageable and because these molecules are transcribed from highly conserved regions of DNA.

Comparison of ribosomal RNA sequences has also been used to challenge the once widely accepted idea that fungi are closely related to plants. According to ribosomal RNA analysis, fungi are more closely related to animals than to plants; that is, animals and fungi share a more recent common ancestor, perhaps a flagellate protist.

In 1997 molecular taxonomist Robert Wayne, of the University of California at Los Angeles, and his international team of researchers compared mitochondrial DNA sequences from 162 wolves at 27 different geographic locations with those from domestic dogs of 67 different breeds (Fig. 22-5). They reported that dog and wolf nucleotide sequences were similar, differing by no more than 12 substitutions. In contrast, dog sequences differ by at least 20 substitutions from jackal and coyote DNA. Wayne and his colleagues concluded that dogs evolved from wolves. Extending Wayne's work, Peter Savolainen, of the Royal Institute of Technology in Stockholm, and his colleagues compared mitochondrial DNA samples from hundreds of dogs throughout the world. Their findings, reported in 2002, supported Wayne's work, and they further concluded that dogs evolved in a single geographic site of origin, most likely China.

The new tools provided by molecular biology have put systematics on the cutting edge of biological research. Biologists are no longer limited by subjective decisions regarding anatomical similarities among organisms. Comparison of molecular structure is far more precise. For example, until recently the African elephant and the Indian elephant were the only two species of living elephants recognized. Using molecular methods, biologists have demonstrated that there are at least two distinct species of African elephants. Each species has its distinctive DNA barcode.

Taxa should reflect evolutionary relationships

Based on molecular data and other taxonomic criteria, systematists recognize three kinds of taxonomic groupings: monophyletic, paraphyletic, and polyphyletic. A **monophyletic taxon** includes an ancestral species and all its descendants (Fig. 22-6a). Mammals, for example, form a monophyletic taxon because all mammals are thought to have evolved from a common ancestral mammal, and all descendants of this ancestor are mammals. Monophyletic taxa are natural groupings, because they represent true evolutionary relationships and include all close relatives.

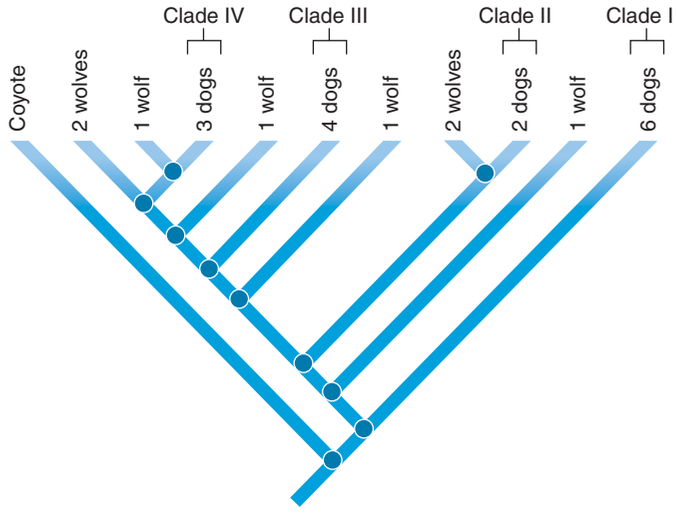

FIGURE **22-5** **Molecular taxonomy.**

Diagram of the relationships of 8 wolves and 15 dogs based on differences in mitochondrial DNA. The researchers compared 1030 base pairs of a segment of mitochondrial DNA. Wolf and dog sequences were very similar, differing by no more than 12 substitutions. Dog and coyote sequences differed by at least 20 substitutions. Four separate clades (lineages) of dogs were identified among various wolf lineages, suggesting multiple origins.

A **paraphyletic taxon** is a group that contains a common ancestor and some, but not all, of its descendants. As discussed later in this chapter, the class Reptilia is paraphyletic because it does not include all descendants of the most recent common ancestor of reptiles. Birds are thought to share a recent common ancestor with reptiles, but evolutionary systematists assign birds to their own class. Cladistic systematists (discussed later in this chapter) avoid constructing paraphyletic taxa.

A **polyphyletic group,** such as the Protista, consists of several evolutionary lines that do not share the same recent common ancestor (Fig. 22-6b). Biologists might have mistakenly grouped together the members of such a taxon because these organisms share similar (homoplastic) features arising from convergent evolution (see Chapter 17). Systematists avoid constructing polyphyletic taxa, because they are unnatural and misrepresent evolutionary relationships.

Review

- How are shared ancestral characters and shared derived characters different?
- Why don't shared ancestral characters provide evidence for relationships between organisms within a taxon that has those traits? Give an example.
- Of what use to a taxonomist is knowledge of the amino acid sequences of the proteins of various organisms?
- How does a monophyletic taxon differ from a polyphyletic taxon?

BiologyNow™ Assess your understanding of **reconstructing phylogeny** by taking the pretest on your BiologyNow CD-ROM.

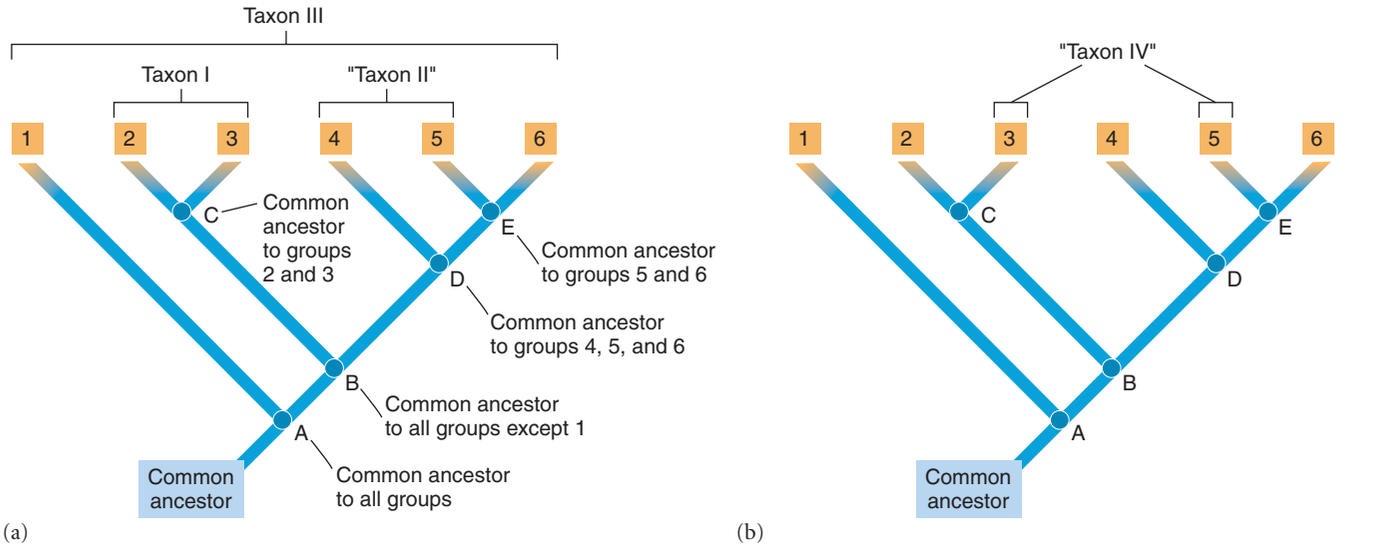

FIGURE **22-6** **Evolutionary relationships.**

In both figures, node A represents the common ancestor of all groups shown. Node C represents the common ancestor for groups 2 and 3. Node D represents the common ancestor for groups 4, 5, and 6. **(a)** Monophyletic and paraphyletic groups. Taxon I and taxon III are monophyletic. Each includes a common ancestor and all its descendants. "Taxon II" is paraphyletic; it does not include all the descendants of a common ancestor. **(b)** "Taxon IV" is polyphyletic; members of this group do not share a most recent common ancestor. (Paraphyletic and polyphyletic "taxa" are indicated with quotation marks because they are not natural evolutionary groupings.)

TWO MAJOR APPROACHES TO SYSTEMATICS

Learning Objective

9 Compare and contrast two approaches to systematics: evolutionary systematics and cladistics (phylogenetic systematics).

In determining the relationships among organisms, systematists use a variety of data and methods. How data are analyzed and interpreted depends on the systematist's approach. **Phenetics,** or **numerical taxonomy,** was an early approach to the quantitative analysis of characters. First gaining attention of systematists in the 1960s, phenetics is based on as many phenotypic similarities (that is, similarities in *appearance*) as possible. In the phenetic approach, computer programs are used to analyze data and group organisms according to the number of shared characteristics. No attempt is made to determine whether their similarities arose from a common ancestor or from convergent evolution. Pheneticists argue that it is not important to try to differentiate between homology and homoplasy, because many more similarities are due to homology than to homoplasy. Thus the number of similarities two organisms have in common reflects the degree of homology.

Some phenetic techniques are currently used in molecular taxonomy. For example, if each amino acid in a protein is considered a character, amino acid sequences of various animals can be determined in the laboratory and compared by computer. The information about differences in amino acid sequences can be used to construct phylogenetic diagrams. Species are placed at relative distances from each other, reflecting the extent of difference in amino acid sequence.

The two major approaches to systematics that are widely used today are **evolutionary systematics** and **cladistics,** also known as **phylogenetic systematics.** Although we discuss them separately here, many modern systematists use aspects of both approaches in their work. Although evolutionary systematists and cladists evaluate phenotypic traits as pheneticists would, they also consider whether similarities arise through common ancestry or convergent evolution. In addition, they consider dissimilar traits that may share a common origin but have diverged over evolutionary time.

Evolutionary systematics allows paraphyletic groups

Evolutionary systematics, sometimes called *classical evolutionary systematics,* uses a system of phylogenetic classification and presents evolutionary relationships in phylogenetic trees. Evolutionary systematists consider both evolutionary branching (as do cladists) and the extent of divergence (structural and other changes) that has occurred in a lineage since it branched from a stem group. They use a combination of shared ancestral characters and shared derived characters to establish evolutionary relationships and build classifications.

Many, perhaps most, of the taxa currently recognized by evolutionary systematists are monophyletic, based on possession of shared derived characters. Cladists also recognize these taxa. For example, proponents of both approaches agree that birds are a monophyletic taxon based on shared derived characters such as feathers. However, evolutionary systematics also recognizes paraphyletic taxa, groups that include some, but not all, subgroups of organisms that share the same most recent

common ancestor. Paraphyletic groupings are based on a combination of shared ancestral and shared derived characters.

Evolutionary systematists recognize class Reptilia as a valid group that does not include birds because it includes the common ancestor of all reptiles and it lacks the derived features of birds (such as feathers). Class Reptilia does not include all subgroups, such as birds, that evolved from the ancestral reptile (Fig. 22-7a); evolutionary systematists assign birds to a separate class because they have diverged markedly from the reptiles. In contrast, cladists do not recognize reptiles as a natural grouping containing snakes, lizards, crocodiles, dinosaurs, and turtles because they do not form a monophyletic group, or **clade.** Instead, they recognize a clade that includes birds.

Cladistics emphasizes phylogeny

The cladistic approach to systematics emphasizes common ancestry, rather than phenotypic similarity, as the basis for classification. Cladists base their assessment on shared derived characters that can be structural, behavioral, physiological, or molecular. The characters must be homologous. According to cladistics, dolphins are classified with mammals rather than with fishes, because dolphins and mammals share derived characters not present in fishes, indicating a more recent common ancestor. Cladistics uses shared derived characters to reconstruct phylogenies.

Cladists determine the evolutionary relationships of organisms and express them in branching diagrams called **cladograms.** Each branch on a cladogram represents the divergence, or splitting, of two or more new groups from a common ancestor. Each branch point, referred to as a **node,** represents the immediate common ancestor of the next monophyletic group depicted in the cladogram. Consider the evolutionary grouping of mammals, lizards, snakes, crocodiles, dinosaurs, and birds (Fig. 22-7b). Birds, along with dinosaurs, are thought to share a common ancestor with modern crocodiles and alligators (node D on Fig. 22-7b). Crocodiles, dinosaurs, and birds, then, constitute a monophyletic group, and cladists would classify them in the same clade. Similarly, snakes and lizards form a clade that is the closest group to birds, dinosaurs, and crocodiles. Mammals form an additional clade.

When cladists consider the evolutionary relationships of organisms, they must choose between multiple, competing cladograms. How do they make this choice? The most common criterion is the principle of **parsimony**—they choose the simplest explanation to interpret the data. Parsimony, a guiding principle in many areas of research, is based on the experience that the simplest explanation is most probably the correct one. Applied to choice of cladograms, parsimony requires that the cladogram with the fewest changes in characters (the one with the fewest homoplasies) be accepted as most probable (Fig. 22-8). In actual practice it is often possible to generate several cladograms that are equally parsimonious.

A crucial step in most cladistic analyses is **outgroup analysis,** a method for estimating which attributes are shared derived characters in a given group of taxa. An **outgroup** is a taxon that is considered to have diverged earlier than the taxa under investigation, the **ingroups,** and thus to represent an approximation of the ancestral condition. An ideal outgroup is the closest relative of the group being studied (its sister group) and has not been highly modified since its origin. Systematists argue that such a group is likely to retain the ancestral state for characters being

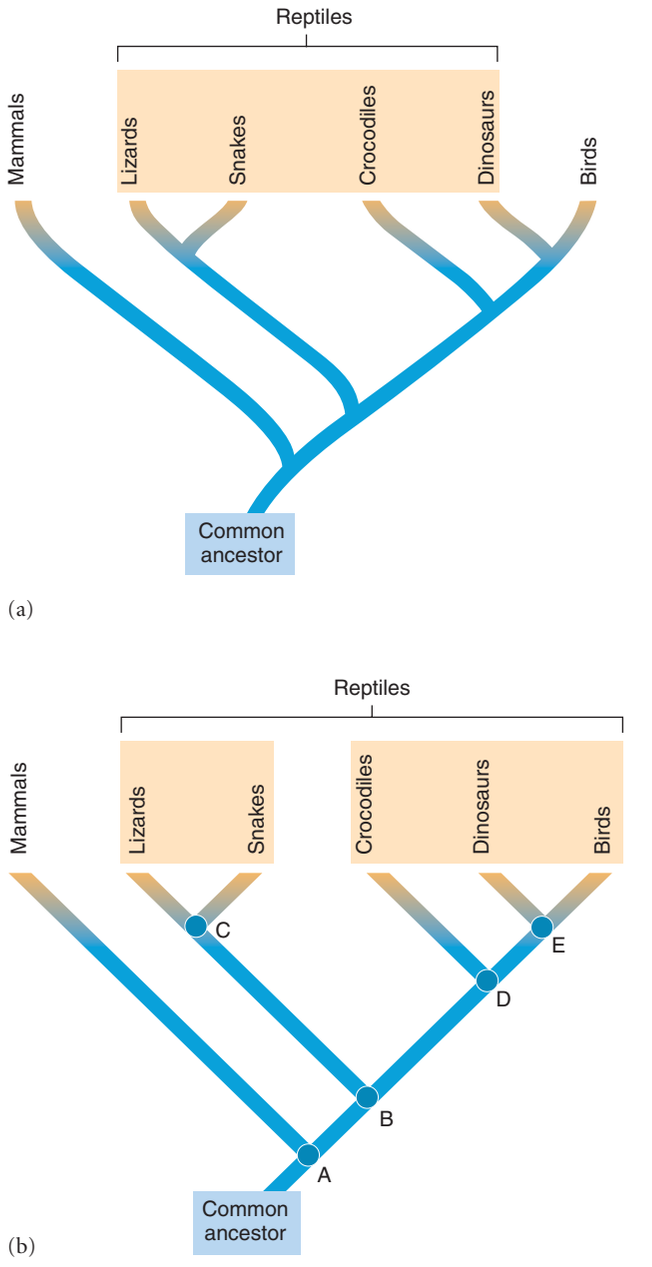

FIGURE **22-7** **Two approaches to the classification of reptiles, birds, and mammals.**

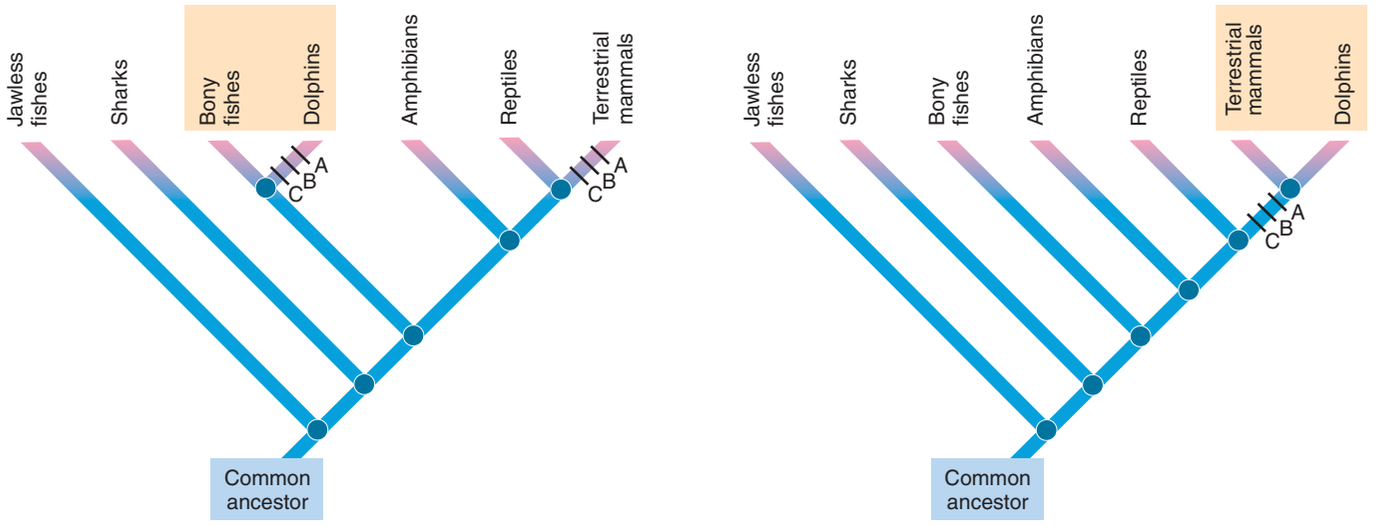
(a) The evolutionary systematics approach considers both common ancestry and extent of divergence that has occurred since two taxa split. The branching points and degrees of difference in the evolution of the major groups of reptiles are shown. Reptiles are a paraphyletic group. Snakes, lizards, and crocodiles are phenotypically most similar, but crocodiles, dinosaurs, and birds are most closely related because they evolved most recently from a common ancestor. **(b)** Cladists classify birds and some reptiles together because they have a recent common ancestor. Node D represents the common ancestor of crocodiles, dinosaurs, and birds.



(a) Hypothesis 1: Dolphins and bony fishes are close relatives

(b) Hypothesis 2: Dolphins and terrestrial mammals are close relatives

FIGURE **22-8** **Using parsimony to choose alternative hypotheses of relationships.**

Are dolphins more closely related to bony fishes or to terrestrial mammals? Three characters are examined: Character A = hair; B = mammary glands; C = middle-ear ossicles. In hypothesis 1, all three characters examined had to evolve independently twice. Hypothesis 2 is chosen because it requires that each character evolve only once.

used in the analysis, allowing them to identify the evolutionary changes leading to derived characters. To help you understand outgroup analysis, we now consider a specific example.

Outgroup analysis is used in building and interpreting cladograms[2]

PROCESS OF SCIENCE

The first step in constructing a cladogram is to select the taxa, which may consist of individuals, species, genera, or other taxonomic levels. Here we use a representative group of eight chordates (Fig. 22-9). The next step is to select the homologous characters to be analyzed. In our example, we use seven characters. For each character, we must define all the different conditions, or states, as they exist in our taxa. For simplicity, we consider our characters to have only two different states: present or absent. Keep in mind that many characters used in cladistics have more than two states. For example, black, brown, yellow, and red may be only a few of the many possible states for the character of hair color.

The last, and often the most difficult, step in preparing the data is to organize the character states into their correct evolutionary order. Outgroup analysis is used. In our example, amphioxus, a small chordate with a fishlike appearance, is the chosen outgroup. It belongs to a taxon that is considered to have diverged earlier than any of the other taxa under investigation but to be closely related to vertebrates; thus amphioxus represents an approximation of the ancestral condition for vertebrates. Therefore, the character state "absent" for a particular character state such as vertebrae is the ancestral condition, and the character state "present" is the derived condition for the characters in Figure 22-9.

A cladogram is constructed by considering shared derived characters

Our objective is to construct a cladogram that requires the fewest number of evolutionary changes in the characters. Recall that in cladistics, taxa are grouped by the presence of shared derived characters. To form a valid monophyletic group, all members must share at least one derived character. Membership in a clade cannot be established by shared ancestral characters.

In our example, notice that all taxa except the outgroup amphioxus possess vertebrae. We can therefore conclude that these seven vertebrate taxa form a valid clade. Next, among the seven vertebrate taxa, note that jaws are present in all groups except for lampreys. Using these data, we construct a preliminary cladogram (Fig. 22-9a).

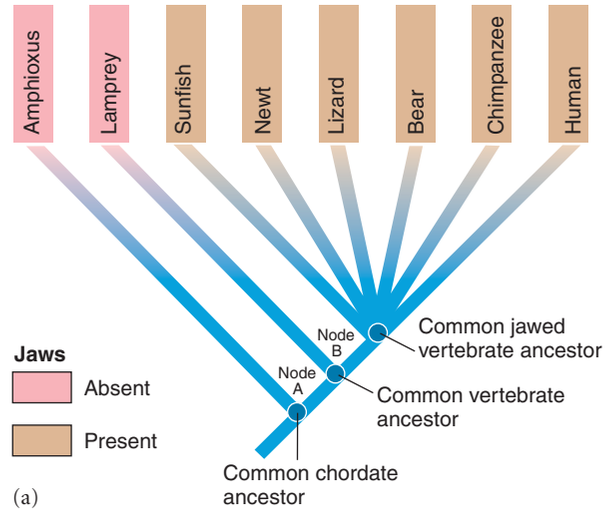
The base of the cladogram represents the common ancestor for all taxa being analyzed. In Figure 22-9a, node A represents the common chordate ancestor from which the outgroup

FIGURE **22-9** **Building a cladogram.** ▶

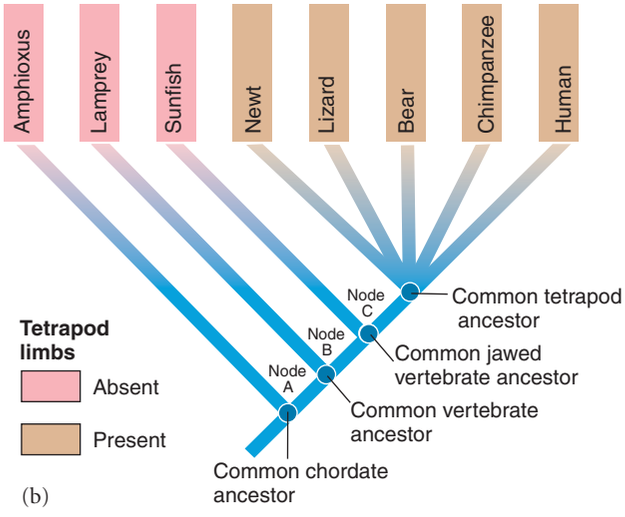
In this example, amphioxus is the chosen outgroup that represents an approximation of the ancestral condition. Refer to the table as you follow the process in (a) through (e).

[2] This discussion of building and interpreting cladograms is based on an essay contributed to *Biology,* 4th ed., by Dr. John Beneski, Department of Biology, West Chester University, West Chester, Pennsylvania.

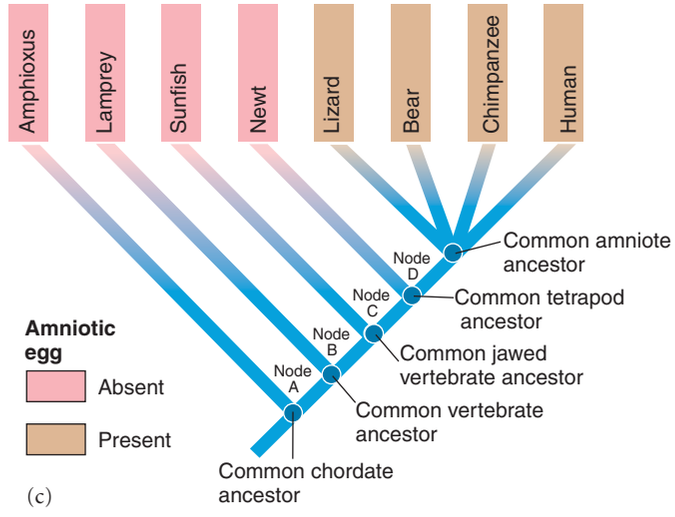
A = Absent B = Present TAXA	CHARACTERS						
	Vertebrae (backbones)	Jaws	Tetrapod (4 limbs)	Amniotic egg	Mammary glands	Opposable thumb	Upright posture
Amphioxus (outgroup)	A	A	A	A	A	A	A
Lamprey	P	A	A	A	A	A	A
Sunfish	P	P	A	A	A	A	A
Newt	P	P	P	A	A	A	A
Lizard	P	P	P	P	A	A	A
Bear	P	P	P	P	P	A	A
Chimpanzee	P	P	P	P	P	P	A
Human	P	P	P	P	P	P	P



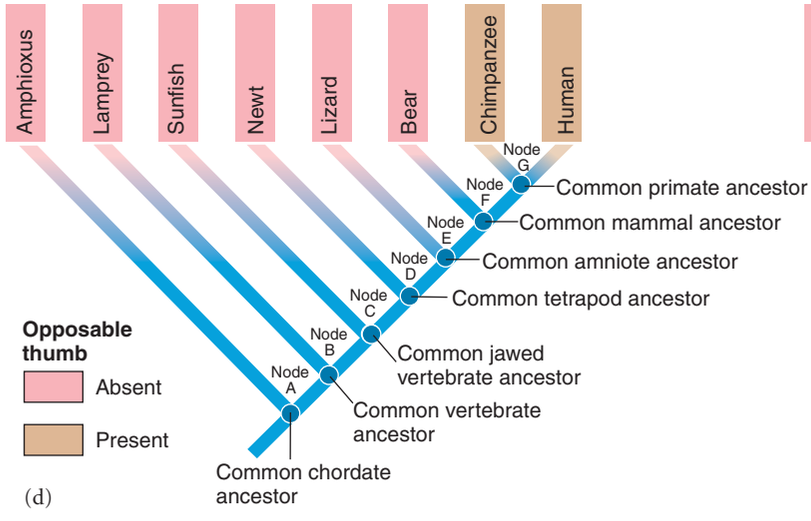
(a)



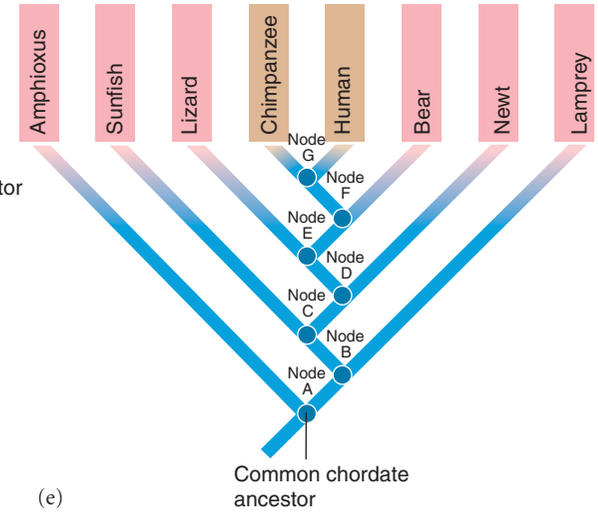
(b)



(c)



(d)



(e)

(amphioxus) and the seven vertebrate taxa evolved. Similarly, node B represents the common ancestor of the vertebrates and node C, the common ancestor of the jawed vertebrates. Continuing with this procedure, notice that among the six-jawed taxa, all but sunfish are tetrapods (animals with four limbs) (Fig. 22-9b). Among the five tetrapods, all but newts have amniotic eggs (Fig. 22-9c). (In an amniotic egg, the embryo is surrounded by a fluid-filled sac, called an *amnion*.) The branching process is continued, using the data in the table in the upper left-hand corner of the figure, until all clades are established (Fig. 22-9d).

In a cladogram each branch point represents a major evolutionary step

In Figure 22-9d, notice that humans and chimpanzees share a recent common ancestor at node G. This hypothesis is supported by the derived characters (synapomorphies) they share. In the same way, bears are more closely related to the human–chimpanzee clade than to any other clade considered in our example, as indicated by the common ancestor at node F. In comparing the nodes, the order of divergence (branching) is indicated by distance from the base of the diagram. The further a node is located up the cladogram, the more recently the group diverged. In our example, node G represents the most recent divergence, and node A represents the most ancient divergence. Thus, in our example, humans are closely related to chimpanzees (through node G) but more distantly related to bears (through node F). Therefore humans and chimpanzees are assigned to a less inclusive taxon (order Primates) whereas humans, chimpanzees, and bears are assigned to a broader, more inclusive taxon (class Mammalia). In addition, the cladogram reveals that lizards are more closely related to the mammal clade than to newts, sunfish, or any other clade. Can you explain why?

Two important concepts guide interpretation of cladograms. First, the relationships among taxa is determined only by tracing along the branches back to the most recent common ancestor (node) and not by the relative placement of the branches along the horizontal axis. It is possible to represent the same relationships with many different types of branching diagrams. For example, the cladogram in Figure 22-9e is equivalent to the one in Figure 22-9d. (Verify this by comparing the numbered nodes and by checking the relationships described earlier.)

A second key concept is that the cladogram tells us which taxa shared a common ancestor and how recently they shared a common ancestor. The ancestor itself remains unspecified. The cladogram does not establish direct ancestor–descendant relationships among taxa. In other words, a cladogram does not suggest a taxon gave rise to any other taxon.

Many evolutionary questions remain. New hypotheses about how organisms are related suggest new taxonomic schemes. Systematics offers tools to help us test these hypotheses. In Chapters 23 through 30 we explore many evolutionary puzzles and discuss current hypotheses about relationships and classifications of organisms.

Review

- How are the methods of cladists and evolutionary systematists similar?
- Which systematists do not recognize paraphyletic groups?
- What does a node represent in a cladogram?
- What is outgroup analysis?

BiologyNow™ Assess your understanding of **the two major approaches to systematics** by taking the pretest on your BiologyNow CD-ROM.

SUMMARY WITH KEY TERMS

1 State at least two justifications for the use of scientific names and classifications of organisms.

- **Systematics** is the scientific study of the diversity of organisms and their evolutionary relationships. The term **biological diversity,** or **biodiversity,** refers to the variety of living organisms and the ecosystems they form.
- **Taxonomy** is the branch of systematics devoted to naming, describing, and classifying organisms. The process of assigning organisms into groups based on their similarities or relationships is **classification.** Classifications help biologists organize their knowledge.
- Scientific names are important because they allow biologists from different countries with different languages to communicate about organisms. Biologists in distant locations must know with certainty that they are studying the same (or different) organisms.
- Biologists name organisms using the **binomial system of nomenclature** developed by Linnaeus in the mid-18th century. In this system the basic unit of classification is the **species.**
- The name of each species has two parts: the **genus** name followed by the **specific epithet.** For example, the scientific name of the human is *Homo sapiens,* and that of the white oak is *Quercus alba.*

2 Arrange the Linnaean categories in hierarchical fashion, from most inclusive to least inclusive.

- The hierarchical system of classification used in this book includes **domain, kingdom, phylum, class, order, family, genus,** and **species.** Each formal grouping at any given level is a **taxon.**

3 Describe the three domains and six kingdoms of organisms introduced in this chapter, and give the rationales for and against this system of classification.

- The three-domain classification system assigns organisms to domain **Archaea,** domain **Eubacteria,** or domain **Eukarya.**
- The six-kingdom classification recognizes the kingdoms **Archaebacteria, Eubacteria, Protista, Fungi, Plantae,** and **Animalia.**

4 Given its distinguishing characters, classify an organism in the appropriate domain and kingdom.

- Domain Eubacteria (kingdom Eubacteria) is distinguished by the presence of the compound peptidoglycan in cell walls. Peptidoglycan is absent in the cell walls of the Archaea.
- Domain Archaea (kingdom Archaebacteria) has a combination of bacteria-like and eukaryote-like genes and may be more closely related to the Eukarya than to the Eubacteria. For exam-

SUMMARY WITH KEY TERMS *(continued)*

ple, the Archaea do not have the simple RNA polymerase characteristic of Eubacteria.

- Domain Eukarya consists of the eukaryotes: kingdoms Protista, Fungi, Plantae, and Animalia.
- For characteristics of the six kingdoms, refer to Table 22-2.

5 Critically summarize the difficulties encountered in choosing taxonomic criteria.

- The goal of systematics is to determine evolutionary relationships, or **phylogeny,** based on shared characteristics. Historically, scientists have depended mainly on structural similarities to make decisions about phylogeny.
- **Homology,** the presence in two or more species of a structure derived from a recent common ancestor, implies evolution from a common ancestor. The term **homoplasy** refers to superficially similar characters that are not homologous, because they evolved independently.
- Biologists now use a variety of criteria to determine relationships, including shared derived characters and comparison of DNA, RNA, and protein. Deciding which traits best reflect phylogeny is challenging.

6 Apply the concept of shared derived characters to the classification of organisms.

- **Shared ancestral characters,** or **plesiomorphic characters,** suggest a distant common ancestor. **Shared derived characters,** or **synapomorphic characters,** indicate a more recent common ancestor.

7 Identify methods of molecular biology now used by taxonomists, and summarize advantages of molecular taxonomy.

- **Molecular systematics** uses methods for comparing macromolecules such as nucleic acids and proteins for assessing evolutionary relationships. Comparison of nucleotide sequences in ribosomal RNA has led to important taxonomic decisions regarding domains, kingdoms, and species.

8 Contrast monophyletic, paraphyletic, and polyphyletic taxa.

- A **monophyletic taxon** includes all the descendants of the most recent common ancestor. A **paraphyletic taxon** consists of a common ancestor and some, but not all, of its descendants. The organisms in a **polyphyletic group** evolved from different ancestors.

9 Compare and contrast two approaches to systematics: evolutionary systematics and cladistics (phylogenetic systematics).

- **Evolutionary systematics** considers both evolutionary branching and the extent of divergence. Evolutionary systematics is based on shared ancestral characters as well as shared derived characters.
- **Cladistics,** also called **phylogenetic systematics,** insists that taxa be monophyletic. Each monophyletic taxon, or **clade,** consists of a common ancestor and all its descendants. Cladists use shared derived characters to determine these relationships, and illustrate them with diagrams called **cladograms.**
- Cladists use **outgroup analysis** to determine which characters in a given group of taxa are ancestral and which are derived. An **outgroup** is a taxon that represents the ancestral condition because it diverged earlier than any of the other taxa being investigated.
- Cladists use the principle of **parsimony:** They choose the simplest explanation to interpret the data.
- In interpreting cladograms, the relationships among taxa are determined by tracing along the branches back to the most recent common ancestor (represented by a node on the cladogram). The cladogram indicates which taxa shared a common ancestor and how recently they shared that ancestor.

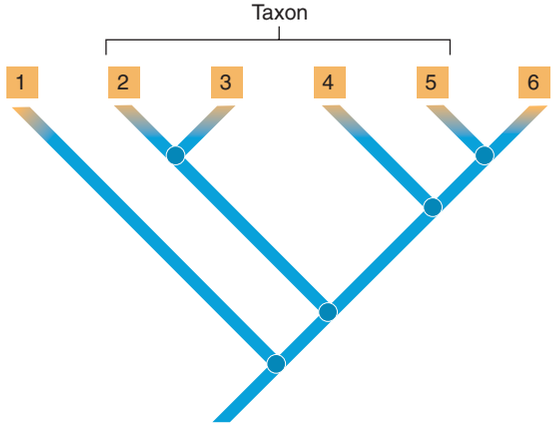
POST-TEST

1. The science of describing, naming, and classifying organisms is (a) systematics (b) taxonomy (c) cladistics (phylogenetic systematics) (d) phenetics (e) evolutionary systematics
2. Using the binomial system of nomenclature, the scientific name of each species consists of two parts (a) class, specific epithet (b) family, genus (c) genus, specific epithet (d) family, species (e) genus, species
3. The mold that produces penicillin is *Penicillium notatum. Penicillium* is the name of its (a) genus (b) order (c) family (d) species (e) specific epithet
4. Closely related genera may be grouped together in a single (a) phylum (b) domain (c) species (d) family (e) kingdom
5. Related classes are grouped together in the same (a) genus (b) phylum (c) order (d) paraphyletic taxon (e) family
6. In the six-kingdom system, the kingdom that includes the protozoa is (a) Plantae (b) Protista (c) Archaea (d) Eukarya (e) Fungi
7. Decomposers such as molds and mushrooms belong to kingdom (a) Plantae (b) Protista (c) Archaebacteria (d) Eukarya (e) Fungi
8. A taxon that contains a recent common ancestor and all its descendants is (a) polyphyletic (b) paraphyletic (c) monophyletic (d) phyletic (e) plesiomorphic
9. The presence of homologous structures in different organisms suggests that (a) the organisms evolved from a common ancestor (b) convergent evolution has occurred (c) they belong to a polyphyletic group (d) homoplasy has occurred (e) independently acquired characters may evolve when organisms inhabit similar environments
10. The dolphin and the human both have the ability to nurse their young, whereas the less closely related fish does not. The ability to nurse their young is a (a) shared derived character of mammals (b) shared ancestral character of all vertebrates (c) plesiomorphy (d) homologous behavior (e) homoplasy
11. Relative constancy in the rates of DNA and protein evolution permits biologists to use these macromolecules as (a) molecular clocks (b) polymerase chains (c) clades (d) paraphyletic clues (e) outgroups
12. Using DNA as a molecular barcode (a) is effective only with bacteria (b) is possible because of similarity in polymerase chains (c) could cause major mistakes in distinguishing among closely related species (d) is an effective way to identify polyphyletic clades (e) could help taxonomists identify and describe new species
13. The conclusion that fungi are more closely related to animals than to plants was based in large part on comparing (a) molecular

POST-TEST *(continued)*

clocks (b) polymerase chains (c) nucleotides in DNA (d) ribosomal RNA sequences (e) amino acid sequences

14. Phenetics (a) is a numerical taxonomy based on phenotypic similarities (b) emphasizes common ancestry (c) emphasizes polyphyletic groups (d) focuses on ancestral characters (e) strives to differentiate between homology and homoplasy.
15. Some systematists classify crocodiles and birds in the same taxon because they are monophyletic. These systematists follow which approach? (a) phyletic (b) cladistic (c) evolutionary systematic (d) polyphyletic (e) either cladistic or evolutionary systematic
16. In cladistic analysis (a) ancestral characters are used to reconstruct phylogenies (b) characters must be homoplastic (c) polyphyletic groups are preferred (d) ancestral character analysis is commonly used (e) outgroup analysis is used
17. When cladists use the principle of parsimony, they (a) choose the simplest explanation to interpret the data (b) select multiple hypotheses to explain each relationship (c) do not use outgroups (d) typically use a polyphyletic approach (e) hypothesize that the most complex explanation is most probably the correct one
18. In the illustration, what kind of grouping is represented by the bracketed area?



CRITICAL THINKING

1. Are members of a genus similar because they share a common ancestor, or do they belong to the same genus because they are similar? How might your answer vary depending on which approach to systematics you are following?
2. How are new techniques in molecular biology affecting the science of systematics?
3. The TATA-binding protein (TBP) is thought to be necessary for transcription in all eukaryotic cell nuclei. Studies show that archaebacteria, but not eubacteria, have a protein structurally and functionally similar to TBP. What does this similarity suggest regarding the evolution of archaebacteria and eukaryotes? How might knowledge of this similarity affect how systematists classify these organisms?

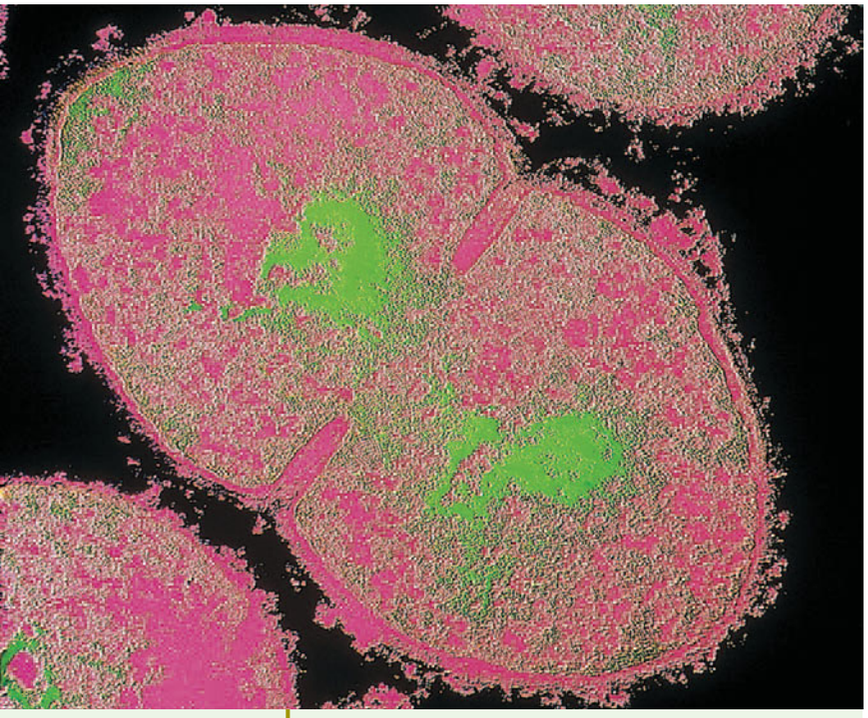
Viruses and Prokaryotes



Dr. Kari Lounatmaa/Science Photo Library/Photo Researchers, Inc.

Color-enhanced TEM of a bacterium (*Streptococcus pyogenes*) dividing by binary fission. This bacterium, a pathogen that inhabits the human nose and throat, can cause scarlet fever and inflammation of the heart tissue. The strain shown here is resistant to antibiotics, and infection can be fatal.

CHAPTER OUTLINE

- **Viruses**
- **Viroids and Prions**
- **Prokaryotes**
- **The Two Prokaryote Domains: Archaea and Eubacteria**
- **Effects of Prokaryotes on the Environment**

Prokaryotes (bacteria and archaea) have inhabited our planet for more than 3.5 billion years—much longer than eukaryotes, which evolved about 1.5 to 1.6 billion years ago. Although prokaryotes are microscopic, they are so numerous that they, together with the fungi, account for approximately half of Earth's biomass, the mass of living material. In contrast, plants account for about 35% and animals for about 15% of the biomass of our planet.

The Dutch microscopist Anton van Leeuwenhoek discovered bacteria and other microorganisms in 1674 when he looked at a drop of lake water through a glass lens. During the late 1800s, many microorganisms, including bacteria, fungi, and protozoa, were identified as **pathogens,** agents that cause disease (see the adjacent photo).

Although bacteria cause many diseases, including respiratory infections and food poisoning in humans, only a small minority of bacterial species are pathogens. In fact, bacteria play an essential role in the biosphere as decomposers, breaking down organic molecules into their components. Along with fungi, prokaryotes are nature's recyclers. Without these microorganisms, carbon, nitrogen, phosphorus, and sulfur would remain locked up in the wastes and dead bodies of plants and animals, unavailable for the synthesis of new cells and organisms.

Some prokaryotes are producers that carry on photosynthesis. Others convert atmospheric nitrogen to ammonia and then to nitrates, forms that are used by plants (see Fig. 53-7). This conversion enables plants and animals (because they eat plants) to manufacture essential nitrogen-containing compounds such as proteins and nucleic acids.

In contrast to prokaryotes, viruses are acellular. Biologists long considered them nonliving particles, but some biologists now view them as life forms. Viruses contain the nucleic acids necessary to make copies of themselves, and they reproduce by invading living cells and commandeering their metabolic machinery. These tiny, but potent, particles infect cells and produce

a wide variety of diseases in plants and animals. Viruses influence many ecological processes, including the recycling of nutrients and the biodiversity of prokaryotes and algae.

This chapter examines the diversity and characteristics of viruses, prokaryotes, and the smaller viroids and prions. They are not a natural group of closely related organisms, and we discuss them in a single chapter only for convenience, not to reflect shared ancestry. ■

VIRUSES

Learning Objectives

1. Describe the structure of a virus, and compare a virus with a free-living cell.
2. Trace the evolutionary origin of viruses according to current hypotheses.
3. Characterize bacteriophages, and contrast a lytic cycle with a lysogenic cycle.
4. Explain how viruses infect animal and plant cells.
5. Describe the reproductive cycle of a retrovirus such as human immunodeficiency virus (HIV).

PROCESS OF SCIENCE

During the late 1800s, botanists searched for the cause of tobacco mosaic disease, which stunts the growth of tobacco plants and gives the infected tobacco leaves a spotted, mosaic appearance. They found they could transmit the disease to healthy plants by daubing their leaves with the sap of diseased plants. In 1892 Dmitrii Ivanowsky, a Russian botanist, showed that the sap was still infective after it had been passed through filters that removed particles the size of all known bacteria. A few years later, in 1898, his work was expanded by Martinus Beijerinck, a Dutch microbiologist. Apparently unaware of Ivanowsky's work, Beijerinck provided independent evidence that the agent that caused tobacco mosaic disease had many characteristics of a living organism. He hypothesized that the infective agent could reproduce only within a living cell, and named it *virus* (the Latin word *virus* means poison).

Early in the 20th century, scientists discovered infective agents, like those responsible for tobacco mosaic disease, that could cause disease in animals or kill bacteria. These pathogens also passed through filters that removed known bacteria and were so small they could not be seen with the light microscope. Curiously, they could not be grown in laboratory cultures unless living cells were present. Microbiologists called viruses that killed bacteria **bacteriophages** ("bacteria eaters"), or **phages.**

A virus particle consists of nucleic acid surrounded by a protein coat

A **virus,** or **virion,** is a tiny, infectious particle consisting of a nucleic acid core (its genetic material) surrounded by a protein coat called a **capsid.** Some viruses are also surrounded by an outer membranous envelope containing proteins, lipids, carbohydrates, and traces of metals. A typical small virus, such as the poliovirus, is about 20 nm in diameter (about the size of a ribosome), whereas a larger virus, such as the poxvirus that causes smallpox, may be 400 nm long and 200 nm wide.

Viruses are acellular and cannot independently perform metabolic activities. They do not have the components necessary to carry on cellular respiration or to synthesize proteins and other molecules. Other living organisms contain both deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), but a virus contains either DNA or RNA, not both. A particular type of virus may have single-stranded (ss) DNA, double-stranded (ds) DNA, ssRNA, or dsRNA.

Viruses reproduce, but only within the complex environment of the living cells they infect. They use their genetic information to force the host cell to replicate the viral nucleic acid and to take over the translational and transcriptional mechanisms of the host cell. The host then synthesizes the capsid and envelope components of the virus.

The organization of protein subunits, called *capsomeres,* that make up the capsid determine the shape of a virus. Viral capsids are generally either helical or polyhedral, or a complex combination of both shapes (Fig. 23-1). Helical viruses, such as the tobacco mosaic virus (TMV), appear as long rods or threads. The capsid is a hollow cylinder made up of proteins that form a groove into which the RNA fits. Polyhedral viruses, such as the adenoviruses (which causes a number of human illnesses, including some respiratory infections), appear somewhat spherical. The T4 phage that infects *Escherichia coli* consists of a polyhedral "head" attached to a helical "tail," a shape commonly found in bacteriophages.

The International Committee on Taxonomy of Viruses classifies viruses

Viruses do not show the characteristics that define living organisms (see Chapter 1). They are acellular, do not carry on metabolic activities, and reproduce only by taking over the reproductive machinery of other cells. For these reasons, viruses cannot be classified in any of the three domains and present a taxonomic challenge to biologists.

Early systems of classifying viruses were based on the host or organ system they infected. Today, viruses are classified by the International Committee on Taxonomy of Viruses (ICTV). This committee groups viruses according to common characteristics such as type of nucleic acid and presence or absence of a capsid. The classification system is not a traditional Linnaean system and does not assign viruses to domains, kingdoms, or phyla.

Viruses may have "escaped" from cells

PROCESS OF SCIENCE

Where did viruses come from? The most widely held hypothesis is that viruses derive from bits of nucleic acid that "escaped"

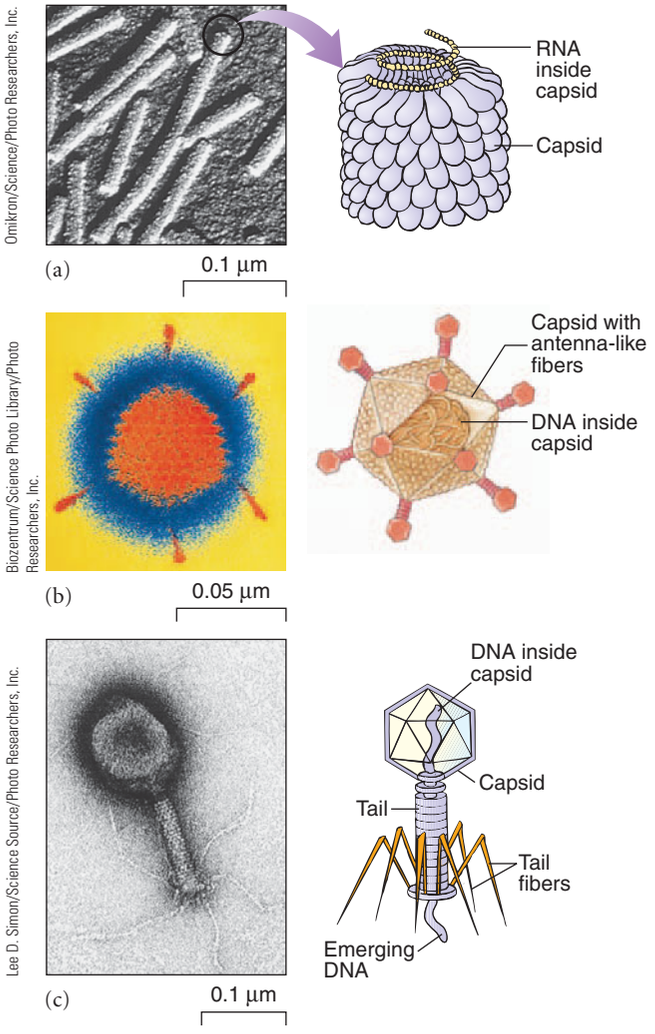


FIGURE **23-1** **Virus structure.**

(a) TEM of tobacco mosaic virus, a rod-shaped virus with a helical arrangement of capsid proteins. **(b)** Color-enhanced TEM of an adenovirus, which has a capsid composed of 252 subunits (visible as tiny ovals) arranged into a 20-sided polyhedron. Twelve of the subunits have projecting protein spikes that permit the virus to recognize host cells. **(c)** TEM of T4, a bacteriophage that has a polyhedral head and a helical tail.

from cellular organisms. Viruses may have originated as mobile genetic elements such as *transposons* (see Chapter 12) or *plasmids* (small, circular DNA fragments discussed in Chapter 14 and later in this chapter). Such fragments could have moved from one cell and entered another through damaged cell membranes.

According to this *escaped gene hypothesis,* some viruses may trace their origin to animal cells, others to plant cells or to bacterial cells. Their multiple origins may explain why many viruses are species specific; perhaps they infect only those species that are closely related to the organisms from which they originated. This hypothesis is supported by the genetic similarity between some viruses and their host cells—a closer similarity than exists between one type of virus and another.

Another hypothesis suggests that viruses arose early in the history of life, even before the three domains diverged. Evidence for this hypothesis comes from similarities found in the protein structures of some viral capsids and also in genetic similarities between some viruses that infect the Archaea and some that infect the Eubacteria. Molecular biologists studying this hypothesis suggest it is improbable that these similarities evolved independently. This suggests viruses diverged very early. However, viruses are parasites, dependent on their hosts. How could they have existed before their hosts evolved?

Bacteriophages are viruses that attack bacteria

Much of our knowledge of viruses has come from studying bacteriophages, because they can be cultured easily within living bacteria in the laboratory. Bacteriophages are among the most complex viruses (see Fig. 23-1c). Their most common structure consists of a long nucleic acid molecule (usually dsDNA) coiled within a polyhedral head. Many phages have a tail attached to the head. The phage may use fibers extending from the tail to attach to a bacterium.

More than 2000 phages have been identified. They infect a wide variety of organisms. For example, phycoviruses infect algae. Some studies suggest that phages inhibit or control the growth rate of algal blooms.

Before the age of sulfa drugs and antibiotics, phages were used clinically to treat infection. Then in the 1940s, they were abandoned (at least in Western countries) in favor of antibiotics, which were more dependable and easier to use. Now, with the widespread and growing problem of bacterial resistance to antibiotics, these bacteria-killing viruses are once again the focus of research. With new knowledge of phages and sophisticated technology, several research groups are investigating phages to determine which ones kill which species of bacteria. Scientists are genetically engineering phages so that bacteria will be slower to evolve resistance to them. Phages can also be used to improve food safety. For example, certain phages can kill deadly strains of *E. coli* in cattle. These bacteria do not appear to make cattle ill, but can cause illness and death in people who eat infected, undercooked hamburgers.

Lytic reproductive cycles destroy host cells

Two types of reproduction among viruses are lytic and lysogenic cycles. In a **lytic cycle,** the virus lyses (destroys) the host cell. When the virus infects a susceptible host cell, it forces the host to use its metabolic machinery to replicate viral particles. Viruses that have only a lytic cycle are described as **virulent.**

Five steps are typical in lytic viral reproduction (Fig. 23-2):

1. **Attachment (or absorption).** The virus attaches to receptors on the host cell wall.

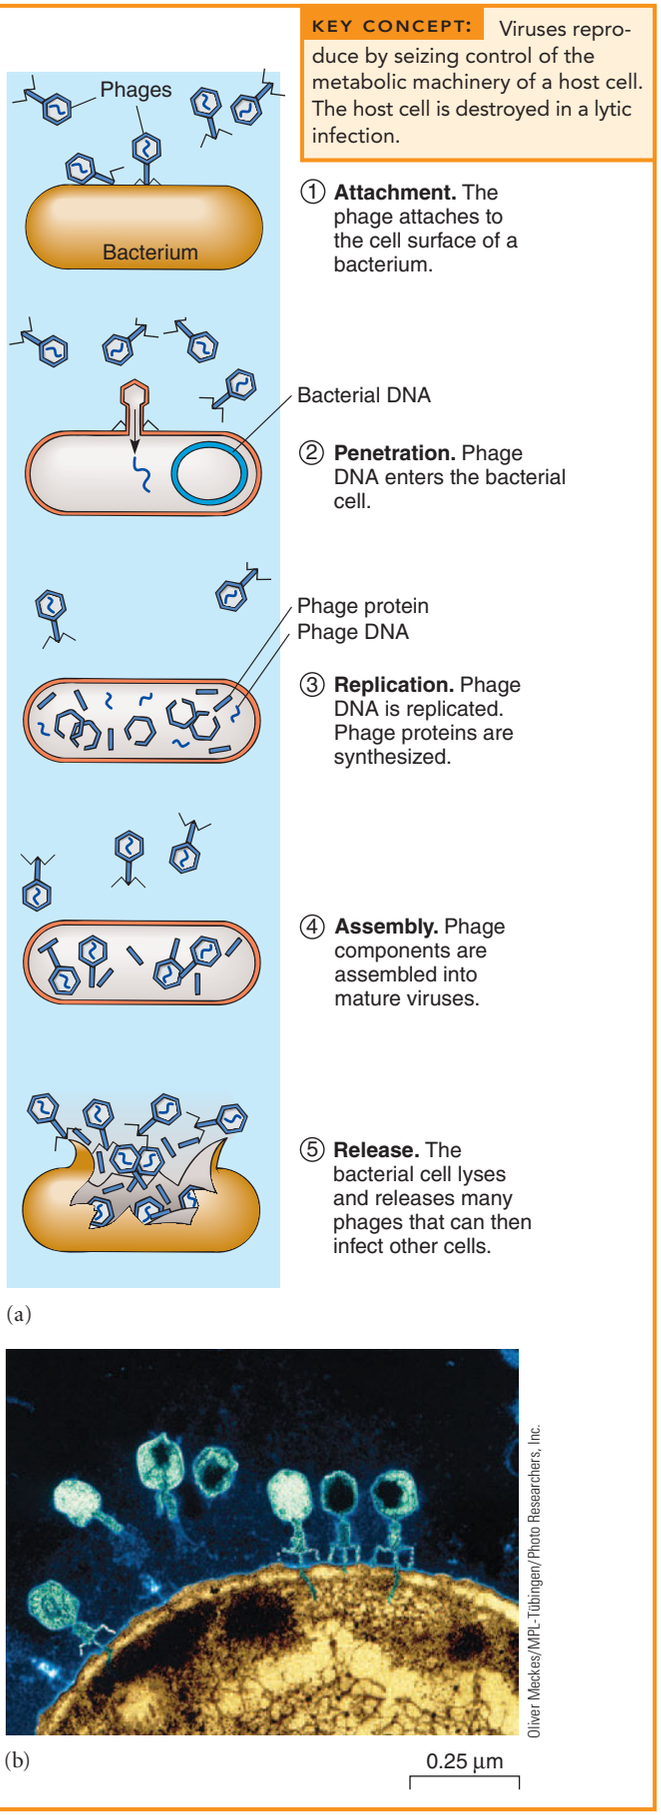

FIGURE **23-2** **Lytic cycle.** ◀

(a) The sequence of events in a lytic infection. **(b)** Color-enhanced TEM of phages infecting a bacterium, *Escherichia coli.*

2. **Penetration.** The nucleic acid of the virus moves through the plasma membrane and into the cytoplasm of the host cell. The capsid of a phage remains on the outside, but many viruses that infect animal cells enter the host cell intact.
3. **Replication and synthesis.** The viral genome contains all the information necessary to produce new viruses. Once inside, the virus degrades the host cell nucleic acid and uses the host cell to synthesize the necessary components for its replication.
4. **Assembly.** The newly synthesized viral components are assembled into new viruses.
5. **Release.** Assembled viruses are released from the cell. Generally, lytic enzymes, produced by the phage late in the replication process, destroy the host plasma membrane. Phage release typically occurs all at once and results in rapid cell lysis, whereas animal viruses are often released slowly or bud off from the plasma membrane.

The new viruses infect other cells, and the process begins anew. The time required for viral reproduction, from attachment to the bacterium to the release of new viruses, varies from less than 20 minutes to more than an hour.

Temperate viruses integrate their DNA into the host DNA

Temperate viruses do not always destroy their hosts. In a **lysogenic cycle** the viral genome usually becomes integrated into the host bacterial DNA and is then referred to as a **prophage.** When the bacterial DNA replicates, the prophage also replicates (Fig. 23-3). The viral genes that code for viral structural proteins may be repressed indefinitely. Bacterial cells carrying prophages are called *lysogenic cells.* Certain external conditions (such as ultraviolet light and x-rays) cause temperate viruses to revert to a lytic cycle and then destroy their host. Sometimes temperate viruses become lytic spontaneously.

Bacterial cells containing certain temperate viruses may exhibit new properties. This is called **lysogenic conversion.** An interesting example involves the bacterium *Corynebacterium diphtheriae,* which causes diphtheria. Two strains of this species exist, one that produces a toxin (and causes diphtheria) and one that does not. The only difference between these two strains is that the toxin-producing bacteria contain a specific temperate phage. The phage DNA codes for the powerful toxin that causes the symptoms of diphtheria. Similarly, the bacterium *Clostridium botulinum,* which causes botulism, a serious form of food poisoning, is harmless unless it contains certain prophage DNA that induces synthesis of the toxin.

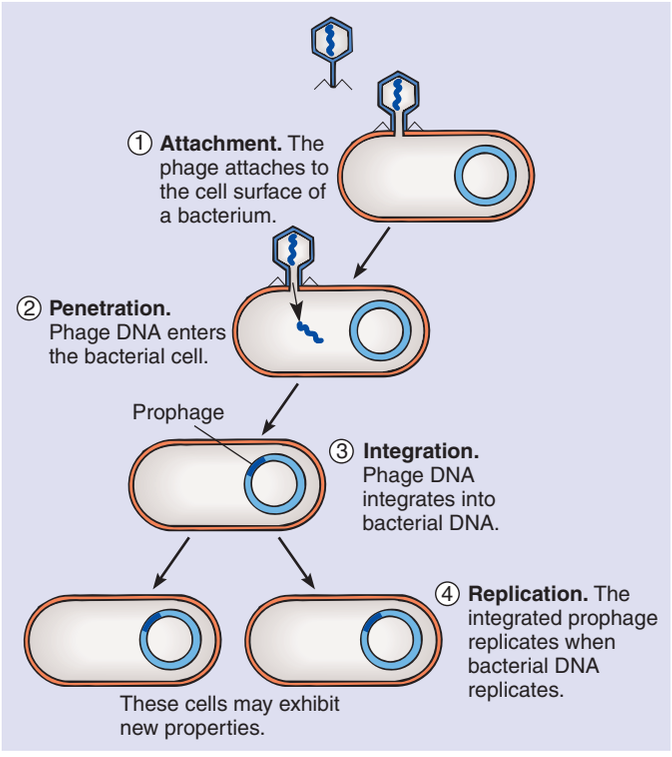

FIGURE **23-3** **Lysogenic cycle.**

Temperate phages integrate their nucleic acid into the host cell DNA, making it a lysogenic cell.

Some viruses infect animal cells
